in connection with the analytical reactions of tin. F. Friedrichs found that stannous chloride forms a yellow compound of low solubility when treated with liquid ammonia ; the soln. separates into two phases at 120°. C. C. Persoz found that warm stannous chloride absorbs gaseous ammonia, forming **stannous amminochloride,** $SnCl_2.NH_3$. J. J. Berzelius added ammonia to a soln. of stannous chloride until the precipitate first formed redissolved, and obtained crystals—supposed to be ammonium chlorostannite—by evaporating the soln. in vacuo. W. Biltz and W. Fischer found for the temp. at which the vap. press. is 100 mm., and for the heat of dissociation in Cals. per mol of NH_3, for **stannous enneamminochloride,** $SnCl_2.9NH_3$, —55°, and 7·6 respectively ; **stannous tetramminochloride,** $SnCl_2.4NH_3$, +15°, and 9·3. G. L. Clark examined the relative stability of these and the corresponding ammines of the other halides. H. Franzen and O. von Mayer added **hydrazine hydrate** drop by drop to a clear alcoholic soln. of stannous chloride, separated the precipitate by suction ; washed it with alcohol, and ether, and the product, dried in vacuo, corresponded with **stannous dihydrazinochloride,** $Sn(N_2H_4)_2Cl_2$. The compound is brownish-white ; insoluble in aq. ammonia, easily decomposed by water ; and when heated decomposes explosively. O. von Dumreicher found that at 100°, **hydroxylamine** is rapidly reduced to ammonia by stannous chloride. According to A. Scheurer-Kestner, **nitric acid** acts on a soln. of stannous chloride, forming stannic chloride, β-stannic acid, and red oxides of nitrogen. A. Naumann and co-workers found that the oxidation of stannous chloride by nitric acid is much accelerated by a trace of vanadic oxide. In the presence of hydrochloric acid, the nitric acid is reduced to ammonia : $8SnCl_2+18HCl+2HNO_3=7SnCl_4+(NH_4)_2SnCl_6+6H_2O$; and in the absence of hydrochloric acid, the nitric acid is reduced to nitric oxide : $6SnCl_2+4HNO_3=3SnCl_4+3SnO_2+4NO+2H_2O$. E. Divers and T. Haga found that with dil. nitric acid in the presence of hydrochloric acid, stannous oxide furnishes hydroxylamine, etc. ; and with nitric oxide, hydroxylamine, nitrogen, etc. F. Raschig said a cold conc. soln. of stannous chloride does not alter nitric acid ; and O. von Dumreicher, that a cold soln. of stannous chloride reduces nitric acid, and nitric oxide to hydroxylamine ; while with a hot soln. ammonia is formed. M. Coblens and J. K. Bernstein found that a drop of ferrous sulphate soln. in one of stannous chloride reduces nitric acid to nitric oxide ; L. H. Milligan and G. R. Gillette obtained a 90 per cent. yield of hydroxylamine by the action of stannous chloride on nitric acid provided the temp. is kept low ; and M. Coblens and J. K. Bernstein obtained hydroxylamine when **sodium nitrate** or **silver hyponitrite** is added slowly to a soln. of stannous chloride. F. Raschig observed that **nitric oxide** is not reduced by a cold conc. soln. of stannous chloride and that an aq. soln. of **nitrous acid** furnishes nitrous oxide, and the red oxides of nitrogen. O. von Dumreicher obtained a similar result, and found that **nitrous oxide** is not reduced by stannous chloride. H. Wölbling found that stannous chloride does not unite with **nitrogen sulphide,** N_4S_4, but reduces that compound to NSH. H. Schiff found **arsenic oxide** is reduced to arsenious oxide ; and, according to P. Woulfe, to arsenic if it be digested for a long time in soln. of stannous chloride in hydrochloric acid ; and A. Bettendorf employed the reaction as distinguishing test for arsenic. M. de Jong used an ethereal soln. of stannous chloride as a test for arsenic. P. Woulfe also reduced **antimonous oxide** to antimony in a similar way. A. Vogel found **bismuth nitrate** is reduced by stannous chloride to black bismuth monoxide.

According to F. von Kügelgen, a mixture of stannous chloride and **calcium carbide** can be inflamed with a match, and the reaction proceeds with incandescence and the production of pulverulent tin. H. Goldschmidt and E. Sunde showed that stannous chloride reduces many organic compounds—e.g. nitro-compounds to amides, etc. Reactions with organic compounds were also studied by O. von Dumreicher, F. Uty, P. Soltsien, G. Gimel, P. Pfeiffer, H. Goldschmidt and co-workers, etc. B. Köhnlein found that **propyl iodide** readily reacts with stannous chloride.

In the general case, tin is precipitated from soln. by the more electropositive

metals in the electrochemical series—**1. 16, 2.** Tin can be precipitated from soln. of stannous salts by many metals—*e.g.* **magnesium, zinc, cadmium, aluminium,** etc. H. Mouraour found that with magnesium powder there is a brisk evolution of hydrogen when tin is precipitated from soln. of stannous chloride. N. W. Fischer found that **iron** precipitates tin from soln. of stannous chloride, but not from boiling soln. ; H. Schulze said that the soln. must be neutral ; and J. Thiele, that electrolytic iron gives the best result, for iron which has been heated to redness does not precipitate the tin. A. M. Pleischel found that **lead** precipitates tin quantitatively from soln. of stannous chloride or nitrate. The reaction $Pb+SnCl_2 \rightleftharpoons Sn+PbCl_2$ was studied by R. Lorenz and M. Mannheimer. H. Reinsch found that **copper** precipitates tin as greyish-black powder from a soln. strongly acid with hydrochloric acid, especially in the presence of air and from boiling soln.

The behaviour of stannous chloride towards **alkali hydroxides,** and **alkali carbonates** is indicated in connection with the analytical reactions of tin, and the action of water on this chloride. E. Lenssen showed that in the presence of tartaric acid, soln. of stannous chloride remain clear when treated with sodium hydroxide or carbonate. The oxidation of stannous chloride by fusion with sodium hydroxide is supposed by M. C. Boswell and J. V. Dickson to be due to the decomposition of the water, and the escape of hydrogen. When stannous chloride is heated with **sodium nitrate** or **potassium chlorate,** H. Schulze found that stannic chloride and oxide are formed. R. Brönner found that potassium chlorate energetically oxidizes stannous to stannic chloride. In general, stannous chloride acts as a strong reducing agent, and it is itself simultaneously oxidized to stannic chloride. According to R. E. Liesegang, the oxidation of the stannous salts is accelerated by exposure to light—stannous bromide is quite sensitive to light, while stannous chloride is but slightly affected. Many salts are reduced to a lower stage of oxidation or to the metal. Thus, **chromic acid** is reduced to a chromic salt ; and, according to H. Schiff, **tungstic acid,** and **molydic acid** form the blue lower oxides. T. Warynsky and M. Mdivani showed that **vanadium pentoxide** is quantitatively reduced to the tetroxide, V_2O_4. J. N. von Fuchs studied the reduction of **manganic salts** by stannous chloride. A. V. Harcourt showed that the greater the amount of water employed in the soln. of a given amount of stannous chloride, the greater the amount of a standard soln. of **potassium permanganate** required for the titration. If air-free water be employed this phenomenon is not observed. The same amount of permanganate is required, however much water be employed. It was hence inferred that the oxygen dissolved in the water as well as the permanganate oxidizes the stannous salt ; but oxygen dissolved in water has no perceptible action on the stannous salt alone. Air can oxidize the stannous chloride only simultaneously with the permanganate. W. Ostwald called such reactions *coupled reactions.* **Cupric oxide** and **cupric salts** are reduced to cuprous chloride ; the reaction was studied by G. Viard. According to A. Vogel, **mercuric oxide, mercuric chloride,** and **mercuric cyanide** are reduced to mercurous chloride ; and **mercurous chloride,** in turn, is reduced to mercury. The reaction : $SnCl_2+2HgCl_2=SnCl_4+2HgCl$, was studied by N. A. Tananaeff. A. Lottermoser found that when a dil. soln. of **mercurous nitrate** is treated with a soln. of stannous chloride containing but a trace of free hydrochloric acid, colloidal mercury is formed. With **silver salts,** metallic silver is precipitated ; according to A. Ditte, the reaction is very sensitive for a purple precipitate is produced by silver nitrate when only 0·001 grm. of stannous chloride is contained in a litre of water. When a **gold salt** is added to a soln. of stannous chloride, purple of Cassius is precipitated. A. Vogel found that red or brown lead dioxide is reduced to lead chloride ; while M. de Jong found that lead sulphate is dissolved by a hydrochloric acid soln. of stannous chloride. J. N. von Fuchs, J. Löwenthal, L. V. Pissarjewsky, and L. Blum studied the reduction of **ferric salts** to ferrous salts by stannous oxide or chloride. L. Kahlenberg indicated that the reaction between stannous and ferric chlorides is bimolecular ; while A. A. Noyes represented it as termolecular : $2FeCl_3+SnCl_2=SnCl_4+2FeCl_2$,

or $dx/dt=k(a-x)(b-x)^2$, where a represents the initial conc. of the stannous chloride, and b that of ferric chloride; x represents the amount of substance changed in the time t; and k the affinity constant dependent on conc., temp., etc. In the presence of acid, the reaction appears to approximate to the bimolecular reaction of L. Kahlenberg. According to F. L. Kortright, the ferric chloride is hydrolyzed in soln., and only the non-hydrolyzed portion takes part in the reaction. The effect of neutral salts on the reaction was investigated by W. F. Timoféeff and co-workers. S. W. Young studied the oxidation of stannous chloride by various reagents.

Complex salts of stannous chloride.—J. L. Proust, and J. J. Berzelius, found on evaporating a soln. of tin-filings in one of ammonium chloride, whereby ammonia and hydrogen are evolved, crystals of a salt which, according to the analyses of J. Apjohn, is **ammonium tetrachlorostannite**, $(NH_4)_2SnCl_4.H_2O$, are obtained; but the analyses of C. F. Rammelsberg, and G. M. Richardson make it a dihydrate, $(NH_4)_2SnCl_4.2H_2O$. The last-named said that the salt is easily obtained by crystallization from a soln. of the component salts. The rhombic bipyramidal crystals have the axial ratios $a:b:c=0.6789:1:0.7522$. A. Johnsen gave $0.67686:1:0.74525$; and he considered this salt to be isomorphous with the corresponding ammonium tetrachloromercuriate, $(NH_4)_2HgCl_4.H_2O$. L. Playfair and J. P. Joule gave 2.104 for the sp. gr. at $3.9°$, and A. Johnsen, 2.11. According to C. F. Rammelsberg, the octahedral crystals reported by J. Apjohn were not this salt, but the corresponding stannate. G. M. Richardson reported that **ammonium trichlorostannite**, $NH_4SnCl_3.H_2O$, crystallizes from a soln. of ammonium chloride mixed with a large excess of stannous chloride. E. Rimbach and K. Fleck made this salt by mixing equimolar proportions of soln. of the component salts, allowing the solid phase to separate, saturating with the same mixture while hot, and allowing to cool. The needle-like crystals readily lose their water. The solubility, S, in grams of anhydrous salt in 100 grms. of soln. is given by $S=57.374+0.3598\theta$, between $16°$ and $81°$. E. Rimbach and K. Fleck made mono- and di-hydrated **ammonium tetrachlorostannite**, $(NH_4)_2SnCl_4$. The solubility, S, in grams of anhydrous salt per 100 grms. of soln. is $S=27.479+0.5816\theta$, between $1.6°$ and $79.0°$. G. M. Richardson could not prepare **ammonium hexachlorostannite**, $(NH_4)_4SnCl_6.3H_2O$, reported by A. B. Poggiale to be formed from a soln. of stannous chloride mixed with an excess of ammonium chloride, but E. Rimbach and K. Fleck obtained the monohydrated salt. Stannous amminochloride has been previously described. T. Curtius and F. Schrader evaporated an aq. soln. containing eq. proportions of hydrazine and ammonium chlorides and obtained a syrupy mass which when crystallized from absolute alcohol furnished white tabular crystals of **hydrazine trichlorostannate**, $(N_2H_5)SnCl_3$. The crystals are not hygroscopic; they melt at $105°$, and the m.p. is lowered when the tetrachlorostannite is present. The two salts can be separated by fractional crystallization. The salt is easily soluble in water, and less soluble in alcohol. The residue obtained by extracting with a small proportion of alcohol the syrupy liquid obtained in preparing the preceding salt consists mainly of colourless crystals of **hydrazine tetrachlorostannite**, $(N_2H_5)_2SnCl_4$. This salt is hygroscopic; it melts at $55°-60°$; and is sparingly soluble in absolute alcohol. Stannous hydrazine chloride, $Sn(N_2H_4)_2Cl_2$, has been previously described. J. G. F. Druce, and P. Pfeiffer studied the complex salts with organic bases.

I. Remsen and G. M. Richardson,[3] and E. Rimbach and K. Fleck prepared white hair-like crystals of **potassium trichlorostannite**, $KSnCl_3.H_2O$, by evaporating a soln. of potassium chloride mixed with a large excess of stannous chloride. The crystals are stable in air; they do not lose water when confined over conc. sulphuric acid, but they do so when heated to $100°$; and at a higher temp., both water and hydrogen chloride are evolved. E. Rimbach and K. Fleck represented the solubility, S, in grams of anhydrous salt per 100 grms. of soln., by $S=23.186+0.83063\theta$, between $3.2°$ and $71°$. According to I. Remsen and G. M. Richardson, the salt

is soluble in hot hydrochloric acid, or in a soln. of potassium chloride, and the evaporation of these soln. furnishes crystals of **potassium tetrachlorostannite,** $K_2SnCl_4.2H_2O$. According to C. F. Rammelsberg, J. A. Streng, and J. C. G. de Marignac, the crystals have only one mol of water. According to I. Remsen and G. M. Richardson, the dihydrate is produced from a mixture of the component salts in nearly equal proportions òr with an excess of potassium chloride. E. Rimbach and K. Fleck made the mono- and di-hydrates, and they found that the solubility, S, in grams of anhydrous salt per 100 grms. of soln. is $S=26\cdot705+0\cdot4829\theta$, between 35·6° and 77·3°. The white crystals belong to the rhombic system, and have the axial ratios $a:b:c=0\cdot6852:1:0\cdot7586$. L. Playfair and J. P. Joule gave 2·514 for the sp. gr. They are stable in air, and crystallize unchanged from aq. soln., but L. Peetz said that salt is partially decomposed in aq. soln. The crystals melt when heated, and lose water and hydrogen chloride ; they are more stable than stannous chloride when heated, and at a red heat some stannous chloride is volatilized. I. Remsen and G. M. Richardson made crystals of the *monohydrate* by rapidly cooling a soln. of the salt in hot hydrochloric acid. A. B. Poggiale reported *potassium hexachlorostannite*, $K_4SnCl_6.3H_2O$, from a mixed soln. of the component salts. E. Rimbach and K. Fleck said the salt is monohydrated. E. H. Ducloux prepared **cæsium trichlorostannite**, $CsSnCl_3$.

G. Hermann showed that the fusion curves of mixtures of *stannous and cuprous chlorides* form a simple **V**, with the eutectic at 172° and 77·5 per cent. $SnCl_2$, Fig. 69. I. Remsen and G. M. Richardson could not confirm this. L. Peetz could not obtain
FIG. 67.—Fusion Curve of the System : $CaCl_2$–$SnCl_2$.

FIG. 68.—Fusion Curve of the System : $MgCl_2$–$SnCl_2$.

calcium chlorostannite by melting a mixture of the component chlorides at a red heat ; and O. Menge found that the thermal diagram of calcium and stannous chlorides showed a continuous series of mixed crystals with no evidence of chemical com-

bination, Fig. 67. A. B. Poggiale reported needle-like crystals of **strontium tetra chlorostannite**, $SrSnCl_4.4H_2O$, to be formed by evaporating a soln. of the component salts; and prismatic crystals of **barium tetrachlorostannite**, $BaSnCl_4.4H_2O$, were made in a similar way. O. Menge found no evidence of the formation of *magnesium chlorostannite* on the fusion curve of the component salts, Fig. 68; there is a continuous series of mixed crystals. G. Hermann measured the fusion curves of *zinc and stannous chlorides* which have a simple V-eutectic at 171°, and 64 per cent. $SnCl_2$, Fig. 70; and *cadmium and stannous chlorides*, with a simple V-eutectic at 229°, and 90 per cent. $SnCl_2$, Fig. 71. J. Kendall and co-workers found that with mixtures of stannous and aluminium chlorides there is a two-liquid layer with between 1·5 and 14·3 per cent. of stannous chloride in equilibrium with the solid phase $xAlCl_3.ySnCl_2$ at 192°. There are the compounds **aluminium octochlorostannite**, $2AlCl_3.SnCl_2$, melting at 209·3°; and **aluminium pentachlorostannite**, $AlCl_3.SnCl_2$, melting at 158·5°. According to E. Korreng, fused mixtures of thallous and stannous chlorides furnish **thallous pentachlorostannite**, Tl_3SnCl_5, melting at 310°, and **thallous trichlorostannite**, $TlSnCl_3$, melting at 244°. The f.p. curves are shown in Fig. 72. C. D. Braun made **cobalt hexamminochlorostannite**, $2[Co(NH_3)_6]Cl_3.3SnCl_2.8(or 10)H_2O$, by the action of stannic chloride on cobalt hexamminochloride. *Vide* the stannous chloroplatinites.

§ 17. The Stannic Chlorides

In 1605, A. Libavius [1] described a fuming liquid which he called *liquor argenti vivi sublimati* or *spiritus argenti vivi sublimati;* he obtained it by distillation from a mixture of tin or tin amalgam and mercuric chloride. The liquid was afterwards called *spiritus fumans Libavii.* According to H. Peters, the preparation of the liquor from tin amalgam and mercuric chloride was described in a circular of the Nürnberg Museum nearly 300 years before A. Libavius' time. R. Boyle thus described its preparation :

If from good Cornish tin, you warily distil an equal or double weight of Venetian sublimate, into a very large receiver, very well luted on to the retort, you will obtain a spirituous liquor, which, as soon as the free air comes to touch it, will, before very long, send up abundance of white exhalations in the form of thick smoak.

The composition of the liquid was shown by J. L. Proust, J. J. Berzelius, and J. Davy to correspond with **stannic chloride, or tin tetrachloride,** $SnCl_4$. Chlorine unites directly with heated tin ; the reaction is attended by the development of much heat and light, and the formation of stannic chloride. Tin-foil catches fire after being in the gas a little while and burns with the emission of red sparks, and the formation of stannic chloride ; and R. Cowper [2] found that tin-foil is attacked by chlorine which has been so thoroughly dried that it does not attack sodium. R. Lorenz also based a method of preparing stannic chloride on the reaction between chlorine and tin at ordinary temp.

The most suitable apparatus is a wide tube closed at one end, 5 to 6 cm. wide, and 75 to 100 cm. long, fitted with a condenser and a tube, by means of which dry chlorine can be passed to the bottom of the vessel, where it bubbles through a little tin tetrachloride. The tube is filled nearly to the top with granulated tin. $1\frac{1}{2}$ to 2 kgrms. of the tetrachloride are easily prepared in about one hour. The product boils at 114°.

H. J. Taverne, and P. S. Brallier used a modification of this process ; and E. A. Sperry made stannic chloride on a large scale by the action of dry chlorine on tin contained in a cast-iron vessel. Liquid chlorine was found by E. Beckmann and P. Geib to dissolve tin, forming the tetrachloride. W. Coldridge purified stannic chloride prepared by the chlorine process by allowing it to stand over granulated tin for some days, and fractionally distilling the product. P. Heermann used a similar process. E. Kotzur purified impure material by distilling it in a stream of hydrogen chloride at as low a press. as possible. The tetrachloride is also formed by the action of chlorine on stannous chloride at ordinary temp. J. Davy heated a conc. aq. soln. of stannous chloride with conc. sulphuric acid and obtained stannic chloride ; and by the rectification of stannic chloride with sulphuric acid, the iron can be removed when present as an impurity. As indicated above, stannic chloride is formed when a mixture of tin and mercuric chloride is heated ; R. Schneider said that when a mixture of sulphur or selenium and stannous chloride is heated, some stannic chloride is produced ; and if an aq. soln. of stannous chloride is heated with sulphur, G. Vortmann and C. Padberg obtained some stannic chloride. J. von Kraskowitz made this compound by distilling from a mixture of sodium chloride and stannic sulphate. K. Heumann and P. Köchlin obtained stannic chloride by the action of chlorosulphonic acid on tin, $Sn+4HClSO_3=SnCl_4+2SO_2+2H_2SO_4$; but with sulphuryl chloride, SO_2Cl_2, and tin only a small proportion of stannic chloride is formed. H. Goldschmidt found that phosphorus pentachloride converted tin into the tetrachloride.

C. Matignon and F. Bourion converted stannic oxide into the chloride, by passing chlorine mixed with the vap. of sulphur chloride, SCl_2, over the heated oxide. B. H. Jacobson used chlorine mixed with a little bromine. A. Michaelis

formed a mixture of stannous and stannic chlorides by the action of phosphorus trichloride on stannic oxide at 160°; G. Rauter, by the action of silicon tetrachloride on stannic oxide at 350°–360°; C. W. Watts and C. A. Bell, and C. Renz, by the action of carbon tetrachloride vap. on red-hot stannic oxide; C. Renz, by the action of chloroform on stannic oxide; and J. Kelley and E. F. Smith, by the action of hydrogen chloride on heated stannic sulphide. L. Czimatis obtained stannic chloride on a large scale by heating a mixture of stannic oxide and magnesium or calcium chloride; F. Meilly, by dissolving stannic hydroxide in hydrochloric acid, and heating the product with magnesium chloride, magnesia, and sand.

In 1770, J. F. Demachy [3] found that when *liquor fumans ex stanno* is treated with a little water, it forms a crystalline mass called *butter of tin*. The union of stannic chloride with water is attended by the development of much heat. According to G. T. Gerlach, when equimolar proportions of stannic chloride and water are mixed, two-thirds of the chloride remains unchanged, and **trihydrated stannic chloride,** $SnCl_4.3H_2O$, is formed. W. T. Casselmann prepared crystals of this same hydrate by exposing stannic chloride to moist air; A. Scheurer-Kestner, by oxidizing stannous chloride with nitric acid, potassium chlorate, or chromic acid, and evaporating the liquid for crystallization, or by evaporating a soln. of stannic hydroxide in an aq. soln. of stannic chloride; and T. Scheerer, by passing moist chlorine over warm tin and stannic chloride. W. Meyerhoffer gave 64°–83° as the limiting range of temp. for the existence of the trihydrate. A. Scheurer-Kestner reported the formation of **dihydrated stannic chloride,** $SnCl_4.2H_2O$, by drying the trihydrate; and B. Lewy, by drying the pentahydrate over sulphuric acid in vacuo. G. T. Gerlach, however, was unable to prepare the dihydrate by the action of water on stannic chloride; and W. Meyerhoffer observed no evidence of its formation in his work on the hydrates of stannic chloride. G. T. Gerlach made **tetrahydrated stannic chloride,** $SnCl_4.4H_2O$, by mixing four mols of water with one mol of stannic chloride; W. Meyerhoffer said that the limits of existence of this hydrate are between 56° and 63°. In 1789, P. A. Adet reported the formation of a crystalline mass of **pentahydrated stannic chloride,** $SnCl_4.5H_2O$, by mixing 22 parts of stannic chloride with 7 parts of water. This hydrate is the easiest to prepare, and it is commercially known as *oxymuriate of tin*, being used in the textile industries; and, according to M. Taufflieb, as a preservative for anatomical specimens. W. Meyerhoffer gave 19°–56° for the limiting range of temp. within which the pentahydrate exists. B. Lewy obtained it by evaporating a soln. of stannic chloride in water; H. Rose, by saturating a soln. of stannous chloride with water; R. Brönner, and M. Rössler, by oxidizing a hydrochloric acid soln. of stannous chloride with nitric acid or potassium chlorate, and evaporating for crystallization; and J. Bellucci and N. Parravano, by keeping the hydrochloride, $SnCl_4.2HCl.6H_2O$, for several days over alkali hydroxide at ordinary temp. and under reduced press. G. T. Gerlach made **octohydrated stannic chloride,** $SnCl_4.8H_2O$, by crystallizing an aq. soln. of stannic chloride at a low temp. C. Nöllner regarded the product as **enneahydrated stannic chloride,** $SnCl_4.9H_2O$. W. Meyerhoffer gave 19° as the upper limit of temp. at which the octohydrate can exist. No *tin-chloroform*, $SnHCl_3$, has been made. According to J. Beckmann, the Dutch alchemist C. Drebbel discovered in 1630 that a soln. of tin in aqua regia with cochineal furnishes a permanent scarlet dye.

The physical properties of the stannic chloride.—Stannic chloride is a colourless fuming liquid, and below −33°, it furnishes white **crystals.** The trihydrate furnishes monoclinic crystals which were examined by W. T. Casselmann;[4] the tetrahydrate was found by G. T. Gerlach to form opaque crystals; and the pentahydrate, monoclinic crystals. J. I. Pierre gave 2·2671 for the **specific gravity** of stannic chloride at 0°; G. T. Gerlach, 2·234 at 5°; P. Heermann, 2·26; A. Stiefelhagen, 2·279 at 16·2°; and T. E. Thorpe, 2·27875 at 0°, 2·2328 at 20°, and 1·97813 at 1 : 4°. I. I. Saslawsky found the ratio of the mol. vol. to the sum of

the at. vol. of the constituent elements to be 1·40; and he calculated the density, D, from the critical density, $D_k=0.7419$ $D=D_k(1+2.73\sqrt{T/T_0})$. R. Lorenz and W. Herz made observations of the sp. vol. F. Schuster gave 1184 atms. for the **internal pressure** of the liquid; W. Herz studied this subject. J. I. Pierre gave 0·00129977 for the coeff. of **cubical expansion** between 0° and 100°; and for the vol., v, assumed by a vol. v_0 when raised to $\theta°$ between $-19.1°$ and 112·6°, $v=v_0(1+0.0011328\theta+0.0_69170\theta^2+0.0_8757980\theta^3)$, whilst T. E. Thorpe gave $v=v_0(1+0.0011605\theta+0.0_6646167\theta^2+0.0_877271\theta^3)$; and for the **specific volume**, 131·07. When stannic chloride is mixed with water, there is a marked contraction; and G. T. Gerlach gave for the sp. gr. of aq. soln. at 15°:

SnCl$_4$	10	20	30	40	50	60	70	100 per cent.
Sp. gr.	1·082	1·174	1·279	1·404	1·556	1·743	1·943	2·234

For the sp. gr. of soln. with different proportions of the pentahydrate, at 15°, he also gave:

SnCl$_4$.5H$_2$O	1	10	15	20	40	60	80	95 per cent.
Sp. gr.	1·006	1·0593	1·0905	1·1236	1·2755	1·4684	1·7271	1·9881

A table of observations on this subject was also compiled by P. Heermann; he also said that when the octohydrate is melted, the liquid has a sp. gr. 1·836 at 17·5°. E. Rabinowitsch, O. Masson, and J. A. Groshaus compared the mol. vol. and b.p. of the family of tetrachlorides. J. B. A. Dumas found that the **vapour density** at 124° is 9·18 when the value calculated for SnCl$_4$ is 9·04; and H. V. Regnault found a litre of the vap. under standard conditions weighs 11·9514 grms. S. Young gave for the **vapour pressure**, p mm., at temp. below the b.p.:

	$-10°$	0°	10°	20°	40°	60°	80°	100°	120°
p	2·78	5·53	10·33	18·58	50·82	122·2	256·7	496·0	895·4

and for the temp. above the b.p. up to near the critical temp.:

	130°	150°	200°	250°	280°	310°	319·35°
$p \times 10^{-3}$	1·171	1·895	5·145	11·514	17·454	25·079	28·079

H. von Jüptner, and R. Lorenz and W. Herz studied this subject. J. B. A. Dumas gave 120° at 767 mm. for the **boiling point**; J. I. Pierre, 115·4° at 753 mm.; T. Andrews, 112·5° at 752 mm.; J. Bongartz and A. Classen, 120°; W. Coldridge, 112°; G. Neumann, 113·5°–114°; A. Haagen, 112° at 755 mm.; J. Kendall and co-workers, 114° at 760 mm.; F. W. Schmidt, 117° at 708·5 mm.; E. Beckmann and P. Geib, 114·5°; P. Walden, 114° at 757 mm.; P. A. Bond and H. T. Beach, 112·1° at 750 mm.; and T. E. Thorpe, 113·89° at 760 mm. S. Young gave 0·000121 (760$-p$) (273+θ) for the correction to be added to the observed b.p. θ, at the barometric press. p corrected to 0°. N. de Kolossowsky gave 0·515 to 0·65 for the **ebullioscopic constant.** S. Young gave 318·7° for the **critical temperature;** 28,080 mm. for the **critical pressure;** 0·732–0·743 for the **critical density** calculated from the formula of R. O. Herzog; and 1·347 for the **critical volume.** Observations were also made by P. Walden, F. Schuster, E. Mathias, and G. Rudorf. E. E. Walker found the association factor at the critical point to be 1·011. W. Herz studied the relations of the critical constants, and of the co-volume.

A. Besson said that stannic chloride is still liquid at $-29°$, and at the **freezing point,** $-33°$, it forms a white crystalline solid if free chlorine be absent, but if chlorine be present, the f.p. is lower. J. Kendall and co-workers gave $-30.2°$ for the f.p., and W. M. Latimer gave $-33.1°$ for the **melting point;** A. Besson, $-33°$; and P. A. Bond and H. T. Beach, $-32.7°$. W. H. Latimer found the **heat of fusion** at the m.p. to be 8·42 cals. per gram. A. Hantzsch and H. Carlsohn found that the m.p. of the halides of silicon, titanium, germanium, and tin can be calculated from the empirical relation: m.p. of halide=(m.p. of n-valent element

$+n \times$ m.p. of halogen)$/(n+1)$. He therefore inferred that the atoms can be little changed by union to form molecules; and inference which directly contradicts the deformation theory of K. Fajans and G. Joos. J. E. Mills and P. K. Smith, and E. Ariès calculated values for the internal **heat of vaporization** at different temp. T. Andrews gave 30·5 cals. for the latent heat of vaporization per gram, or 253·5 cals. per litre; D. L. Hammick, 32·6 cals.; W. Herz, 21·49 cals.; and H. V. Regnault gave 46·838 Cals. per kilogram for the total heat of vaporization from 0° to the temp. of vaporization. According to W. Meyerhoffer, if the trihydrate be heated above 83° it forms two non-miscible liquids—the one is a soln. of stannic chloride sat. with water, and the other, a soln. of water sat. with stannic chloride. G. T. Gerlach gave about 60° for the m.p. of the pentahydrate. H. V. Regnault gave for the **specific heat** of the vapour of stannic chloride 0·0939 for equal weights and 0·8416 for equal vols.; for the liquid between 14° and 98°, 0·1476; and for the aq. soln. between 10° and 15°, 0·1402. W. M. Latimer gave for the sp. ht. C_p per mol. wt. $\div 5$ (when the * refers to the liquid state):

	$-184°$	$-178°$	$-111·8°$	$-72·5°$	$-45·7°$	$-6·1°$	$21°$
C_p	4·59	47·3	5·89	6·32	6·62	7·56*	7·86*

T. Andrews gave for the **heat of formation** of stannic chloride, $(Sn,2Cl_2)=127·0$ Cals.; M. Berthelot, 129·8 Cals.; and J. Thomsen, 127·25 Cals. M. Berthelot gave $(SnCl_{2aq.},Cl_2)=77·0$ Cals.; and J. Thomsen, 76·03 Cals. The last-named gave for the oxidation $SnCl_2.2HCl_{aq.}$ to $SnCl_4.Aq.$, 65·7 Cals., and 29·92 Cals. for the **heat of solution** of stannic chloride in water. G. T. Morgan and co-workers found the heat of soln. of stannic chloride in 200 parts of carbon tetrachloride to be 0·87 Cal. W. Herz gave 2·66 for the **chemical constant.**

A. Haagen found for the **index of refraction** of stannic chloride at 20°, 1·5070 for the H_α-line; 1·5225 for the H_β-line; and 1·5318 for the H_γ-line; while the **refraction equivalent** $(\mu_a-1)/D=0·2271$. J. H. Gladstone gave for the index of refraction 1·512 for $\lambda=0·589\mu$, and 1·503 for $\lambda=0·759\mu$. W. J. Pope gave 86·5 for the refraction eq. of the $SnCl_6$-radicle. J. H. Gladstone made some observations on the index of refraction of stannic chloride, and A. Stiefelhagen found for rays of wave length $\lambda=263$, 394, and $768\mu\mu$, the indices of refraction $\mu=1·678$, 1·54720, and 1·50689 respectively, and $\mu^2=1·63524+0·60045\lambda(\lambda^2-180·38)^{-1}$. F. F. Martens gave 1·544 for $\lambda=0·434\mu$; 1·530 for $\lambda=0·486\mu$; and 1·523 for $\lambda=0·535\mu$. W. Herz, and H. H. Marvin discussed the **optical dispersion,** etc. E. Bichat found that the vap. of stannic chloride rotates the plane of polarization of light. C. Sheard and C. S. Morris measured the **emission spectrum** of stannic chloride between 5800 and 4400.

L. Bleekrode found that stannic chloride is a very poor conductor of electricity; and W. Coldridge said that both at ordinary temp. and at the b.p. the **electrical conductivity** is nil or very small, the resistance at 112° being more than 1600 megohms; the liquid becomes a conductor if alcohol or hydrogen chloride is added, but not with chloroform, hydrogen sulphide, or chlorine. G. von Hevesy said it is as bad a conductor as benzene. As W. Madelung said, the salt is non-ionized. According to W. von Kowalewsky, the conductivity of stannic chlorides and of the liquid hydrates up to the enneahydrate is negligibly small. In dil. soln., the salt is hydrolyzed: $SnCl_4+4H_2O \rightleftharpoons 4HCl+Sn(OH)_4$; and some *hydrochlorostannic acid*, H_2SnCl_6, appears to be formed. The low velocity of the hydrolysis proves that few ions are present in the soln. The electrical conductivity increases with time; and equilibrium is attained before the hydrolysis is complete. The degree of hydrolysis is diminished by raising the temp. An excess of Cl'-ions hinders the hydrolysis, and the conductivity of a soln. of stannic chloride and hydrochloric acid may be less than that of the acid alone, owing, presumably, to the formation of a complex acid. The tendency of the tetrachlorides of tin, titanium, and silicon decreases in this order; and the same remark applies to the tendency to form complex salts. W. Foster, and A. Heydweiller made observa-

tions on this subject. Stannic acid separates from soln. of stannic chloride between 0·01N- and 0·5N-soln.; above and below these limits, the soln. remains clear. F. Kohlrausch traced the change in the conductivity with time, and it becomes less rapid as hydrolysis proceeds. Light has no hydrolyzing influence. The rate of hydrolysis increases at higher temp. The differences in the results with platinic and stannic chlorides show that these two salts are essentially different in type. The increase in the conductivity k per degree, dk/dt, is:

Conc.	0·001N	0·01N	0·02N	0·5N	N	2N	5N	17·7N
At 16°	—	—	—	0·0163	0·0163	0·0168	—	—
At 22°	0·0163	0·0162	0·0162	—	0·0160	0·0167	0·0225	0·0636

W. Dittenberger and R. Dietz observed that in the electrolysis of aq. soln. of stannic chloride, some tin is deposited at the cathode, but this is due to secondary reactions since it is improbable that the salt is resolved into $Sn^{....}$ and $4Cl'$-ions. P. Walden found that the conductivity of soln. of stannic chloride in liquid sulphur dioxide is very small, but is raised considerably by the addition of triphenylmethylchloride; D. Helbig and G. Fausti showed that soln. in liquid hydrogen chloride conduct like liquid hydrogen chloride alone; and W. von Kowalewsky showed that when a soln. of stannic chloride in a sat. soln. of sodium chloride is dil. with water, the sp. conductivity increases to a certain point with dilution. H. Schlundt gave 3·2 for the **dielectric constant** at 22°; and J. H. Mathews gave 2·0. The latter also gave 3·15 for the dielectric constant of a soln. of stannic chloride sat. with hydrogen chloride. W. Herz discussed the relation to the critical temp. G. Quincke gave $-0·18 \times 10^{-6}$ mass units for the **magnetic susceptibility** of stannic chloride.

The stannic oxychlorides.—If a mixture of the vapours of stannic chloride and water be passed through a red-hot tube, crystalline stannic oxide is formed (q.v.). The hydrolysis of the aq. soln. has been traced by the electrical conductivity of the soln. (q.v.). The aq. soln. is produced by the soln. of stannic chloride in water; of tin in aqua regia; of α-stannic acid in hydrochloric acid; or by the oxidation of a soln. of stannous chloride. H. Rose [5] showed that the soln. of stannic chloride in water gradually changes, and the change depends on the temp. and conc. of the soln. A conc. soln. is stable, while a dil. soln. deposits stannic acid; and, according to W. T. Casselmann, a very dil. soln. deposits stannic acid in the cold. C. E. Carstanjen observed that the hydrolysis of the aq. soln. is favoured by the presence of the sulphates of the alkalies, alkaline earths, ammonium, and aluminium. J. de la Puente directed attention to the possibility of a complete series of compounds, H_2SnCl_6, $H_2Sn(OH)Cl_5$, ... $H_2Sn(OH)_6$. J. Löwenthal showed that the older an aq. soln. of stannic chloride, the greater the quantity required to unite with potassium ferrocyanide; the change is faster the more dil. the soln.; and it is hindered when tartaric acid is present. R. Lorenz supposed that with the ageing of the soln., the proportion of tin-ions gradually decreases, and E. H. Loomis showed that the mol. depression of the f.p. is greater than corresponds with ionization into five ions $Sn^{....}$ and $4Cl'$; and he assumed that the soln. contained H_2SnCl_4. W. O. de Coninck, and P. Geiseler showed that charcoal accelerates the separation of stannic acid or an oxychloride from the aq. soln. L. Vignon regarded the soln. of stannic chloride in water as a mixture of stannic hydroxide and aq. hydrochloric acid; and at ordinary temp., the product is partially polymerized and α- and β-stannic acids are formed. If an excess of potassium hydroxide be added to the soln. of stannic chloride, the clear liquid becomes turbid in a few hours owing to the formation of a polystannate, $K_2Sn_nO_{2n}.(n-1)H_2O$. According to E. Biron, when α-stannic acid undergoes change, it yields an uninterrupted series of varieties of β-stannic acid, differing as regards their degree of condensation, which becomes greater as the temp. rises. The action of hydrochloric acid on these various β-stannic acids gives rise to oxychlorides which have an indefinite composition and contain a larger or smaller proportion of chlorine according as the condensation of the β-acid is small or great.

The reverse reactions, by which the oxychlorides are converted into a derivative of the α-acid, namely, stannic chloride, proceed the more readily the less the condensation. W. Smirnoff showed that when the tri-, tetra-, and penta-hydrates of stannic chloride are shaken up with xylene at various temp. between 60° and 111°, the value C_1/C_2 gradually changes, where C_1 denotes the percentage of the chloride in water, and C_2, the percentage in xylene. With the pentahydrate, the ratio falls from 504·4 at 66° to 59·3 at 111°; with the tetrahydrate, the ratio falls from 45·3 at 66° to 12·9 at 111°; and with the trihydrate, the ratio is independent of temp. It is assumed that the hydrates are readily dissociated into their components, that only free stannic chloride is soluble in xylene, and that the degree of dissociation of the hydrate increases with rising temp. and diminishing content of water; even at 66°, the trihydrate is completely dissociated.

As in the case of the stannic acids (q.v.), there are two views as to the nature of the chlorides of the stannic acids. The work of J. M. van Bemmelen, and G. Jörgensen shows that the first action of hydrochloric acid on the stannic acids is an absorption process. The products of definite composition obtained by R. Engel, and A. Kleinschmidt were the result of using stannic acid of practically the same degree of condensation, and absorption products of similar composition were obtained. F. Musculus, H. Kühl, and R. Zsigmondy consider that α-stannic acid passes into soln. on treatment with dil. or conc. hydrochloric acid, the β-acid is considered to be insoluble, although D. B. Dott held the contrary view. According to W. Mecklenburgh, once the β-acid is formed it can furnish a soln. only by peptization with conc. hydrochloric acid for a definite time, followed by dilution. G. E. Collins and J. K. Wood obtained stable sols by the direct action of dil. hydrochloric acid on β-stannic acid, provided the action be continued for a longer time. They showed that the first of the reactions between hydrochloric acid and stannic acid is probably simple absorption; and other things being constant, the amount of hydrochloric acid adsorbed by a given weight of stannic acid will depend on the surface exposed by the particles of the latter; and this will be smaller with a sample of β-stannic acid than with one of the α-acid. In agreement therewith a larger weight of the β-acid than of α-acid is needed to adsorb a given weight of hydrochloric acid. The adsorption may be followed by a chemical reaction between adsorbent and some of the adsorbed acid owing to the neutralization of the latter by some of the basic affinities of the original stannic hydroxide still possessed by the condensed acid; this will result in the formation of a certain amount of salt on the surface of the particle. Such a salt would be capable of ionization, and would then yield a complex positive ion and chloride ion. It will depend primarily on the conc. of hydrochloric acid still remaining in soln. whether or not this ionization actually occurs; the salt and the acid give rise to a common ion, and in view of this fact and the small solubility product which the salt will have, at any rate in the case of a highly condensed stannic acid, a small conc. of acid will be sufficient to repress almost entirely the ionization of the salt. If the ionization of the salt is not prevented, the complex particles will acquire a positive charge, and it will depend on the ratio between its mass and the charge it carries, whether or not a particle can separate itself from adjacent ones and thus acquire a greater degree of dispersion. Owing to the greater degree of condensation and therefore the greater mass and smaller adsorptive power of the β-stannic acid, it follows that this variety will not be so readily peptized as the α-acid. The latter modification will the more easily be brought into a state of true soln.; with an acid of β-character, however, it may easily arise that the ratio of mass to charge is of such dimensions that the particle is not raised to the potential which will enable it to lead a separate existence, in which case the substance will not peptize but will remain in the condition of a gel. Conversely, sols of β-stannic acid will be more readily coagulated than sols of the α-modification, as the particles in the former sol are, for a given charge, less dispersed than those in the latter sol; this is in agreement with the observations of W. Mecklenburgh. Another kind of

reaction may occur, for, continued G. E. Collins and J. K. Wood, the more the character of the acid approaches that of the β-acid, the greater is the extent to which salt formation between acidic and basic stannic hydroxide has taken place.   If a highly condensed stannic acid, therefore, be in the presence of hydrochloric acid, there will be a tendency for this salt-like complex to be decomposed by the stronger acid, and by this reaction there will be formed a less condensed stannic acid.   This decomposition or reversal of the α-β change will, for a given preparation, take place to a greater degree the higher the conc. of the hydrochloric acid, the longer the time of contact, and the more elevated the temp.   This view is supported by the observations of C. T. Barfoed, F. Musculus, and W. Mecklenburgh.   The formation of a less condensed acid results in an increase in the surface area of the particles, thus changing the adsorptive power and chemical affinity, which, in turn, changes the amount of hydrochloric acid remaining in soln., and in the degree of dispersion of the stannic acid.   Hence, G. E. Collins and J. K. Wood concluded that a degree of condensation of the stannic acid is eventually arrived at, which is in equilibrium with the free hydrochloric acid and with the substance which has been dispersed, so that no further peptization or coagulation takes place.   Such a state of equilibrium is attained only after the lapse of a very considerable time, for certain of the reactions involved are taking place in a solid medium.   During the period of attainment of this equilibrium, the liquid manifests continual change of composition, and the amount of tin existing in true and in colloidal soln. is continually changing.

According to W. T. Casselmann, when a soln. of stannous chloride is treated with chlorine, and evaporated, hydrogen chloride is evolved ; and after several evaporations from aq. soln., the soluble product has the composition, $SnOCl_2$, **stannyl chloride,** or **tin oxydichloride.**   A. Scheurer-Kestner obtained it by oxidizing a soln. of stannous chloride with nitric acid in the presence of an excess of hydrochloric acid, or by means of chromic acid.   J. M. Ordway used potassium chlorate as the oxidizing agent.   A. Scheurer-Kestner also obtained the salt from a filtered soln. of stannic hydroxide in a not too dil. soln. of stannic chloride. M. Berthelot obtained it by heating stannous chloride and oxygen in a sealed tube at 500° : $SnCl_2 + O = SnOCl_2 + 50.4$ Cals. ;   and by heating stannous oxide and chlorine : $SnO + Cl_2 = SnOCl_2 + 62.2$ Cals.   J. W. Mallet reported **stannyl hydroxychloride,** $SnO(OH)Cl$, to be formed when a conc. aq. soln. of stannous chloride is kept for a couple of years in an incompletely stoppered glass bottle.   It decomposes when heated, forming hydrogen chloride and stannic oxide ; sodium hydroxide precipitates stannic hydroxide ; and with ammonia it forms **stannyl ammonium chloride,** $SnO(ONH_4)Cl$.   P. Pfeiffer reported **tin hydroxytrichloride,** $Sn(OH)Cl_3$, to be formed by the hydrolysis of stannic chloride, for if a 50 per cent. soln. of stannic chloride, freshly prepared by dissolving the salt in water externally cooled by ice, is shaken with ether and the ethereal soln. dried and evaporated, 29 per cent. of the salt is obtained as the hydroxytrichloride, $SnCl_3.OH,H_2O,Et_2O$.   Only traces of this are obtained from stannic chloride soln. which have been prepared some hours before extraction.   On soln. in ether and precipitation with light petroleum, it forms colourless, deliquescent crystals melting and decomposing at 160°, and decomposing when dissolved in water.

J. J. Berzelius obtained a **β-stannic chloride** corresponding with the β-stannic acid which is formed by the action of nitric acid on tin.   When this compound is boiled with hydrochloric acid, the stannic acid does not dissolve, but it takes up some hydrochloric acid, forming a yellow mass which can be dried on filter-paper.   The product is soluble in water, but the soln. coagulates when boiled ; it gives a precipitate with conc. hydrochloric acid, and the precipitate dissolves in water after the acid has been removed.   When distilled, hydrochloric acid is evolved, then hydrogen chloride mixed with a little stannic chloride, and stannic oxide remains.   According to C. T. Barfoed, the aq. soln. contains the eq. of $8HCl + 9SnO_2$.

R. Weber reported *tin hexoxytetrachloride*, $Sn_4O_6Cl_4.5H_2O$, to be formed by evaporating a hydrochloric acid soln. of stannic acid ; the product is soluble in a small proportion of water but is precipitated when more water is added. He also reported *tin octoxytetrachloride*, $Sn_5O_8Cl_4.7H_2O$, to be precipitated by adding conc. hydrochloric acid to a hydrochloric acid soln. of stannic acid. There is nothing to establish these products as chemical individuals.

According to R. Engel, when 400 grms. of air-dried β-stannic acid, obtained by the action of nitric acid of sp. gr. 1·3–1·4, on tin, are digested in 100 c.c. of hydrochloric acid, of sp. gr. 1·18, for 15 mins., the gummy mass diluted with water, and the filtered soln. treated with an equal vol. of hydrochloric acid, a white amorphous precipitate is formed which settles very slowly. The precipitate, after washing with hydrochloric acid of sp. gr. 1·18, and dilution with its own vol. of water, can be dried first on porous tiles, and afterwards in vacuo over sulphuric acid and potassium hydroxide. The composition corresponds with β-**stannic dichloride,** $Sn_5O_9Cl_2.4H_2O$, analogous with β-stannic acid, $Sn_5O_9(OH)_2.4H_2O$. According to E. Biron's analysis, the product has twice this amount of chlorine. R. Engel reported this chloride to form a translucent deliquescent mass which dissolves in a small proportion of water or alcohol. The conc. aq. soln. can be diluted with water if a small proportion of hydrochloric acid has been added previously ; an excess of hydrochloric acid gives a precipitate. The addition of water to the soln. without acid gives a gelatinous precipitate of β-stannic acid which, after being washed and dried, will recombine with hydrochloric acid to form the original compound.

According to R. Engel, when a soln. of β-stannic dichloride in dil. hydrochloric acid is heated to 100° for some time, it rapidly acquires the property of giving a precipitate with dil. sulphuric acid which is characteristic of J. J. Berzelius' β-stannic chloride. No compound of definite composition could be isolated from the soln., but the composition of the solute approximates to that of β-stannyl chloride. R. Engel found that although parastannic acid is insoluble in hydrochloric acid, combination occurs, and, when dried, the resulting **parastannic dichloride**, $Sn_5O_9Cl_2.2H_2O$, dissolves in a small proportion of water, but with an excess of water furnishes a precipitate of parastannic acid. The opalescent soln. in water gives a precipitate with sulphuric acid, and is slowly precipitated by hydrogen sulphide.

G. Tschermak obtained a soln. of β-stannic acid in a hot hydrochloric acid soln. of stannous chloride. When the brownish-yellow liquid was cooled it furnished yellow lustrous plates difficult to obtain free from the mother-liquor. The composition approximated $(SnO)_4Cl_7.5H_2O$, *stannyl heptachloride*, and it was considered to be a *stannostannic or stannosic chloride* because it gives reactions characteristic of stannous chloride and β-stannic chloride. The salt is readily soluble in water and in alcohol, but it cannot be crystallized from the former without decomposition.

F. de Carli [6] studied the reducing action of **hydrogen** on stannic chloride. The action of water has just been discussed. A. Besson showed that stannic chloride at a low temp. absorbs large quantities of **chlorine,** with a considerable increase in vol., and a lowering of the f.p. W. Biltz and E. Meinecke found the f.p. curve of mixtures of chlorine and stannic chloride to have a eutectic at —106° and 80 at. per cent. of chlorine as indicated in Fig. 73. There is no evidence of the existence of complex salts. According to J. Girardin, **sulphur** may be crystallized unchanged from stannic chloride. H. Rose said that when stannic chloride is warmed with **hydrogen sulphide,** hydrogen chloride and stannic sulphide are formed ; in the cold, W. Coldridge observed the formation of white crystals of a complex **stannic chloropentasulphohydrate,** $SnCl_4.5H_2S$, or, according to J. B. A. Dumas, liquid **stannic disulphotetrachloride,** $SnCl_4.SnS_2$. W. Biltz and E. Keunecke found

FIG. 73. — Freezing-point Curves of Cl–SnCl₄ Mixtures.

that a *disulphohydrate*, $SnCl_4.2H_2S$, and a *tetrasulphohydrate*, $SnCl_4.4H_2S$, are formed respectively with heats of formation 6·98 Cals. and 6·60 Cals., and at —58° and —81°, the dissociation press. is 100 mm. H. Rose made stannic sulphochloride, $SnCl_4.2SCl_4$, by the action of dry chlorine on stannic sulphide ; the reaction is slow

in the cold, but fine crystals were obtained under these conditions by W. T. Cassel-
mann. H. Rose also obtained it by the action of chlorine on stannous sulphide
and from a cold mixture of stannic chloride and sulphur monochloride, S_2Cl_2, and
W. T. Casselmann said that if the mixture is sealed in a glass tube, rhombohedral
crystals are produced by spontaneous sublimation. O. Ruff and G. Fischer obtained
it by a modification of this process. The yellow crystals, according to H. Rose,
melt at a summer's heat, and, according to O. Ruff and G. Fischer, at 37°. W. T. Cas-
selmann said that when heated above 40° the compound is decomposed, chlorine
is evolved, and a mixture of sulphur monochloride and stannic chloride is produced.
At 30°, the compound sublimes with very little decomposition, especially in a
current of hydrogen chloride. The compound fumes in air more strongly than
stannic chloride. W. T. Casselmann said that the compound slowly decomposes
at 0° in moist air, forming a white mass impregnated with an acid liquid. The
mass dissolves in water without the separation of sulphur. The soln. contained
stannic chloride, and hydrochloric and sulphuric acids, but no thiosulphuric or
sulphurous acid. According to H. Rose, the salt attracts moisture from the atm.,
and with water forms a turbid liquid owing to the separation of sulphur; when
the aq. soln. is boiled, stannic oxide and chloride, and sulphuric, thiosulphuric, and
hydrochloric acids are formed. The crystals dissolve completely in dil. nitric acid
evolving nitrogen oxides, and the soln. contains stannic oxide and sulphuric acid.
Fuming nitric acid forms a white mass which is soluble in water. Aq. ammonia
separates sulphur and part of the stannic oxide, but dissolves a large proportion
of the stannic oxide, and there are formed thiosulphuric, sulphuric, and hydrochloric
acids. The crystals absorb ammonia with a great evolution of heat, forming a
yellowish-brown mass, which, when digested with water, forms undissolved stannic
oxide and sulphur, and the filtrate, which is neutral at first, becomes acidic, and
contains ammonium thiosulphate, sulphate, and chloride. O. Ruff and G. Fischer
found that the compound $SnCl_4.2SCl_4$ is soluble in chloroform, carbon disulphide,
phosphoryl chloride, benzene, ether, acetic ether, and sulphur chloride. The soln.
in phosphoryl chloride was found by W. T. Casselmann to form crystals of the
complex $SnCl_4.POCl_3$. P. A. Bond and H. T. Beach observed that no compound
is formed with sulphur dioxide above the m.p., $-72°$; and they found a
percentage solubility curve:

SnCl$_4$	.	100·00	86·16	71·75	58·54	31·96	11·78	5·40 per cent.
M.p.	.	$-32·7°$	42·6°	43·7°	44·0°	47·1°	63·0°	72·7°

They also obtained an unstable binary liquid system below the solubility curve.
According to H. Rose, stannic chloride absorbs much sulphur trioxide without
giving off sulphur dioxide, and a white mass is produced which dissolves in a small
proportion of water, forming a clear soln., and with an excess of water, a turbid
soln. When distilled, a brittle colourless mass collects in the receiver, and is
decomposed by water; a white sublimate collects in the neck of the retort; and
the residue in the retort contains stannic oxide and sulphate. O. C. M. Davis,
and H. Wölbling obtained stannic nitrogen chlorosulphide, $SnCl_4.2N_4S_4$, by mixing
dry chloroform soln. of nitrogen sulphide, N_4S_4, and stannic chloride. The red
crystals are decomposed at 165°, and by exposure to moist air. R. Weber made
stannic selenoxychloride, $SnCl_4.2SeOCl_2$, by dropping selenium oxychloride into
stannic chloride. If the latter be in excess, two immiscible liquids are formed,
and when slowly cooled, the lower layer furnishes white fusible crystals which are
rapidly decomposed by water. H. Friedrich found that sulphuric acid does not
react with stannic chloride. According to R. G. Durrant, sulphur dioxide has a
slight reducing action on stannic chloride: $SnCl_4+H_2SO_3+H_2O \rightleftharpoons SnCl_2+2HCl$
$+H_2SO_4$—vide stannous chloride. F. Clausnitzer showed that chlorosulphonic
acid, HSO_3Cl, does not react with stannic chloride; the two liquids are not com-
pletely miscible.

J. Davy [7] found that at ordinary temp. stannic chloride absorbs dry ammonia

with the development of heat, forming a white solid. H. Rose showed that the product should be repeatedly ground and exposed to the gas in order to saturate it completely. J. Davy said that the product can be sublimed without decomposition, and the sublimate appears in the form of yellowish-white acicular crystals. H. Rose's analysis of the sublimate corresponds with **stannic diamminochloride,** $SnCl_4.2NH_3$; both P. Grouvelle, and J. Persoz consider the unsublimed product is stannic tetramminochloride, $SnCl_4.4NH_3$. W. G. Mixter found the vap. density of the diammine to be 46·45, when the calculated value is 44·5 ; and it is inferred that there is some dissociation in the vaporous state. H. Rose said that it can be sublimed in hydrogen gas without decomposition, but, when it is heated in air, J. Davy said that it gives off white, pungent fumes. P. Grouvelle, and H. Rose said that the salt dissolves completely in cold water ; only that which has not been sublimed forms a turbid soln. ; the aq. soln. reddens litmus. According to H. Rose, when the aq. soln. is evaporated in vacuo over sulphuric acid, a mass of crystals of the undecomposed salt is obtained ; but if the cold soln. which gives no turbidity with ammonia, be heated or left standing for a few days, it deposits a gelatinous precipitate. Sulphuric acid gives a gelatinous precipitate when added to the aq. soln. Similar characteristics are shown by an aq. soln. of stannic chloride to which a little ammonia has been added. The diammine is not altered by phosphine in the cold, but when heated it gives off ammonia and becomes superficially red. When heated with sodium, it emits a brilliant violet light, and forms tin, sodium chloride, and ammonia gas. P. P. Dehérain said that hydrochloric acid transforms the diammine into ammonium chlorostannate. P. Fireman observed no reaction between stannic chloride and **ammonium chloride** after heating for several days at 400°.

J. L. Gay Lussac [8] found that when stannic chloride is treated with **nitric acid,** chlorine and nitrogen oxides are evolved, and β-stannic acid is formed. According to F. Kuhlmann, stannic chloride unites with **nitric oxide,** forming crystals of *stannic nitrosyl chloride,* $SnCl_4.NO$, but neither W. Hampe nor R. Weber could confirm this ; the latter obtained a lemon-yellow crystalline mass of *stannic nitrogen trioxychloride,* $SnCl_4.N_2O_3$, by the action of dry **nitrogen trioxide** on stannic chloride. V. Thomas passed **nitrogen peroxide** into a chloroform soln. of stannic chloride, and obtained a white crystalline mass with the composition of *stannic nitrogen oxychloride,* $SnOCl_2.3SnCl_4.N_2O_5$. R. Weber obtained a product corresponding with **stannic dinitroxylchloride,** $SnCl_4.2NOCl$, by the action of the vap. from aqua regia on stannic chloride ; a similar result was obtained by A. Baeyer, and S. M. Jörgensen. W. Hampe represented the composition $3SnCl_4.4NOCl$. V. Thomas obtained a white crystalline mass purporting to be $3SnCl_4.4NOCl$, by sublimation from the stannic nitrogen oxychloride, $SnOCl_2.3SnCl_4.N_2O_5$, cited above. J. J. Sudborough obtained a like product by the action of **nitrosyl chloride** on tin. W. J. van Heteren obtained it by the action of a large excess of nitrosyl chloride on stannic chloride, distilling off the nitrosyl chloride, and subliming the product. W. Hampe prepared this compound by the action of nitrogen trioxide on stannic chloride, and subliming the product : $3SnCl_4+2N_2O_3=SnO_2+2SnCl_4(NOCl)_2$. The pale yellow octahedral crystals were found by S. M. Jörgensen to have the sp. gr. 2·60 ; W. J. van Heteren said that they melt in a sealed tube at 180°, and volatilize without decomposition. According to R. Weber, and W. Hampe, the crystals fume in air, and are easily decomposed by water with the evolution of nitric oxide. S. M. Jörgensen said the compound attacks benzene and chloroform, but not carbon disulphide.

According to H. Rose,[9] stannic chloride absorbs **phosphine,** forming a yellow solid with the composition **stannic ditritaphosphinochloride,** $3SnCl_4.2PH_3$. The solid fumes in air and absorbs moisture with avidity ; when heated out of contact with air it forms stannous chloride, hydrogen chloride, and phosphorus. R. Mahn found it decomposes in carbon dioxide at 100°, forming hydrogen chloride and *chlorophosphorzinn,* $Sn_3P_2Cl_6$, **tin diphosphohexachloride** : $3SnCl_4.2PH_3=6HCl+Sn_3P_2Cl_6$. Stannic ditritaphosphinochloride is coloured black by ammonia

gas; with water, or aq. soln. of alkali hydroxide or carbonate, or of ammonium carbonate. Phosphine is evolved and tin phosphide is precipitated. W. T. Casselmann found that while stannic chloride mixes with **phosphorus trichloride** without union, it combines directly with **phosphorus pentachloride,** forming **stannic phosphoric chloride,** $SnCl_4.PCl_5$. If a mixture of the component chlorides be heated in a retort, stannic chloride distils over between $120°-130°$; phosphoric chloride between $140°-160°$; and the compound sublimes between $200°-230°$. E. Baudrimont found that phosphorus pentachloride reacts with tin, $3PCl_5+Sn=SnCl_4.PCl_5$ $+2PCl_3$; it was also made by heating a mixture of stannic disulphochloride and phosphorus trichloride : $SnCl_4.2SCl_2+PCl_3=S_2Cl_2+SnCl_4.PCl_5$, or by the action of chlorine and phosphorus pentachloride on the same compound. The white product has a penetrating odour, and at about $200°$ sublimes, forming colourless crystals which, in a hermetically sealed vessel, soon disintegrate into a white powder; the compound fumes in air and attracts moisture, forming colourless monoclinic crystals of what may be a hydrate. The compound is decomposed by water, forming stannic chloride, hydrochloric and phosphoric acids, and what appears to be stannic phosphate. According to W. T. Casselmann, **phosphoryl chloride** unites directly with stannic chloride, forming **stannic phosphoryl chloride,** $SnCl_4.POCl_3$; he also made it by heating in a sealed tube a mixture of phosphoryl chloride and stannic sulphochloride, $SnCl_4.2SCl_4$. A. W. Cronander prepared it by the action of phosphoric oxide on $SnCl_4.PCl_5$. According to W. T. Casselmann, the crystals melt at $58°$, forming a clear liquid which may remain for days in an undercooled state and then suddenly crystallize. It boils at $180°$ without decomposition. It fumes in air and attracts moisture, forming crystals of hydrated stannic chloride, stannous chloride, and hydrochloric and phosphoric acids. With a large excess of water it forms stannic phosphate. According to E. and P. Fireman, stannic chloride reacts slowly with **phosphonium iodide** at $90°-160°$: $4SnCl_4$ $+4PH_4I=SnI_4+3SnCl_2+10HCl+2PH_3+2P$; and at $250°-260°$: $6SnCl_4$ $+6PH_4I=3SnCl_2+3SnI_2+18HCl+2PH_3+4P$. For the action of **sodium hypophosphite,** *vide* the hypophosphites. R. Mahn observed no reaction between stannic chloride and **stibine.**

J. Davy [10] found that stannic chloride decomposes **alcohol,** forming stannous oxychloride and ethyl chloride; C. Girard and P. Chapoteaut, J. H. Mathews, H. Goldschmidt and H. Larsen, G. Gustavson, H. Meyer and R. Turnau, E. Besthorn, B. Holmberg, A. Bauer and E. Klein, and A. Rosenheim and R. Schnabel prepared complex compounds of stannic chloride and alcohol. B. Lewy, and F. Kuhlmann prepared an addition product with **ether,** namely, $SnCl_4.2(C_2H_5)_2O$. According to J. Davy, stannic chloride reacts with **turpentine ;** and, at the same time, the mixture becomes strongly heated, sometimes inflaming the mass and forming stannic oxide. F. Wöhler observed no reaction with **ethylene ;** A. Bertrand found that stannic chloride decomposes **acetic acid,** and **acetic anhydride.** N. Trifonoff examined the magnetic susceptibility of mixtures with **ethyl acetate,** and found a maximum corresponding with $SnCl_4.3C_4H_8O_2$. G. N. Antonoff studied the f.p. curve of mixtures of stannic chloride and **methyl oxalate.** L. Klien obtained an addition product with **hydrogen cyanide,** namely, $SnCl_4.HCy$. P. Pfeiffer and R. Lehnardt, and J. G. F. Druce prepared *methyl stannic chloride,* $Sn(CH_3)Cl_3$; and various other substitution products and complex salts. J. G. F. Druce also made *ethyl stannic chloride,* $Sn(C_2H_5)Cl_3$; *isopropyl stannic chloride,* $Sn(C_3H_7)Cl_3$; as well as complex salts of these compounds, and *diisopropyl stannic dibromide,* $(C_3H_7)_2SnBr_2$; G. Scagliarini complexes with organic bases; and G. T. Morgan and H. D. K. Drew made chloro-derivatives of the β-ketones. P. Pfeiffer represented tin hexavalent in the compounds of stannic chloride with two mols. of a ketone; and on the co-ordinate valency theory the co-ordination number of tin is 6, *e.g.* $SnCl_4(·O : CR_2)_2$. N. S. Kurnakoff and co-workers measured the viscosity and f.p. of mixtures of stannic chloride with various esters; N. S. Kurnakoff and co-workers, prepared other organic compounds. B. Köhnlein found that

propyl iodide reacts nearly completely with stannic chloride. F. Fichter and co-workers hold that in weighting silk with stannic chloride, the process begins with the formation of an additive compound of the two. E. Elöd doubted this. W. Anosoff studied the refractive index of mixtures of benzene and stannic chloride.

A. C. Vournasos [11] found that **potassium** reduced tin tetrachloride in boiling toluene soln., forming fine particles of tin. According to J. B. A. Dumas, stannic chloride reacts with **mercury,** forming mercurous and stannous chlorides. A. Levallois studied the action of stannic chloride on **lead sulphide.** A number of complex salts with the metal chlorides have been prepared. Many of these are to be regarded as chlorostannates or stannichlorides, derivatives of **hydrochloro-stannic acid,** H_2SnCl_6. E. Biron [12] prepared chlorostannates of the alkalies, calcium, strontium, beryllium, magnesium, manganese, iron, nickel, cobalt, and zinc, but not of barium, cadmium, silver, copper, lead, and thallium. He found that the chlorides of the elements which furnish chlorostannates retard the speed of hydrolysis of stannic chloride to about the same extent. The increase in the conductivity of the soln. with time and the change in the absorption of light enable the affinity constants, k, of the respective chlorides for stannic chloride to be calculated with the results :

	LiC	NaCl	KCl	NH_4Cl	$MgCl_2$	$ZnCl_2$	$CdCl_2$
k	1·00	0·62	0·48	0·59	0·80	0·16	0·06

	$CaCl_2$	$SrCl_2$	$BaCl_2$	$MnCl_2$	$CoCl_2$	$NiCl_2$	$FeCl_2$
k	0·71	0·75	0·80	0·62	0·80	0·76	0·48

R. Engel prepared hexahydrated hydrochlorostannic acid, $H_2SnCl_6.6H_2O$, by the action of dry hydrogen chloride on pentahydrated stannic chloride. The crystals form a homogeneous liquid which when sat. has a sp. gr. 1·971 at 28° ; the liquid solidifies at 0° to tabular crystals which melt at 20°. K. Seubert and E. Schürmann prepared similar crystals by the following process :

Stannic chloride is mixed with conc. hydrochloric acid in such proportions that the water in the acid shall be in relation to the stannic chloride as $SnCl_4 : 6H_2O$. 100 parts of stannic chloride require 62·15 parts of 33 per cent. hydrochloric acid. Combination ensues, the mass becomes hot and softens, and hydrogen chloride is evolved. About 8 parts more of dry hydrogen chloride are then slowly passed into the mixture, which is then cooled. The whole solidifies to a scaly crystalline mass of hydrochlorostannic acid.

K. Seubert and E. Schürmann gave 19·2° for the m.p. The crystals lose hydrogen chloride in air ; they are very deliquescent ; but can be preserved in sealed tubes. According to J. Bellucci and N. Parravano, when kept in air or in vacuo, over potassium hydroxide, pentahydrated stannic chloride is formed ; and dil. aq. soln. at ordinary temp. deposit stannic acid.

According to P. A. Bolley,[13] when conc. soln. of stannic chloride and ammonium chloride are mixed, or when a mixture of the dil. soln. is evaporated, octahedral crystals of **ammonium chlorostannate,** $(NH_4)_2SnCl_6$, are deposited. J. G. F. Druce also prepared this salt. It was formerly used by the calico printer under the name *pink-salt* in allusion to its use as a mordant for madder-red colours. G. C. Wittstein made it by mixing a soln. of 40 parts of tin in aqua regia and 35 parts of ammonium chloride at 100°, evaporating the soln. to dryness, and recrystallizing from its aq. soln. H. Silbermann, and E. Biron used a modification of these processes. L. Gmelin obtained it as a sublimate during the preparation of stannic sulphide from a mixture of tin, sulphur, and ammonium chloride. The salt furnishes octa-hedral crystals belonging to the cubic system ; the cleavage is also octahedral. R. G. Dickinson studied the X-radiogram of this salt, and the result is indicated in connection with potassium chlorostannate. E. Carozzi gave 1·677 for the index of refraction with the D-line at 18°. He found the crystals form isomorphous mixtures with those of the corresponding lead and platinum compounds, but in the latter case there is a gap in the miscibility curve with between 22 and 74·5 per cent. of the chlorostannate. S. M. Jörgensen gave 2·390 for the sp. gr. ; H. G. F. Schröder, 2·387 ; E. Carozzi, 2·39 ; and R. Romanis, 2·511. The last-named gave 146·1

for the mol. vol.   P. A. Bolley found that 100 parts of water at 14·5° dissolve 33·3 parts of salt ; the conc. aq. soln. is not decomposed by boiling, but the dil. soln. may form flocculent stannic hydroxide.   A. Gutbier and co-workers prepared a number of organic ammonium chlorostannates.

A. Chassevant [14] prepared **lithium chlorostannate**, $Li_2SnCl_6.8H_2O$, by oxidizing a mixed aq. soln. of stannous and lithium chlorides.   The soln. becomes turbid if it is allowed to stand for some time owing to the formation of stannous hydroxide, but if evaporated over sulphuric acid, small, colourless, octahedral crystals are formed. J. G. F. Druce also prepared this salt.   The salt easily decomposes, and is deliquescent in air ; it is easily soluble in water, but is hydrolyzed by an excess of water. It loses hydrogen chloride and chlorine at 140°–150°.   E. Biron prepared this salt but regarded it as a hexahydrate.   G. C. Wittstein, and J. G. F. Druce prepared **sodium chlorostannate**, $Na_2SnCl_6.6H_2O$, by evaporating a mixed soln. of stannic and sodium chlorides, and they described the product as forming anhydrous cubes ; P. A. Bolley said rhombic laminæ ; and B. Lewy, small prisms.   The evidence is not clear that the salts obtained by P. A. Bolley and G. C. Wittstein had the same crystalline form.   The analysis of B. Lewy corresponded with a pentahydrate ; S. M. Jörgensen's, E. Biron's, and H. Töpsöe and C. Christiansen's analyses, with a hexahydrate.   The last-named said that the ignition of the complex furnishes sodium chloride and stannic chloride ; P. A. Bolley added that 12·13 per cent. of water is lost during ignition, and stannic chloride is evolved at a red heat.   The crystals are permanent in cold air, but effloresce in warm air.   W. von Kowalewsky found that when a soln. of stannic chloride is added to a sat. soln. of sodium chloride, the sp. conductivity of the mixed soln. increases to a certain point with dilution. J. de la Puente found a mol of stannic chloride reacts with 4 mols of sodium hydroxide, forming **sodium dihydroxydichlorostannate**, $Na_2Sn(OH)_2Cl_2$, and the same product is obtained by the action of a mol of orthostannic acid and 2 mols of hydrogen chloride and sodium hydroxide.

V. A. Jacquelin evaporated an aq. soln. of equimolar parts of potassium and stannic chlorides and obtained crystals of **potassium chlorostannate**, K_2SnCl_6 ; P. A. Bolley found that the same salt is produced if the potassium chloride be in large excess.   The salt was made by E. Biron and J. A. Streng.   J. G. F. Druce made it by oxidizing with chlorine a conc. soln. of potassium chlorostannite, or an acid soln. of stannous chloride in a conc. soln. of potassium chloride.   V. A. Jacquelin said the crystals are rhombohedral ; P. A. Bolley, G. C. Wittstein, B. Lewy, and C. F. Rammelsberg said that the crystals are octahedral.   The X-radiograms of the isomorphous ammonium and potassium chlorostannates were shown by R. G. Dickinson to be in agreement with the space lattice of calcium fluoride in which the calcium atoms are replaced by the chlorostannate radicle $SnCl_6$, and this group, A, Fig. 74, is represented by ● in the lattice diagram, Fig. 74.   The lattice of the potassium salt is a system of potassium atoms and $SnCl_6$-groups ; similarly with the ammonium salt.   The potassium atoms K, or NH_4-radicles, are represented by ○ in the diagram.   Each potassium atom has four tin atoms equidistant from it ; and each tin atom has eight potassium atoms equidistant from it ; each chlorine atom has four

Fig. 74.—Space Lattice of the Alkali Chlorostannates.

potassium atoms equidistant from it ; and each potassium atom has twelve chlorine atoms equidistant from it ; each chlorine atom is at a shorter distance from one tin atom than from any other ; and each tin atom has six chlorine atoms at this distance from it.   The distance between the atoms in the ammonium and potassium chlorostannates are :

	Sn Cl	K–Sn, or NH_4–Sn	K–Cl, or NH_4–Cl
K_2SnCl_6 .	. 2·44 A.	4·31 A.	3·52 A.
$(NH_4)_2SnCl_6$	. 2·46 A.	4·35 A.	3·55 A.

S. M. Jörgensen gave 2·70 for the sp. gr.; H. G. F. Schröder, 2·687; and R. Romanis, 2·948. A. E. van Arkel and J. H. de Boer examined the at. vol. J. Thomsen's value for the heat of formation from the component salts is 34·16 Cals.; and the heat of soln. in water, —3·38 Cals. H. Töpsöe and C. Christiansen found for the refractive index 1·6517 with the C-line; 1·6574 with the D-line; and 1·6717 with the F-line. The crystals are permanent in air, and decrepitate when heated giving off stannic chloride and leaving a residue of potassium chloride mixed with a little stannic chloride, according to G. C. Wittstein, or stannic oxide, according to P. A. Bolley. J. Bellucci and N. Parravano saw that this salt is less stable than the isomorphous potassium chloroplatinate; it is hydrolyzed in hot conc. soln., and in cold dil. soln. with the separation of stannic hydroxide. They were unable to make other complex salts by the double decomposition of conc. soln. of potassium chlorostannate and soln. of the metal salts. J. Morel obtained **monohydrated potassium chlorostannate**, $K_2SnCl_6.H_2O$, by crystallization from an aq. soln. at a temp. below 25°. The rhombic crystals have the axial ratios $a:b:c=0.6843:1:0.7588$. The crystals are colourless and transparent; they are stable in air and in a moist atm. They lose 4–5 per cent. in weight at 110°–120°; and the loss is not attended by a change in the crystalline form. R. Godeffroy deposited octahedral crystals of **rubidium chlorostannate**, Rb_2SnCl_6, from a mixed hydrochloric acid soln. of rubidium chloride and stannic chloride. The octahedral crystals, said E. Biron, are isomorphous with those of the corresponding potassium salt. J. G. F. Druce also made this salt. It is the basis of a method for separating rubidium from other alkali chlorides. F. Stolba, E. H. Ducloux, and J. G. F. Druce obtained **cæsium chlorostannate**, Cs_2SnCl_6, from a mixed aq. soln. of the component salts. The microscopic crystals are octahedral and cubic. The sp. gr. is 3·3308 at 20·5°. They are virtually insoluble in conc. hydrochloric acid; they are decomposed by heating with ammonium chloride; by sulphuric acid; and by hydrofluosilicic acid. E. Biron also prepared this salt. H. Behrens used the salt as a means of recognizing cæsium microscopically. E. Biron did not succeed in making *copper and silver chlorostannates*.

H. Töpsöe and C. Christiansen, E. Biron, F. de la Provostaye, and B. Lewy prepared crystals of **calcium chlorostannate**, $CaSnCl_6.6H_2O$, by evaporating a mixed soln. of the component chlorides over sulphuric acid. The rhombohedral crystals are very deliquescent. B. Lewy regarded the crystals as pentahydrated. J. G. F. Druce obtained anhydrous crystals. H. Töpsöe and C. Christiansen, E. Biron, and B. Lewy made prismatic crystals of **strontium chlorostannate**, $SrSnCl_6.6H_2O$. B. Lewy regarded the salt as pentahydrated; J. G. F. Druce, as tetrahydrated; and H. Töpsöe and C. Christiansen, as octohydrated. E. Biron also reported **tetrahydrated strontium chlorostannate**, $SrSnCl_6.4H_2O$. B. Lewy reported crystals of **barium chlorostannate**, $BaSnCl_6.5H_2O$, but E. Biron could not make this salt, and J. G. F. Druce obtained it only in an impure form. A. Atterberg, and E. Biron obtained a white powder of **beryllium chlorostannate**, $BeSnCl_6.8H_2O$, by evaporating a soln. of the component salts. B. Lewy, J. G. F. Druce, and E. Biron made **magnesium chlorostannate**, $MgSnCl_6.6H_2O$, by evaporating a soln. of the component salts. S. M. Jörgensen evaporated the soln. at 45°–50°, and, on slowly cooling, obtained deliquescent rhombohedral crystals belonging to the trigonal system with the axial ratio $a:c=1:0.508$. The crystals were optically positive. The sp. gr. is 2·08. B. Lewy regarded the salt as a pentahydrate. H. Töpsöe and C. Christiansen also examined the optical properties of the crystals, and gave for the indices of refraction for the D-line, $\omega=1.5885$ and $\epsilon=1.597$; and for the C-line, $\omega=1.5715$, and $\epsilon=1.583$. At 100°, they lose water and stannic chloride. E. Biron, and J. G. F. Druce made crystals of **zinc chlorostannate**, $ZnSnCl_6.6H_2O$, by evaporating a mixed soln. of the component salts; but he could not obtain *cadmium chlorostannate* in this way.

J. Kendall and co-workers found evidence of no compound on the f.p. curve of mixtures of *aluminium and stannic chlorides*. The m.p. falls from 188·6° with

6·8 per cent. of $SnCl_4$ to 65·7° with 99·6 per cent. E. Biron could not prepare *thallous chlorostannate;* nor *lead chlorostannate.* S. M. Jörgensen reported **manganese chlorostannate,** $MnSnCl_6.6H_2O$, to be formed in pale red rhombohedra belonging to the trigonal system, and with the axial ratio $a : c = 1 : 0.5194$. The sp. gr. is 2·215. The crystals are optically positive ; they deliquesce in moist air, and effloresce in dry air, losing at 100°, water and stannous chloride. E. Biron made the same salt, S. M. Jörgensen, and J. G. F. Druce made **nickel chlorostannate,** $NiSnCl_6.6H_2O$, in greenish rhombohedra belonging to the trigonal system with the axial ratio $a : c = 1 : 0.5048$, and $a = 112° 30'$. The sp. gr. is 2·699. H. Töpsöe and C. Christiansen found that the double refraction is feeble and positive. S. M. Jörgensen, and J. G. F. Druce made the corresponding **cobalt chlorostannate,** $CoSnCl_6.6H_2O$, in rhombohedral crystals belonging to the trigonal system with the axial ratio $a : c = 1 : 0.5103$. The sp. gr. is 2·699. The crystals effloresce in dry air and at 100° lose water and stannic chloride. E. Biron studied the hydrolysis of the salt. E. Biron studied the **ferrous chlorostannate** in soln. *Vide* the stannic chloroplatinites and chloroplatinates.

§ 18. The Stannous Bromides

A. J. Balard[1] prepared **stannous bromide,** $SnBr_2$, by heating tin in an atm. of hydrogen bromide. An oily liquid condenses close to· the hot zone, and it freezes on cooling to a grey mass. B. Rayman and K. Preis purified the product of this operation by fractional distillation. A. E. Nordenskjöld treated tin with dry hydrogen bromide, and sublimed the white product in a sealed tube. C. Löwig made stannous bromide by heating a mixture of tin and mercurous bromide ; J. Nicklès, by heating stannic ethoxybromide, $SnBr_4.2(C_2H_5)_2O$; and F. Freyer and V. Meyer, by dissolving powdered tin in hot hydrobromic acid, and gently evaporating the soln. Stannous bromide forms a pale yellow crystalline mass, consisting, according to J. Nicklès, of hexagonal columns, which A. E. Nordenskjöld said belong to the rhombic system and have the axial ratios $a : b : c$ $= 0.5735 : 1 : 0.5305$. S. Motylewsky found 75 for the drop weight of stannous bromide with respect to water at $0° = 100$. B. Rayman and K. Preis found the

sp. gr. at 17° to be 5·117 ; W. Beltz and E. Birk gave 4·923 for the sp. gr. of fused stannous bromide at 25°/4°, and 56·57 for the mol. vol. I. I. Saslawsky gave 1·03 for the ratio of the mol. vol. to the sum of the at. vols. of the constituent elements. B. Rayman and K. Preis found that stannous bromide melts to a pale yellow liquid at 215·5° ; J. Kendall and co-workers gave 232° for the m.p. ; and T. Karantassis, 226·7° ; T. Carnelley and W. C. Williams found the b.p. to be 617°–634° ; and F. Freyer and V. Meyer, 619°. M. Berthelot gave for the heat of formation $(Sn,Br_2)=71·4$ Cals., or with solid bromine 68·8 Cals. ; and for the heat of soln. in water, 16·0 Cals. ; W. Biltz and W. Fischer gave −1·6 cals. for $SnBr_2$. R. E. Liesegang showed that stannous bromide is sensitive to light. A. Naumann and J. Schröder found stannous bromide is soluble in pyridine ; and A. Werner found a mol. wt. of 268·35 in boiling pyridine ; and 257 in boiling ethyl sulphide when the value calculated for $SnBr_2$ is 278. When stannous bromide is heated in air or with potassium nitrate, stannic bromide and oxide are formed ; when heated in dry oxygen, M. Berthelot found that it catches fire at a red heat, forming bromine and stannic oxide. T. Karantassis could not obtain **stannous chlorobromide,** SnClBr, by the action of bromine on a soln. of stannous chloride in hydrochloric acid, and reducing the product with an excess of tin. The mixed chloride and bromide has a eutectic at 213° and 62·8 molar per cent. of stannous chloride.

B. Rayman and K. Preis said that the salt is hydrolyzed by water, forming a white **stannous oxybromide. A stannosic oxybromide,** or **stannostannic oxybromide,** $Sn_3OBr_6.12H_2O$, was also obtained in colourless prismatic crystals, by B. Rayman and K. Preis, by placing tin in a soln. of barium bromostannate. A. J. Balard evaporated an aq. soln. of stannous bromide, and found that while part of the salt is decomposed, colourless crystals of **monohydrated stannous bromide,** $SnBr_2.H_2O$, are formed. C. Löwig showed that tin dissolves very slowly in cold hydrobromic acid, and rapidly when boiled. The evaporation of the soln. gave a gelatinous mass without crystallization, and hydrogen bromide was produced on heating the product. B. Rayman and K. Preis showed that if the soln. be evaporated until a drop on a cold slab shows signs of crystallization and the liquid be then seeded with ready-formed crystals, the monohydrate forms needle-like or prismatic crystals. A. J. Balard also obtained the monohydrate from a soln. of stannous hydroxide in hydrobromic acid, or by reducing an aq. soln. of stannic bromide with tin. W. Biltz and W. Fischer found the heat of soln. of stannous bromide in one per cent. hydrochloric acid to be −1·6 Cals. They also found the temp. at which the vap. press. of the ammines is 100 mm., and the heats of dissociation in Cals. per mol. of NH_3 to be respectively for **stannous enneamminobromide,** $SnBr_2.9NH_3$, −57°, and 7·55 ; **stannous pentamminobromide,** $SnBr_2.5NH_3$, −2°, and 9·8 ; **stannous triamminobromide,** $SnBr_2.3NH_3$, 66°, and 12·4 ; and for **stannous diamminobromide,** $SnBr_2.2NH_3$, 102°, and 13·6. G. L. Clark also made observations on this subject. P. Pfeiffer studied the dialkyl stannous bromides ; and H. Goldschmidt and co-workers, the reduction of organic nitro-compounds by stannous bromide.

B. Rayman and K. Preis found that stannous bromide unites with metal bromides, forming **bromostannites.** A conc. soln. of stannous bromide and ammonium bromide, for example, deposits colourless, needle-like crystals of **ammonium tetrabromostannite,** $(NH_4)_2SnBr_4.H_2O$. E. Rimbach and K. Fleck made the same salt, and also **ammonium tribromostannite,** $NH_4SnBr_3.H_2O$, by the method employed for the corresponding chlorostannite ; while E. Rimbach and K. Fleck, and I. Remsen and G. M. Richardson obtained **potassium tribromostannite,** $KSnBr_3.H_2O$, from a soln. of potassium bromide containing a large excess of stannous bromide ; and a soln. of the component salts in equimolar proportions yields **potassium tetrabromostannite,** $K_2SnBr_4.H_2O$, in rhombic bipyramids with axial ratios $a:b:c$ $=0·6828:1:0·7467$. A. C. Vournasos made **sodium dichlorodibromostannate,** $Na_2[SnCl_2Br_2]$. E. Rimbach and K. Fleck obtained **ammonium hexabromo-**

stannite, $(NH_4)_4SnBr_6.H_2O$, in stable crystals. B. Rayman and K. Preis reported **ammonium dibromodichlorostannite,** $2NH_4Cl.SnBr_2H_2O$, or $(NH_4)_2SnBr_2Cl_2.H_2O$, to be formed in prismatic crystals by cooling a soln. of stannous bromide. The crystals belong to the rhombic system and have the axial ratios $a:b:c$ $=0.6959:1:0.7724$. If a larger proportion of stannous bromide is used, the product contains more bromine, $2NH_4(Cl,Br).SnBr_2.H_2O$. J. Kendall and co-workers found that with mixtures of aluminium and stannous bromides there is a two-liquid region extending from 1·8 to 14·2 per cent. $SnBr_2$ in equilibrium with **aluminium octobromostannite,** $2AlBr_3.SnBr_2$, at 161·1° ; the critical soln. temp. being 204·5° with 8·4 per cent. $SnBr_2$; the octobromostannite melts at 205°, and **aluminium pentabromostannite,** $AlBr_3.SnBr_2$, melts at 183°.

§ 19. The Stannic Bromides

A. J. Balard [1] found that tin burns in an atm. of bromine, forming stannic bromide, $SnBr_4$. T. Carnelley and L. T. O'Shea, and A. E. Nordenskjöld also prepared the bromide by the action of bromine on tin ; C. G. Cook added bromine drop by drop to granulated tin contained in a hot retort ; and R. Lorenz carried on the process as follows :

Tin, in pieces 2–3 cms. long, is placed in a distillation flask, closed at the top with a cork fitted with a separating funnel drawn out to a capillary point ; the funnel is filled with bromine, which is added to the tin so slowly that the temp. remains at 35°–59°, and the side tube does not become filled with bromine vap. ; the action proceeds quietly. When the greater portion of the tin has disappeared, the contents of the flask are distilled ; the first few drops contain a little bromine, but that which subsequently passes over is pure stannic bromide. It boils at 201°, is colourless, readily forms crystals, and fumes slightly on exposure to moist air. The bromide may be stored in a corked flask ; if this is heated to about 40°, the bromide readily melts, and can be withdrawn in any desired quantity.

B. Rayman and K. Preis purified the product from chlorides by fractional distilla-tion. C. Löwig obtained the same salt by the action of bromine on stannous bromide ; J. Personne, by the action of metallic tin on a soln. of bromine in carbon disulphide, or, according to J. Bongartz and A. Classen, in chloroform, distilling off the solvent, and purifying the product by fractional distillation ; and A. L. Poti-lizin, by the action of bromine on stannic chloride in a glass tube at about 420°.

According to A. J. Balard, stannic bromide is a white crystalline substance which, according to B. Rayman and K. Preis, can be obtained from its soln. in stannic chlorobromide in fine crystals ; the bromide sublimed in a sealed glass vessel also appears in well-developed crystals. A. E. Nordenskjöld showed that the crystals form rhombic pyramids with axial ratios $a:b:c=0.556:1:1.487$. The

crystals were also examined by J. W. Retgers. The sp. gr. given by C. H. D. Boedeker is 3·322 at 39°, and by B. Rayman and K. Preis, 3·340 at 35°. I. I. Saslawsky gave 1·40 for the ratio of the mol. vol. to the sum of the at. vols. of the constituent elements. The vap. density determined by T. Carnelley and L. T. O'Shea corresponds with the formula $SnBr_4$. The m.p. is near 30°; J. Kendall and co-workers gave 31·0; F. Garelli, 29·45; P. A. Bond and H. T. Beach, 29·45°; and B. Rayman and K. Preis gave 33°, and said that the molten bromide is a colourless, strongly refracting liquid—*vide supra*, stannic chloride. F. M. Raoult gave 26·4° for the m.p., and 243 for the mol. lowering of the f.p. R. Lorenz found that during the solidification of the molten bromide, an increase in vol. occurs often resulting in the fracture of the glass containing vessel. T. Carnelley and L. T. O'Shea gave 201° for the b.p.; B. Rayman and K. Preis, 203·3°; P. A. Bond and H. T. Beach, 205·05° and 734 mm.; and R. Lorenz, 201°. M. Berthelot gave for the heat of formation, $(Sn,2Br_2)=11·54$ Cals. for the crystalline salt, and 11·24 Cals. for the melted bromide; and $(SnBr_2,Br_{2solid})=32·2$ Cals. S. U. Pickering gave 0·007169 cal. per gram for the latent heat of fusion; 18·6 Cals. for the heat of soln. in water; and for the heat of hydration, $(SnBr_4,8H_2O)=14·906$ Cals. for the liquid, and 9·748 for the solid. G. T. Morgan and co-workers gave −3·15 Cals. for the heat of soln. of stannic bromide in 200 parts of carbon tetrachloride. S. Tolloczko studied the ionizing power of stannic bromide as a solvent.

B. Rayman and K. Preis found that stannic bromide is fairly stable when heated; very little decomposition occurs when the vap. is passed through a red-hot tube. M. Berthelot showed that when stannic bromide is heated in oxygen, bromine is evolved and stannic oxide formed without incandescence. According to R. Lorenz, when stannic bromide is exposed to air, it absorbs water; and when the aq. soln. is evaporated over sulphuric acid, colourless crystals of **tetrahydrated stannic bromide,** $SnBr_4.4H_2O$, are produced. The crystals fume a little on exposure to air. The aq. soln. of stannic bromide becomes turbid faster than is the case with stannic chloride. The clear aq. soln. soon becomes opalescent, and it deposits α-stannic acid which soon forms the β-acid. One c.c. of a $\frac{1}{10}N$-soln. of stannic bromide contained after

	0	1010	1430	1490	2510	2870	3890	7590 min.
Sn	0·01180	0·0₃9676	0·0₃9027	0·0₃8614	0·0₄590	0·0₄295	0·0₄177	0·0₄177 grm.

B. Rayman and K. Preis obtained colourless, needle-like crystals of a **stannic oxybromide,** $Sn_3O_2Br_8.10H_2O$; and A. J. Balard reported one to be formed by the action of bromine on stannous oxide; he added that bromine has no action on stannic oxide. P. Pfeiffer obtained a complex of **stannic hydroxytribromide,** $Sn(OH)Br_3$, with ether, namely, $Sn(OH)Br_3.H_2O.(C_2H_5)_2O$, analogous to the corresponding hydroxychloride. P. Pfeiffer and R. Lehnardt, and J. G. F. Druce prepared *methyl stannic bromide,* $Sn(CH_3)Br_3$; *ethyl stannic bromide,* $Sn(C_2H_5)Br_3$; *isopropyl stannic bromide,* $Sn(C_3H_7)Br_3$; and normal *propyl stannic bromide,* $Sn(C_3H_7)Br_3$, as well as some complex salts. G. T. Morgan and H. D. K. Drew made complexes with the β-ketones. J. Nicklès obtained a complex of ether with stannic bromide, $SnBr_4.(C_2H_5)_2O$. W. Biltz and E. Keunecke observed no reaction or dissolution of stannic bromide and liquid hydrogen sulphide at −78·5°; and P. A. Bond and H. T. Beach found that stannic bromide does not form a compound with sulphur dioxide below the m.p., −72°; but there is a critical soln. temp. in the binary system at 48·6°. There is a eutectic at 16·3° on the stannic bromide side of the percentage solubility in sulphur dioxide curve:

$SnBr_4$	100	94·12	78·97	21·67	16·55	9·45	6·29	1·88	0·39
m.p.	29·45°	16·60°	47·70°	16·3°	13·2°	3·25°	−3·5°	−24·0°	53·05°

The reducing action of hydrogen was studied by F. de Carli. Molten stannic bromide was found by B. Rayman and K. Preis to dissolve iodine readily, and

sulphur, and P. Walden found the soln. in liquid sulphur dioxide is not a good electrical conductor.   A. J. Balard said that stannic bromide dissolves in sulphuric acid, without perceptible decomposition, forming an oily liquid.   B. Rayman and K. Preis found that stannic bromide absorbs ammonia with avidity, forming white **stannic diamminobromide**, $SnBr_4.2NH_3$.   V. Thomas found that with nitrogen peroxide, a compound $3SnOBr_2.SnO_2.N_2O_5$ is formed; and A. J. Balard, that with nitric acid, the vap. of bromine is vigorously given off.   P. Walden found stannic bromide is soluble in arsenic tribromide.

B. Rayman and K. Preis dissolved stannic bromide in a very small proportion of water, sat. the soln. with hydrobromic acid, and obtained fine colourless prisms or needle-like crystals of what was regarded as **hydrobromostannic acid,** $H_2SnBr_6.8H_2O$.   They obtained the same product by the action of bromine on a soln. of stannic bromide in amyl alcohol.   K. Seubert and E. Schürmann made a similar substance by the method employed for hydrochlorostannic acid, using 100 parts of molten stannic bromide and 74·1 parts of 50 per cent. hydrobromic acid. The product was regarded as a heptahydrate; but the analysis was difficult on account of the deliquescence of the salt, and the ease with which it gave off hydrogen bromide.   The acid occurs in amber-yellow, needle-like crystals; or if a conc. soln. is cooled it occurs in plates which are probably triclinic.   The crystals fume in air.   G. N. Antonoff studied the f.p. curves of mixtures of stannic bromide and methyl oxalate.

B. Rayman and K. Preis prepared a number of **bromostannates.**   When ammonium bromide is added to a conc. soln. of hydrobromostannic acid, **ammonium bromostannate**, $(NH_4)_2SnBr_6$, is precipitated in pale yellow or colourless crystals. H. Töpsöe found the octahedral crystals have a sp. gr. 3·505; E. Carozzi gave 3·51; and F. Leteur added that they are inactive in polarized light, and stable in air.   B. Rayman and K. Preis found ammonium chloride reacts with a soln. of stannic bromide, forming *ammonium chlorobromostannate*.   They prepared **cæsium bromostannate**, Cs_2SnBr_6, and **rubidium bromostannate**, Rb_2SnBr_6, in a similar manner.   They prepared **potassium bromostannate**, K_2SnBr_6, by pouring a soln. of hydrobromostannic acid on solid potassium bromide.   H. Töpsöe said the octahedral crystals are easily soluble in water, and have a sp. gr. 3·783; F. Leteur added that the crystals are stable in air.   B. Rayman and K. Preis obtained **sodium bromostannate**, $Na_2SnBr_6.6H_2O$, by evaporating over conc. sulphuric acid an aq. soln. of stannic bromide with the calculated quantity of sodium bromide; K. Seubert and E. Schürmann obtained it by evaporating a soln. of hydrobromostannic acid sat. with sodium carbonate.   The pale yellow prismatic or acicular crystals belong, according to F. Leteur, to the monoclinic system, and have a strong double refraction.   They are very soluble in water; and, according to K. Seubert and E. Schürmann, they effloresce in air.   At 90°, water and stannic bromide are given off.   It is supposed to correspond with the sodium bromoplatinate, $Na_2PtBr_6.6H_2O$. B. Rayman and K. Preis, and F. Leteur prepared **lithium bromostannate,** $Li_2SnBr_6.6H_2O$, in small, yellow, hygroscopic plates which have a strong double refraction.   They lost a mol of water over sulphuric acid.

B. Rayman and K. Preis obtained slender, needle-like, deliquescent crystals of **calcium bromostannate**, $CaSnBr_6.6H_2O$, by evaporating over conc. sulphuric acid a mixed soln. of the component bromides.   The corresponding **strontium bromostannate**, $SrSnBr_6.6H_2O$, could be obtained only in admixture with tetrahydrated stannic bromide as a pale yellow, deliquescent, crystalline mass.   They obtained pale yellow tabular crystals of **magnesium bromostannate**, $MgSnBr_6.10H_2O$.   J. Kendall and co-workers obtained no evidence of a compound on the f.p. curves of mixtures of *stannic and aluminium bromides*.   F. Leteur said that the crystals are monoclinic; very deliquescent; and when heated give off water and stannic bromide.   B. Rayman and K. Preis used a similar process to prepare **manganese bromostannate,** $MnSnBr_6.6H_2O$, in large, pale yellow, deliquescent crystals, **ferrous bromostannate,** $FeSnBr_6.6H_2O$, in greenish-yellow, granular crystals; **cobalt bromostannate,**

$CoSnBr_6.10H_2O$, in yellowish-red, tabular, deliquescent crystals; and **nickel bromostannate,** $NiSnBr_6.8H_2O$, in apple-green, granular, deliquescent crystals.

A number of mixed salts containing both chlorine and bromine have been reported—**stannic bromochlorides.** J. W. Retgers doubted whether these products are chemical individuals, but A. Besson considered the individuality of some of them to be established. A. Ladenburg dropped bromine into cooled stannous chloride, and found that much heat is developed, and that two gram-atoms of bromine are fixed by a mol of stannous chloride. The yellow fuming liquid was quickly decomposed by water; and it boiled between 130° and 190°. The fractions with the lower b.p. were richer in bromine. B. Rayman and K. Preis obtained a chlorobromide by the action of chloriferous bromine on tin, and it boiled between 170° and 196°. A. Besson prepared a mixture of the chlorobromides by the slow action of dry hydrogen bromide on stannic chloride at a temp. below 0°; by the action of dry hydrogen bromide on a carbon tetrachloride soln. of anhydrous stannous chloride. The constituents were separated by fractional distillation in vacuo. They fume in air and are soluble in water, being at the same time decomposed. A. Besson found the **stannic tribromochloride,** $SnClBr_3$, is a liquid with a sp. gr. 3·12 at 13°; m.p. 1°; and b.p. 73° at 30 mm. press. It corresponds with the fraction obtained by A. Ladenburg boiling between 170° and 190°, and with the product prepared by B. Rayman and K. Preis. A. Besson found that **stannic dibromodichloride,** $SnBr_2Cl_2$, had a sp. gr. 2·82 at 13°; m.p., −20°; and b.p., 65° at 30 mm. press. It corresponds with the fraction obtained by A. Ladenburg, boiling between 160° and 170°. A. Besson obtained **stannic bromotrichloride,** $SnBrCl_3$, as a colourless liquid of sp. gr. 2·51 at 13°; m.p.−1°; and b.p. 50° at 30 mm. press. or 45° at 20 mm. press.

§ 20. The Stannous Iodides

Tin forms two iodides, **stannous iodide,** SnI_2, and stannic iodide, SnI_4. According to H. Davy,[1] C. F. Rammelsberg, and J. L. Gay Lussac, when a mixture of tin-filings with twice its weight of iodine is heated, brownish-red translucent

stannous iodide is formed, but W. C. Henry showed that the product really contains both stannous and stannic iodides which can be separated by sublimation, for stannic iodide volatilizes at 180°, and stannous iodide remains fixed at a red heat ; and he added that if the product be mixed with finely divided tin, stannous iodide alone is obtained. J. Personne said that only stannic iodide can be prepared by the direct union of iodine and tin. W. Reinders and S. de Lange found that while it is true that stannic iodide is the first product of the action of iodine on tin, stannous iodide can be made by the prolonged heating of tin and stannic iodide in a sealed tube at 360°, by the reaction indicated by W. C. Henry : $Sn + SnI_4 = 2SnI_2$; and that the failure of J. Personne to obtain a partial conversion was due to his having failed to accelerate the reaction by the use of an excess of finely powdered tin which was done by W. C. Henry. If a soln. of stannous chloride be treated with iodine, stannous iodide is precipitated, and a mixture of stannous iodide and chloride, and stannic chloride remains in soln. P. Boullay found that if potassium iodide be added to a soln. of stannous chloride, the liquid soon deposits yellowish-red crystalline tufts of stannous iodide, and, if the mixture be warm, the iodide is deposited in yellowish-red needles. With eq. quantities of stannous chloride and potassium iodide, B. Köhnlein found that the stannous iodide is mixed with potassium iodostannite ; but if half the calculated potassium iodide be employed, stannous iodide alone is formed. J. Personne obtained similar results. J. L. Gay Lussac added that if tin is heated with an excess of iodine and a large proportion of water, a violent reaction occurs, the tin is rapidly oxidized, and a soln. of hydriodic acid is formed. J. Personne prepared stannous iodide by adding hydriodic acid to a soln. of stannous chloride ; and also by the action of hydriodic acid on pulverulent tin. F. Wöhler and F. Dünhaupt obtained stannous iodide by the action of boiling hydriodic acid on tin-foil for a day ; or by heating the mixture for an hour in a sealed tube at 120°–150°. A. E. Nordenskjöld used the latter process, and afterwards sublimed the product. F. Wöhler and F. Dünhaupt also obtained the iodide as sulphur-yellow prisms by heating tin-foil with amyl iodide in a sealed tube at 180°. When crystallized from its aq. soln., *dihydrated* stannous iodide, $SnI_2.2H_2O$, is formed in yellowish-red needles, and one mol. of the water is lost on drying the hydrate over sulphuric acid. P. Freundler and Y. Laurent said that when prepared from soln. of stannous chloride and potassium iodide the product is a mixture of red and yellow modifications—an excess of stannous chloride favouring the red form, and an excess of potassium iodide the yellow form. Exposure to sunlight changes the yellow to the red form, and conversely in darkness. With potassium iodide the red form is at once produced if the mixture is heated on the water-bath ; but with sodium iodide, and an excess of stannous chloride, the yellow form is produced. The yellow form is considered to be the stable modification at 100°. P. Freundler and Y. Laurent obtained the *monohydrate*, $SnI_2.H_2O$, by mixing cold, conc. soln. of sodium iodide and stannous chloride ; it is dehydrated by drying in the cold.

C. J. H. Warden said that if the moist precipitated iodide in a glass vessel be exposed to light, ruby-red crystals are formed on the side exposed directly to light, while the salt on the other side remains amorphous. A. E. Nordenskjöld said that the sublimed anhydrous salt furnishes colourless rhombic crystals with the axial ratios : $a : b : c = 0.5638 : 1 : 0.4993$. H. S. van Klooster stated that the crystals are monoclinic prisms $a : b : c = 1 : - : 0.5911$, and $\beta = 82° 55'$. C. H. D. Boedeker gave 4.696 for the sp. gr. ; J. W. Retgers, 4.7 ; and H. S. van Klooster, 5.21 at 15°/15°. S. Motylewsky gave 46 mgrms. for the drop-weight of stannous iodide when that of water at 0° is 100. J. Personne said that the crystals melt at a dull red heat, and, added W. C. Henry, the mass freezes to a dark red crystalline mass. J. Personne found that the salt sublimes at the temp. of melting glass, forming bright red crystals. W. Biltz and co-workers found 5.283–5.287 for the sp. gr. of crystalline stannous iodide at 25°/4°, and 70.48 for the mol. vol. T. Karantassis gave 320° for the m.p., while W. Reinders and S. de Lange gave 320°, and 720°

for the b.p. of stannous iodide. When heated in air, P. Boullay found that stannous iodide furnishes stannic oxide and a substance which is broken down by water into stannic acid and hydriodic acid. W. Biltz and W. Fischer gave —5·8 cals. for the heat of soln. of stannous iodide. G. T. Morgan and co-workers gave —3·81 for the heat of soln. of stannous iodide in 200 parts of carbon tetrachloride.

C. A. Kraus and H. F. Kurtz studied the reduction by sodium of stannous iodide dissolved in liquid ammonia. C. F. Rammelsberg found that stannous iodide is decolorized by ammonia, the gas is absorbed with the evolution of heat, and **stannous tetramminoiodide,** $SnI_2.4NH_3$, is formed. F. Ephraim and T. Schmidt add that this tetrammine was probably a stannic salt because, with dry ammonia and dry stannous iodide they could prepare only **stannous diamminoiodide,** $SnI_2.2NH_3$, which is white with a faint yellow tinge. W. Biltz and W. Fischer gave for the temp. at which the vap. press. of the amminoiodides is 100 mm. and the heats of dissociation in Cals. per mol of NH_3 respectively **stannous enneammino-iodide,** $SnI_2.9NH_3$, —48°, and 7·9 ; **stannous pentamminoiodide,** $SnI_2.5NH_3$, 10°, and 10·2 ; **stannous triamminoiodide,** $SnI_2.3NH_3$, 55°, and 11·9 ; **stannous diamminoiodide,** $SnI_2.2NH_3$, 94°, and 13·3 ; and **stannous monamminoiodide,** $SnI_2.NH_3$, 157°, and 16. G. L. Clark also made observations on this subject. P. Pfeiffer studied the dialkyl stannous iodides ; and T. Karantassis, complexes with organic bases.

The stannous iodide prepared by J. L. Gay Lussac, and C. F. Rammelsberg was said to be easily decomposed by water, especially by hot water, forming stannous hydroxide and an aq. soln. of hydriodic acid ; the hydrolysis is the more complete the greater the proportion of water; and J. Personne reported a number of **stannous oxyiodides** which he obtained by the action of water either on stannous iodide, or on potassium iodostannite. The analyses made of the products he obtained corresponded with the molar ratios $SnO : SnI_2 = 1 : 2$, $2 : 3$, $1 : 1$, and $2 : 1$, but there is no evidence to determine whether the products are chemical individuals or different stages in the progressive hydrolysis of stannous iodide. W. C. Henry, and P. Boullay said that the salt dissolves sparingly in water without decomposition, and the solubility is greater in hot than in cold water. The discrepancy in the results may be due to the contamination of J. Personne's stannous iodide with some stannic iodide. S. W. Young gave for the percentage solubility in water :

	20·8°	30·5°	41·0°	51·5°·	60·1°	73·9°	84·9°	98·5°
Per cent. SnI_2 .	1·30	1·21	1·50	1·79	2·09	2·56	3·05	3·43

P. Boullay added that the salt is soluble in a soln. of stannous chloride so that no precipitation occurs if only a small proportion of potassium iodide is added to the stannous salt soln. J. Personne found that stannous iodide is soluble in soln. of the alkali chlorides, in benzene, chloroform, and carbon disulphide. P. Boullay also showed that it combines with the more basic metal iodides, forming complex salts.

S. W. Young measured the solubility of stannous iodide in aq. soln. of hydriodic acid at 23·5°, and, expressing the results in percentages, he found :

HI .	0	3	4	6	8	10	12	14	15
SnI_2 .	1·0	0·26	0·22	0·16	0·17	0·26	0·45	0·62	0·81

The solubility of stannous iodide in water increases as the temp. rises. In hydriodic acid soln. containing 3 to 8 per cent. of acid, the solubility is less than in water, increasing with the temp. and diminishing with the conc. of the acid. With soln. of 9 to 15 per cent., the solubility is still less than in water, and increases with the temp., but it now also increases with the conc. When the soln. contain 25 per cent. and upwards, the solubility is greater than in water, and as the temp. rises the solubility at first diminishes until a point of minimum solubility is reached lying between 30° and 40° ; beyond this, the solubility again increases. A sat.

soln. of stannous iodide in hydriodic acid—25 per cent. and upwards—when cooled by ice-cold water, deposits pale yellow needles quite different in appearance from the red needles of stannous iodide. This yellow substance readily decomposes, giving the red iodide, and is so unstable that its composition could only be obtained by indirect methods. The yellow solid is **hydroiodostannous acid,** HSnI₃, which P. Pfeiffer called *stannoiodoform*. From 0° to 15° the solubility in hydriodic acid of 39·6 per cent. strength increases ; and from 15° to 20°, it still increases, but much more slowly ; on allowing the mixture to remain for some hours at 20°, the undissolved yellow hydroiodostannous acid changes to red stannous iodide, and this change is accompanied by a marked decrease in solubility ; from 20° to 30°, the solubility diminishes gradually, and from 30° upwards it increases regularly. With a similar soln. in 30 per cent. acid, the rapid decomposition of hydroiodo- stannous acid occurs at 1·5°, and in this case the change is accompanied by an increase in solubility. When in contact with stronger hydriodic acid, the hydro- iodostannous acid is stable at higher temp. The peculiarities observed in the curves of solubility are due to the gradual decomposition of solid and dissolved hydroiodostannous acid over a considerable range of temp. T. Karantassis observed that no compound of sulphur and stannous iodide could be prepared. B. Köhnlein found that stannous iodide scarcely reacts with propyl chloride.

A number of **iodostannites** have been obtained from mixtures of the metal iodide with a soln. of stannous chloride, or from a soln. containing the component iodides. The iodostannites are usually hydrolyzed by water. P. Boullay said that **ammonium iodostannite** is precipitated when ammonium iodide is added to a conc. soln. of stannous chloride ; or, according to J. Personne, when iodine acts on powdered tin in a conc. soln. of ammonium chloride. The greenish-yellow needles were found by P. Boullay to be readily decomposed by water. He showed that when a soln. of sodium iodide in one of conc. stannous chloride is allowed to stand for a few hours, it deposits crystals of stannous iodide followed by pale yellow crystals of **sodium iodostannite** which are decomposed by water. He also observed that when conc. soln. of stannous chloride and potassium iodide are mixed, there is deposited a mass of yellow silky needles of **enneahydrated potas- sium hexaiododistannite,** 2KI.2SnI₂.9H₂O. The salt can be recrystallized from alcohol. J. Personne obtained the salt by the action of iodine on powdered tin, in a conc. soln. of potassium chloride. When the enneahydrate is confined in vacuo over sulphuric acid, or heated to 110°, six mols of water are given off and the *trihydrate* is formed ; between 140° and 150°, hydrogen iodide is given off. When chlorine gas is passed over the salt, the tin burns with the emission of light, forming stannous and potassium chlorides. When the salt is treated with a small proportion of water, potassium iodide is removed, and the residue dissolves when more water is added. Hot alcohol dissolves the complex salt leaving a little stannous iodide, and the soln. furnishes crystals of the salt on cooling. V. Auger and T. Karantassis found that when stannous iodide is added to warm aq. soln. of rubidium iodide containing hydriodic acid, the liquid turns brown and deposits stannic iodide ; but if tin be present, and air absent, **rubidium triiodostannite,** RbSnI₃, is formed in yellow needles ; and if an excess of stannous iodide be present, orange-yellow, cubic crystals of **rubidium pentaiododistannite,** RbSn₂I₅, are formed. Similarly also with **cæsium triiodostannite,** CsSnI₃, and **cæsium pentaiododistannite,** CsSn₂I₅. The dry salts are fairly stable, they oxidize rapidly in air, forming in part iodostan- nates, and hence they do not correspond with the reaction products of stannous halides with potassium and ammonium halides. P. Boullay obtained **barium iodostannite** from a soln. of stannous and barium iodides ; and **strontium iodo- stannite** from a soln. of stannous and strontium iodides.

W. C. Henry reported that if soln. of stannous chloride and iodine be mixed, either stannous or stannic iodide is deposited according to the proportion of iodine employed ; and when the mother-liquor is evaporated and cooled, yellow crystals of **stannous chloroiodide,** SnClI, are formed. The salt is decomposed by water into

soluble stannous chloride and sparingly soluble stannous iodide. S. W. Young and M. Adams regard the salt as a solid soln. of stannous chloride and iodide which may be obtained in isomorphous admixture in various proportions. S. W. Young also prepared yellowish-red prisms of **stannostannic tetrachlorodiiodide**, $SnCl_4.SnI_2$, by the action of iodine chloride on stannous chloride. T. Karantassis prepared **stannous chloroiodide**, SnICl, by dissolving iodine in a soln. of stannous chloride and hydrochloric acid, and reducing the red liquid by addition of excess of tin: $2SnCl_2 + 4I = SnCl_4 + SnI_4$; $SnI_4 + Sn = 2SnI_2$ and $SnCl_4 + Sn = 2SnCl_2$; $2SnCl_2 + 2SnI_2 = 4SnClI$. If the original soln. contains an excess of iodine, red crystals of stannous iodide are first deposited, and these are slowly converted in the cold into white needles of the chloroiodide. With a large excess of stannous chloride, white crystals of the chloroiodide are deposited at once. The existence of the chloroiodide is further confirmed by thermal analysis of mixtures of the chloride and iodide. The f.p. curve falls from 320°, the m.p. of the pure iodide, to a eutectic at 244° and 52·4 molar per cent. of stannous iodide; it then rises to a maximum 259° corresponding with $SnI_2.SnBr_2$; it then falls to a second eutectic at 221° and 84·5 molar per cent. of $SnCl_2$; and finally rises to 254°, the m.p. of the pure chloride. A soln. of **stannous bromoiodide**, SnIBr, was prepared in an analogous manner. The pale yellow needles deposited in presence of an excess of stannous bromide consist of a solid soln. of the iodide in the bromoiodide. Thermal analysis confirms the existence of mixed crystals with a tendency to form the bromoiodide. The f.p. curve falls from 326·7°, the m.p. of the pure bromide, to a eutectic at 220°, and it then rises to a maximum of 240° with between 42·8 and 62·7 molar per cent. of the stannous iodide; and then rises to 320°, the m.p. of the pure iodide. A. C. Vournasos prepared **potassium dibromodiiodostannite**, $Na_2[SnBr_2I_2]$. P. Freundler and Y. Laurent said that sodium iodide and stannous chloride do not form a complex, a mixture of conc. soln. of the two yields the monohydrate; stannous chloride and potassium iodide form yellow needles of **potassium triiodostannite**, $KSnI_3.3H_2O$, in neutral soln., and in the cold (22°), warm (45°), and hot acidic soln., **potassium hydrodiiodotrichlorostannite**, $K_2HSnI_2Cl_3$, or $2KI.HCl.SnCl_2$, and **potassium hydrotriiodotrichlorostannite**, $K_3HSnI_3Cl_3$, or $3KI.HCl.SnCl_2$, and anhydrous stannous iodide are formed. These complex salts are stable in neutral soln., but oxidize in acidic soln. especially in sunlight, forming deep brown soln. It is argued that the colloidal complex of iodine, sodium, and rubidium is contained in some marine plants. The existence of rubidium and iodine in association with protoplasm is further supported by the presence of rubidium and iodine in the eq. proportions, by the absence of iodine and rubidium from the salts resulting from spontaneous desiccation, and by the similar behaviour of the compound obtained from *Laminaria flexicaulis* and the rubidium-stannous iodide complex, $2SnI_2,RbI$, on exposure to sunlight.

§ 21. The Stannic Iodides

J. L. Gay Lussac [1] prepared **stannic iodide,** SnI_4, by heating a mixture of tin and iodine; J. Personne found that in a sealed tube the reaction begins at 50°, and is attended by incandescence. The excess of tin remains unaffected without producing stannous iodide. A. E. Nordenskjöld melted a mixture of iodine and tin, and obtained stannic iodide by the sublimation of the product. J. Personne, and E. R. Schneider allowed a warm soln. of iodine in carbon disulphide to act on tin. E. R. Schneider obtained it by mixing conc. soln. of stannic chloride and potassium iodide; and by the action of iodine on stannous or stannic selenide. J. J. Berzelius prepared it from a soln. of stannic hydroxide in hydriodic acid; and W. C. Henry obtained it by sublimation from stannous iodide, heated in air—stannic oxide remains. He also found that stannic iodide is formed by mixing a conc. soln. of stannous chloride with an equal proportion of iodine.

P. Groth said that crystals obtained from carbon disulphide are red and singly refracting, belonging to the cubic system; but A. E. Nordenskjöld showed that they belong to the rhombic system. J. W. Retgers obtained octahedral crystals by evaporating a soln. of the salt in an excess of hydriodic acid, in carbon disulphide, methylene iodide, and other solvents. R. G. Dickinson found the X-radiograms corresponded with a mol. of $(SnI_4)_8$ per unit cube with edge 12·23 A. The iodine atoms are not all in eq. positions, and are probably at points eq. to (vvv) and (xyz), while the tin atoms are at points (uuu). The arrangement is illustrated by Fig. 75, where the cube has been divided along the plane $ABCD$
FIG. 75.—Arrangement of the Atoms in the Space Lattice of Stannic Iodide.

for convenience in drawing. Measurements were also made by H. Ott, and H. Mark and K. Weissenberg. E. Beckmann and P. Geib found the raising of the b.p. of stannic chloride by stannic iodide corresponded with only one-third the normal mol. wt.; but E. Beckmann and F. Junker found the lowering of the b.p. of antimonic chloride by the dissolved stannic iodide does not agree with the normal mol. wt. C. H. D. Boedeker gave 4·696 for the sp. gr. at 11°; J. Personne said the crystals melt at 160°, and the molten liquid freezes at 142°; F. Emich gave 160°, and W. Reinders and S. de Lange, 143·5° for the m.p. W. C. Henry said the salt sublimes at 180°, forming reddish-yellow needles. J. Personne could not measure the b.p., but he found a thermometer near the surface of the boiling liquid registered 295°; F. Emich gave 341° for the b.p. W. Reinders and S. de Lange found the m.p. of

FIG. 76.—Fusion and Boiling Curves of Mixtures of Tin and Stannic Iodide.

mixtures of stannic iodide and iodine consists of two branches with a eutectic at 79·6°, and 12·06 at. per cent. or 60 per cent. by weight of tin, Fig. 76—*vide supra*, stannic chloride. The b.p. curve follows the normal course, and the curves indicated. A fused mixture of stannous and stannic iodides forms two liquid layers. At 350°, the one layer consists of stannic iodide with traces of stannous iodide; and the other, of stannous-iodide with a maximum of 6 per

cent. stannic iodide. Tin is not perceptibly soluble in molten stannous iodide, and there is a very narrow line of homogeneous mixing which, at 350°, extends from pure stannous iodide to stannous iodide with 6 per cent. by weight of stannic iodide. Similar results were obtained by H. S. van Klooster, and A. M. Vasiléeff. The latter found the eutectic at 77·8° and $SnI_4 + 3·257I$. A. H. Chapman measured the emission spectrum of stannic iodide. F. de Carli studied the reducing action of hydrogen.

The salt is hydrolyzed in aq. soln., as noted by J. L. Gay Lussac, C. F. Rammelsberg, W. C. Henry, and J. Personne; but no definite stannic oxyiodide was observed. E. R. Schneider said that 100 parts of carbon disulphide at ordinary temp. dissolve 145 parts of stannic iodide; and J. Personne noted that it is soluble in chloroform, alcohol, ether, and benzene, forming compounds with all but the first of these four solvents. J. W. Retgers found that methylene iodide at 10° dissolves 22·9 per cent. of stannic iodide, and the sp. gr. of the soln. is 3·481 at 10°. W. Biltz and E. Kuenecke observed no reaction or dissolution with liquid hydrogen sulphide at −78·5°. Arsenic tribromide dissolves the salt; the sp. gr. of the sat. soln. is 3·73 at 15°, and, according to P. Walden, the soln. is a poor electrical conductor. J. H. Mathews found the salt is soluble in allylthiocarbamide, and the sp. conductivity of the soln. is $4·08 \times 10^{44}$ mhos at 25°. A. Rosenheim and H. Aron prepared complexes with pyridine and quinoline. There is evidence of the formation of *hydroiodostannic acid* by the union of stannic iodide and hydrogen iodide. The soln. is readily hydrolyzed. V. Auger and T. Karantassis observed that stannic iodide is gradually hydrolyzed in dil. hydriodic acid soln. and more readily in aq. soln. The addition of sodium, potassium, or ammonium iodide to these soln. does not modify their properties, but the addition of rubidium or cæsium iodides or of the hydriodides of strong bases leads to the formation of stable complex salts; e.g. **rubidium iodostannate,** Rb_2SnI_6, by adding rubidium iodide to a soln. of stannic iodide in hydriodic acid; and similarly with **cæsium iodostannate,** Cs_2SnI_6; but *ammonium, potassium, and sodium iodostannates* could not be made. They also prepared mixed crystals of **potassium bromoiodostannate,** $K_2Sn(Br_{5·75}I_{0·25})$, and **ammonium bromoiodostannate,** $(NH_4)_2Sn(Br_{5·35}I_{0·65})$, as well as of *tetramethylarsonium iodostannate.* J. G. F. Druce made *methyl stannic iodide,* $Sn(CH_3)I_3$; and normal *propyl stannic iodide,* $Sn(C_3H_7)I_3$. M. Wildermann studied the reaction with several organic bromides. V. Auger and T. Karantassis studied some complexes with organic compounds. J. Personne said that dry ammonia reacts with stannic iodide dissolved in carbon disulphide or ether, forming **stannic triamminoiodide,** $SnI_4.3NH_3$; **stannic tetramminoiodide,** $SnI_4.4NH_3$, and **stannic hexamminoiodide,** $SnI_4.6NH_3$. F. F. Fitzgerald showed that in liquid ammonia it reacts with potassium amide, forming potassium stannic tetramminoimide, $Sn(NK)_2.4NH_3$. F. Ephraim and T. Schmidt prepared **stannic octamminoiodide,** $SnI_4.8NH_3$, by passing ammonia into a soln. of stannic iodide in carbon disulphide and evaporating off the solvent on a bath of warm water; also by passing ammonia over the solid iodide, when much heat is evolved. Evidence of higher ammines was obtained, but they were not stable. Stannic iodide dissolves in stannic chloride, and antimonic chloride as indicated above. A. Ditte noted the formation of a basic nitrate, $4SnO_4.N_2O_5.4H_2O$, by reaction with nitrogen peroxide. Stannic iodide was found by H. Moissan to be reduced when heated with boron. G. Scagliarini studied complexes with organic bases.

C. Lenormand heated a mixture of stannous chloride and iodine in a flask or in a sealed tube at 100°, and obtained **stannic dichlorodiiodide,** $SnCl_2I_2$, as a red mobile liquid of sp. gr. 3·287 at 15°. The liquid fumes in air, and it begins to distil at 190°, and the b.p. during distillation remains stationary at 297°. It is decomposed by repeated distillation. The dichlorodiiodide is soluble in water with the development of much heat; with a small proportion of water, a hydrate is formed which is soluble in an excess of water. The dil. soln. at 65° is quantitatively

decomposed into stannic hydroxide, and hydrochloric and hydriodic acids. The dichlorodiiodide is soluble in benzene, chloroform, and carbon disulphide. It yields complexes with ether, and with ethyl, propyl, butyl, and amyl alcohols. If this liquid be fractionally distilled, substances corresponding with **stannic trichloro-iodide**, $SnCl_3I$, and **stannic chlorotriiodide**, SnI_3Cl, as well as stannic chloride, and stannic dichloro-diiodide are formed. C. Lenormand also found that iodine is without action on stannous bromide in the cold, but when the mixture is heated in a sealed tube at 100° an orange-red, crystalline mass of hexagonal plates is produced, consisting of **stannic dibromodiiodide**, $SnBr_2I_2$. The compound begins to melt at 50°, and forms a ruby-red liquid which does not fume in the cold. The sp. gr. is 3·631 at 15°; it boils at 225°, or at 130° in vacuo. It is soluble in cold water, and the soln. decomposes at 80° into stannic oxide, and hydrogen iodide and bromide. When this compound is fractionally distilled, **stannic tribromoiodide**, $SnBr_3I$, passes over at 230°–250° and condenses as a mass of yellowish-red crystals and of undecomposed stannic dibromodiiodide; and **stannic bromo-triiodide**, $SnBrI_3$, remains as a residue. If the dibromodiiodide be distilled in vacuo, the undecomposed salt passes over at 130°; the tribromo-iodide, at 180°, and the bromotriiodide remains as a residue. M. G. Räder said the method of preparation of the dibromodiiodide really gives a mixture of the two salts; and there is no evidence on the f.p. or b.p. curves, Fig. 77, to show the existence of salts of the mixed acids; with stannous bromide and iodine, the reaction is symbolized : $2SnBr_2 + 2I_2 = SnBr_4 + SnI_4$.

FIG. 77.—Freezing- and Boiling-point Curves of Mixtures of Stannic Iodide and Bromide.

§ 22. Stannous Sulphides

Estimates of the affinity of sulphur for tin were made by K. Jellinek and J. Zakowsky. Tin forms two well-established sulphides, **stannous sulphide,** SnS, and stannic sulphide, SnS_2 ; and a less well established *tin sesquisulphide*, Sn_2S_3. There are also hydrated forms of these sulphides, and a series of sulpho-derivatives. J. Kunckel, in his *Völlstandiges Laboratorium chymicum* (Berlin, 1767), described the product obtained by fusing tin with sulphur. J. L. Proust [1] supposed that when molten stannous chloride is treated with sulphur, stannic chloride and sulphide are formed, but E. R. Schneider showed that stannic chloride and stannous sulphide are formed, and that the latter dissolves in the excess of molten stannous chloride from which it crystallizes on cooling. According to G. C. Winkelblech, narrow strips of tin-foil catch fire in sulphur vapour. Stannous sulphide is formed when a mixture of sulphur and tin is heated above the m.p. of the metal ; and since the product still contains uncombined tin, it is pulverized, mixed with fresh sulphur, and again heated in a closed vessel. This method of preparation was used by P. Berthier, and E. R. Schneider. W. Biltz and W. Mecklenburg said that the yield of stannous sulphide obtained by fusing tin and sulphur is poor because of the volatilization of most of the latter ; they made it by heating to 900° a mixture of tin with twice the calculated quantity of sulphur in a tube ; and repeating the operation with the resulting product. A. Ditte sublimed the stannous sulphide from the product obtained by the repeated fusion of a mixture of sulphur and tin.

J. L. Gay Lussac found that at a red-heat stannic sulphide decomposes into stannous sulphide and sulphur ; and F. Damm and F. Kraft, that when heated in vacuo in the cathode rays, stannic sulphide, even at 250°, gives off half its sulphur and passes into the more stable stannous sulphide. According to H. Pélabon, the f.p. curve for mixtures of tin and sulphur rises rapidly from 232°, the f.p. of tin, to 840°, the f.p. of the mixture containing 5 per cent. of sulphur, and then rises more gradually to the maximum point 880°, the f.p. of stannous sulphide ; beyond this point the mixtures lose sulphur on being heated, but their m.p. are lower than 880°. W. Biltz and W. Mecklenburg found that with mixtures containing over 23·4 per cent. of sulphur, the sulphur is lost by volatilization. The compound melts at 881°, and the eutectic at 232° is almost pure tin. The sulphide passes into a viscous liquid at 950° and becomes limpid again at near 1100°, Fig. 78. W. Spring obtained stannous sulphide by compressing a mixture of powdered sulphur and tin. O. B. Kühn obtained stannous sulphide

FIG. 78.—The Fusion Curve of Some Mixtures of Sulphur and Tin.

by melting a mixture of tin and sodium pentasulphide ; J. Milbauer, by melting stannic oxide mixed with potassium thiocyanate; and G. Tocco and N. Jacob, by the alternating current electrolysis of soln. of sodium thiosulphate using tin electrodes.

According to A. Ditte, when tin is heated to 100° in a stream of hydrogen sulphide, it acquires a coating of stannous sulphide ; and when the tin melts, the formation of the sulphide proceeds more quickly. Above the decomposition temp. of hydrogen sulphide, the production of stannous sulphide is due to the direct union of sulphur and tin. K. Jellinek and J. Zakowsky studied the reaction between 500° and 1100°. When hydrogen sulphide is passed into a neutral or feebly acid soln. of stannous chloride, dark brown or black stannous sulphide is precipitated ; and A. Ditte added that it is necessary to exclude air because, otherwise, the stannous

chloride would be partially oxidized, and therefore some stannic chloride formed. H. Reinsch found that if a soln. of one part of stannous chloride in 100 parts of water and 15 parts of hydrochloric acid, of sp. gr. 1·168, be treated with hydrogen sulphide, all the tin is precipitated at once, but if 25 parts of acid be used, a precipitate appears only after some time, and if 40 parts of acid be used, no tin sulphide is precipitated, although it is if some water be added. The meaning of H. Reinsch's crude data is represented diagrammatically, Fig. 79. Fig. 79 means that there is a state of equilibrium in the system: $H_2S+SnCl_2 \rightleftharpoons 2HCl+SnS$. A. Ditte found that 8·3 per cent. hydrochloric acid at ordinary temp. begins to act on stannous sulphide, forming a soln. of stannous chloride, and giving off hydrogen sulphide. The formation of stannous chloride is faster the greater the conc. of the acid, and the higher the temp. According to A. Ditte, the precipitate dried in vacuo at 20° has the composition **trita-hydrated stannous sulphide,** $3SnS.H_2O$, with a sat. soln. of stannous chloride; the first product of the action of hydrogen sulphide appears as an orange-red crystalline separation, the colour then changes to brown and finally to black; the brownish-red crystals are formed if an acid soln. of stannous chloride be treated with a small proportion of hydrogen sulphide, or if water be added to an acid soln. of stannous chloride sat. with hydrogen sulphide. These coloured crystals are considered to be **stannous hydrosulphochloride,** $Sn(HS)Cl$, which is transformed by hydrogen sulphide into stannous sulphide; the intermediate hydrosulphochloride was not isolated because it is decomposed when washed with water. When the hydrated stannous sulphide is thoroughly dried, it passes into the anhydrous sulphide. Stannous sulphide appears as a dark brown crystalline powder when the tritahydrate is dissolved to saturation in molten stannous chloride, and the cold product washed with dil. hydrochloric acid.

The physical properties of stannous sulphide.—The product obtained by the direct union of molten sulphur and tin is a dark lead-grey mass of lamellar, micaceous crystals; the sublimed product appears in long, needle-like crystals. The native sulphide appears in thin scales, plates, or blades, which are pliable but not elastic, and resemble flaky graphite. A. C. Becquerel claimed to have obtained cubic crystals by the method indicated above; but W. P. Headden found iron-black or graphite-black crystals of stannous sulphide as a deposit on some slags from an old Cornish tin furnace, and he considered the crystals to be monoclinic; but S. Stevanovic showed that the crystals are rhombic bipyramids with axial ratios $a:b:c=0.3883:1:0.3566$; or, according to C. O. Trechmann, $0.3874:1:0.3558$. L. J. Spencer showed that the crystals of rhombic tin reported by C. O. Trechmann, and H. von Foullon, were really crystals of stannous sulphide. Owing to the thinness of the plates—$\frac{1}{90}$ mm.—it was not possible to determine if there is any cleavage parallel to the surface. There is often a repetition of parallel growths giving rise to comb-like and feathery forms and also to plates with serrated edges. L. J. Spencer gave illustrations of the twinning of these crystals. W. P. Davey discussed the sizes of the tin atoms in stannous sulphide. C. J. B. Karsten gave 4·852 for the sp. gr. of stannous sulphide; P. A. Boullay, 5·267; E. R. Schneider, 4·973; and A. Ditte, 5·0802 at 0°. The hardness is 2. When molten stannous sulphide freezes, A. Ditte said that there is a considerable dilation; and that it melts at a red heat. J. Guinchant gave 950°–1000° for the m.p.; H. Pélabon, 880°; and W. Biltz and co-workers, 882°—Fig. 78. As indicated above, W. Biltz and co-workers found that stannous sulphide has two m.p. The lower m.p. is at 882°, and as the temp. is raised quickly from 1000° to 1100°, the viscosity increases very quickly, so that at the latter temp. the sulphide has the properties of a solid. At about 1200°, liquefaction again occurs. A. Ditte said that stannous sulphide begins to give off greenish vap., and to sublime close to its m.p.; and

A. Mourlot found that it volatilizes unchanged in the electric furnace. J. Guinchant said that stannous sulphide boils at about 1090°, and W. Biltz and W. Mecklenburg found the b.p. of mixtures with different proportions of sulphur to be 1293° with 11·5 per cent. of sulphur ; 1276°, with 15·6 per cent. ; 1266°, with 17·9 per cent. ; and 1240°, with 20·3 per cent., Fig. 78. W. Spring said that stannous sulphide is decomposed when heated in vacuo, forming stannic sulphide and tin ; *au contraire*, A. Mourlot found that it can be distilled unchanged in the electric furnace, although there is evidence of a partial dissociation at very high temp. N. R. Campbell found that stannous sulphide exhibits a feeble radioactivity (induced). B. Aulenkamp, and W. W. Coblentz, studied the photoelectric sensitivity. K. Bädeker studied the electrical conductivity ; and A. C. James, the effect of stannous sulphide on galena as a rectifier of alternating currents. F. Trey said that the electrical conductivity is electrolytic.

The chemical properties of stannous sulphide.—H. Rose found that when stannous sulphide is heated in a stream of **hydrogen,** some hydrogen sulphide is formed ; and L. Elsner showed that if the hydrogen be passed a long enough time, nothing but tin remains. A. Ditte, however, said that stannous sulphide can be sublimed in a stream of hydrogen without forming hydrogen sulphide, provided the temp. does not exceed dark redness ; at a cherry-red heat, a trace of hydrogen sulphide is formed ; at a bright red heat, the issuing hydrogen has 1·8 to 2·0 per cent. of hydrogen sulphide ; and at a white heat, 4·7 per cent. hydrogen sulphide ; and, as observed by L. Elsner, tin alone remains. It is inferred that only the vap. of the stannous sulphide is decomposed by the hydrogen, for at lower temp., stannous sulphide is produced by the action of hydrogen sulphide on tin: $Sn+H_2S \rightleftharpoons SnS+H_2$. C. J. Brookes found that when roasted in **air** or **oxygen,** stannous sulphide is converted into stannic oxide, with a loss of some of the tin. E. Pollacci found that moist stannous sulphide is gradually oxidized by exposure to air. P. B. Ganguly and N. R. Dhar found a colloidal soln. of stannous sulphide is oxidized in sunlight and air, forming colloidal sulphur. O. Weigel showed that stannous sulphide is very sparingly soluble in **water,** for a litre of water at 18° dissolves $0·14 \times 10^{-6}$ mol. H. Rose found that in a stream of water-vapour, red-hot stannous sulphide forms hydrogen sulphide and stannic oxide. F. M. Perkin showed that stannous sulphide is readily oxidized by **hydrogen dioxide** in alkaline soln., forming a sulphostannate.

According to H. Rose, stannous sulphide reacts with **chlorine** at ordinary temp., forming a compound of stannic chloride and sulphur tetrachloride, but at a higher temp. stannic chloride is produced. A. Ditte said that dried **hydrogen chloride** does not attack stannous sulphide at ordinary temp., but at a higher temp. hydrogen sulphide and stannous chloride are formed, and this the more rapidly the higher the temp. J. Kelley and E. F. Smith found that at ordinary temp. hydrogen chloride completely transforms stannous sulphide into the chloride. The action of **hydrochloric acid** has been indicated above in connection with the reversible reaction : $SnS+2HCl \rightleftharpoons SnCl_2+H_2S$. The solubility of stannous sulphide in this acid was utilized by L. Loviton in the separation of antimony and tin. A. Ditte found that hydrochloric acid attacks hydrated stannous sulphide more readily than it does the anhydrous salt, for 8·3 per cent. hydrochloric acid attacks the anhydrous sulphide at ordinary temp., while a 4 per cent. acid attacks the hydrated sulphide in the cold and one per cent. acid attacks it at 100° ; while W. R. Lang and C. M. Carson found that stannous sulphide is soluble in hydrochloric acid of sp. gr. 1·16 diluted with about half its weight of water.

P. Berthier found that stannous sulphide is not dissolved by **sulphurous acid.** A. Ditte compared the action of **alkali sulphides** on stannous sulphide with the action of alkali hydroxides on stannous oxide. An aq. soln. with less than 20 per cent. potassium sulphide does not attack the sulphide at ordinary temp., but more conc. soln. gradually form metallic tin, and sulphostannates—*confer,* the action of potassium hydroxide on stannous oxide. Its reaction also accounts for the reprecipita-

tion of tin as stannic sulphide after the addition of an acid to the alkaline soln. The action is faster the more conc. the soln., and the higher the temp. ; and with very conc. soln. the separated tin is attacked, forming potassium sulphostannate (*q.v.*). Dil. soln. of the alkali sulphide in the presence of air gradually transform stannous sulphide into the alkali sulphostannate. The sulphide is not attacked by cold or hot soln. of **ammonium sulphide,** but in the presence of air, ammonium sulphostannate is slowly formed. Stannous sulphide is soluble in soln. of **alkali or ammonium polysulphide.** According to O. Ruff, **sulphuryl chloride** transforms stannous sulphide into the chloride which passes into soln., and sulphur is separated. A. Ditte showed that stannous sulphide is but slightly attacked by aq. **ammonia,** but in the presence of air, ammonium stannate and sulphostannate are slowly formed. E. R. Schneider said that **nitric acid** readily oxidizes amorphous stannous sulphide to stannic oxide, but the crystalline sulphide is but slowly attacked. H. Rose found that **phosphine** is reduced by warm stannous sulphide, forming hydrogen sulphide and phosphorus.

According to J. L. Proust, stannous sulphide is not attacked by **potassium hydroxide** soln., but F. M. Perkin found that some preparations of precipitated stannous sulphide readily dissolve in the alkali-lye. A. Ditte showed that stannous sulphide suspended in water reacts with potassium hydroxide : $SnS+2KOH =SnO+K_2S+H_2O$; the reaction is considered to be reversible, and the equilibrium to be dependent on the temp. and conc. of the soln. ; with conc. alkali-lye, however, tin and alkali stannate and sulphostannate are formed. O. Materne said that a boiling 10 per cent. soln. of sodium hydroxide readily dissolves stannous sulphide, and that brownish-red sulphide is precipitated from the soln. by acids, ammonium chloride, or hydrogen sulphide. According to P. Berthier, when a mixture of stannous sulphide and **sodium carbonate** is heated in a carbon crucible to a white heat, about three-fourths of the tin is reduced to metal ; the slag contains some tin sulphide ; at a red-heat, sodium carbonate decomposes part of the sulphide. A. Höring found that when a mixture of stannous sulphide, sulphur, carbon, and sodium carbonate is fused, the tin is converted into alkali sulphostannate which is soluble in water. H. Rose found that fused **potassium cyanide** reduces stannous sulphide to tin. E. Schürmann showed that stannous sulphide is completely converted into the sulphate when heated with soln. of **copper sulphate** or **cadmium sulphate,** but not by soln. of **zinc sulphate, lead nitrate,** or **potassium antimonyl tartrate ;** and F. Raschig found that with a soln. of **cuprous chloride** in one of sodium chloride, cuprous sulphide and stannous chloride are formed ; and with a boiling dil. soln. of **cupric chloride,** cuprous sulphide and stannic chloride are formed. J. B. Cammerer found that the hydrated sesquioxide reduces a soln. of **ferric chloride** to ferrous chloride, with the formation of stannic chloride and the separation of sulphur. A. Mourlot showed that when mixed with **magnesium chloride,** and heated in the electric furnace, stannous chloride is volatilized and magnesium sulphide remains. R. Zsigmondy and C. Haller showed that stannous sulphide dissolves in molten **glass,** with scarcely any effect on the colour of the glass.

According to J. J. Berzelius,[2] when stannic sulphide is digested with a sat. soln. of potassium sulphostannate, **hydrated tin sesquisulphide,** $Sn_2S_3.nH_2O$, is formed which is reconverted to stannous sulphide by digestion with alkali-lye. When an intimate mixture of stannous sulphide and 25 per cent. of sulphur is heated in a retort a greyish-yellow mass of what J. J. Berzelius regarded as **tin sesquisulphide,** Sn_2S_3, is formed. H. Pélabon found that a mixture of tin and sulphur, in the proportion required for the sesquisulphide, decomposes on fusion, yielding a sublimate of sulphur and a residue of stannous sulphide. J. J. Berzelius said that when tin sesquisulphide is strongly ignited in a closed vessel, two-thirds of the contained sulphur is volatilized ; digestion with potash-lye converts it into potassium stannate and sulphostannate and stannous sulphide ; and conc. hydrochloric acid converts it into stannic sulphide and stannous oxide. U. Antony and E. Niccoli dissolved the sesquisulphide in hydrochloric acid. The available evidence is not satisfactory proof of the chemical individuality of this product.

§ 23. Stannic Sulphide

Mosaic gold was in use in the eighteenth century as a pigment for painting, and it was called *aurum mosaicum—mosaic gold*—or *aurum musioum—muscovite gold*. It was prepared by heating a mixture of tin, sulphur, ammonium chloride, and mercury. Owing to the use of mercury in its preparation, it was at one time supposed to contain that element, and was used medicinally in venereal diseases. P. Woulfe [1] showed that it can also be obtained by omitting the mercury and ammonium chloride. B. Pelletier regarded it as a sulphuretted oxide of tin. J. L. Proust showed that mosaic gold contained very little oxygen ; and J. Davy, and J. J. Berzelius proved that it is stannic sulphide. Mosaic gold is now used as a bronzing powder for wood, metals, wall-paper, etc., although its application is being displaced by cheaper bronze powders.

Stannic sulphide cannot be obtained by direct fusion of the constituents at ordinary press. ; but W. Spring [2] obtained it by compressing an intimate mixture of the constituents at 6500 atm. ; and J. L. Proust, by heating a mixture of stannous chloride or ammonium chlorostannite and sulphur. E. R. Schneider said that only stannous sulphide, and not stannic sulphide, can be produced in this way. B. Pelletier, L. J. Thénard, J. Lagutt, J. B. van Mons, H. Hadert, and P. Woulfe have recommended various recipes—*e.g.* (i) heating a mixture of sulphur, tin filings, and ammonium chloride ; (ii) tin, mercury, sulphur and ammonium chloride ; (iii) tin amalgam, sulphur and ammonium chloride ; (iv) stannic oxide, sulphur and ammonium chloride ; (v) stannous oxide, and sulphur ; (vi) stannous sulphide,

sulphur, and ammonium chloride; (vii) stannous sulphide, chloride and sulphur; etc. For a pale yellow mosaic gold, J. Lagutt recommended heating an intimate mixture of stannous chloride with half its weight of flowers of sulphur ; and for reddish-yellow mosaic gold, 50 parts of tin amalgam (1 : 1), 25 of flowers of sulphur, and 25 of ammonium chloride. The heating was done in a retort, and the temp. was slowly raised during 3–3½ hrs. On account of the poor thermal conductivity of the mixture only small quantities were made at a time. L. Gmelin assumed that in the preparation of mosaic gold from sulphur, ammonium chloride, and tin, the first stage of the reaction involves the formation of ammonium chlorostannite : $Sn+4NH_4Cl=(NH_4)_2SnCl_4+H_2+2NH_3$; and afterwards, as the temp. rises higher, the sulphur reacts with the ammonium chlorostannite, forming stannic sulphide, and ammonium chloride and chlorostannate which sublime : $2(NH_4)_2SnCl_4+2S=SnS_2+(NH_4)_2SnCl_6+2NH_4Cl$. According to J. Lagutt, ammonium bromide can be used in place of the chloride, but ammonium sulphate or thiocyanate do not furnish mosaic gold. The halogen of the ammonium halide is considered to be the active agent. If tin amalgam is used mercuric sulphide also sublimes. J. L. Proust said that he obtained stannic sulphide by heating stannous or stannic oxides with sulphur. J. B. Senderens found that tin oxide is not affected by boiling with water in which sulphur is suspended. B. Pelletier said that stannic sulphide is produced by heating a mixture of stannous and mercuric sulphides, but J. L. Proust denied this. P. Woulfe obtained stannic sulphide by heating a mixture of stannous sulphide and mercuric chloride ; or a mixture of stannous sulphide, sulphur, and ammonium chloride. H. Rose obtained stannic sulphide by passing a mixture of the vap. of stannic chloride and hydrogen sulphide through a red-hot tube. V. Kletzinsky obtained an amorphous precipitate by boiling a soln. of stannous chloride and a little sulphuric acid or hydrochloric acid and sulphur dioxide ; the sublimation of the washed and dried product furnishes crystals of mosaic gold. According to L. Dede and T. Becker, with a $0.001N$-soln. of stannic chloride the normality of the hydrochloric acid required for the appearance of a precipitate, by treatment with hydrogen sulphide, was $2.28N$-, or $2.06N$- in 5 hrs. ; $1.87N$- in 9 hrs. ; and $1.38N$- in 24 hrs. ; and in the presence of potassium chloride, the following proportions of hydrochloric acid completely hindered precipitation :

KCl	.	0	$0.3N$-	$0.6N$-	$1.0N$-	$1.5N$-	$2.0N$-	$2.6N$-
HCl	.	$2.28N$-	$1.95N$-	$1.80N$-	$1.59N$-	$1.40N$-	$1.17N$-	$1.06N$-

Amorphous or **colloidal stannic sulphide** is produced when hydrogen sulphide is passed into an acidified soln. of stannic chloride, or into water in which freshly precipitated stannic hydroxide is suspended ; it is also precipitated when hydrochloric or sulphuric acid is added to an aq. soln. of a sulphostannate. L. Storch said that the precipitate obtained by hydrogen sulphide in a soln. of a stannic salt contains no stannous sulphide ; and T. Scheerer found the product obtained by the action of the gas on the hydroxide has the composition $SnS_2.2H_2O$ when undried and $SnS_2.H_2O$ when dried at 140°. C. T. Barfoed said that the pale yellow or reddish-yellow stannic sulphide precipitated from freshly prepared soln. of stannic chloride contains sulphur, and this the more the greater the dilution ; no chlorine is present ; but some stannic hydroxide is formed. The precipitate obtained with a hydrochloric acid soln. of β-stannic acid is mainly white β-stannic acid which is slowly converted into brown stannic sulphide. According to F. W. Schmidt, the egg-yellow precipitate obtained by the action of hydrogen sulphide on stannic chloride when moist contains SnS_2, but during the drying it decomposes giving off hydrogen sulphide and becomes dark brown. A dil. acid soln. of stannic chloride gives a precipitate with hydrogen sulphide which, when washed by suction, treated with alcohol to remove water, and with carbon disulphide to remove sulphur, and then washed with alcohol and finally with water, gave Sn : S=1 : 1·946, very nearly SnS_2 ; but when dried in air, the composition was Sn : S=1 : 1·638, owing

to the loss of hydrogen sulphide. A neutral dil. soln. of stannic chloride gives at first a white precipitate which contains chlorine—stannic chlorosulphide—and which passes into the disulphide by the continued action of the hydrogen sulphide. G. Jörgensen found that the precipitate produced by hydrogen sulphide with hydrochloric acid soln. of metastannic acid has a sulphur content which varies with the conc. of the acid and the salt, with time, and with temp. W. Spring showed that during the washing of the precipitated stannic sulphide, it is peptized forming a colloidal hydrosol. E. R. Schneider obtained a colloidal hydrosol by passing hydrogen sulphide into a hydrosol of metastannic acid, and heating the mixture. The addition of an acid flocculates the hydrosol into hydrogel. N. R. Dhar and S. Ghosh found that stannic sulphide and the complex stannates are peptized by alkali-lye, yellow aluminium sulphide, and sodium arsenite. W. Biltz studied the colour changes of colloidal stannic sulphide.

The properties of stannic sulphide.—Crystalline stannic sulphide furnishes golden-yellow plates which are soft and feel like graphite. C. J. B. Karsten gave 4·600 for the sp. gr., and P. A. Boullay, 4·425. H. V. Regnault gave 0·11932 for the sp. ht. between 12° and 95°. H. J. Houston found that the colour passes to dark red and finally black when heated; the reverse changes occur on cooling. According to J. J. Berzelius, when heated, stannic sulphide sublimes, but at a higher temp. it decomposes into stannous sulphide and sulphur; and if the action of heat has not been too prolonged, stannous sulphide will be found at the bottom of the mass, stannic sulphide at the top, and tin sesquioxide in between. According to J. L. Gay Lussac, and J. J. Berzelius, the sulphur dioxide reported by J. L. Proust is not evolved unless air be present. Stannic sulphide was found by W. W. Coblentz not to be appreciably photoelectric. O. Stelling studied the X-ray absorption spectrum of stannic sulphide.

When heated in **air,** stannic sulphide furnishes sulphur dioxide and stannic oxide; and, added P. Jannasch and O. Heydenreich, the reaction is much more rapid and complete in **oxygen.**

According to F. W. Schmidt, when stannic sulphide obtained by the action of hydrogen sulphide on a soln. of stannic chloride, is allowed to remain in contact with ammonia, it dissolves, forming a soln., which, on acidification, yields a very voluminous white precipitate. The same substance may be obtained by digesting stannic sulphide with ammonium carbonate soln., filtering, and acidifying; about 10 per cent. of the stannic sulphide is dissolved. This compound, when freed from sulphur by treatment with carbon disulphide, corresponds with **stannic oxytrisulphide,** $Sn_2S_3O.11\frac{1}{2}H_2O$; it is easily and completely soluble in ammonium carbonate, and is also slowly soluble in water. When dried, the white mass gradually loses its property of dissolving in ammonium carbonate soln., and becomes amber-yellow. The solubility of the substance in ammonia is not affected by keeping for a long time. It is assumed, therefore, that the decrease of solubility in ammonium carbonate soln. is not due to polymerization, but to loss of water and to a gradual change from a voluminous colloidal condition to an amorphous state in which the composition varies from $Sn_2S_3O,11\frac{1}{2}H_2O$ to $Sn_2S_3O,5H_2O$, according to the time of drying. Stannous sulphide dissolves in ammonia, forming an orange-red soln., which behaves like a colloidal soln. of stannic sulphide; the sulphide, SnS_2, is precipitated by acids from freshly-prepared soln. The soln. loses its colour on exposure to air for four to five days, ammonium sulphide being first formed and then ammonium thiosulphate; the oxysulphide and sulphur are precipitated by acids, but neither hydrogen sulphide nor sulphur dioxide is formed. The oxysulphide may be purified and any tin sulphide removed by dissolving in ammonium carbonate. The oxysulphide is not precipitated from very dil. soln. in ammonium carbonate until carbon dioxide has been liberated, and it then separates as a very fine, flocculent, white mass which has a blue tinge; the precipitate after washing three or four times with water forms colloidal soln. which have an acid reaction and from which the colloid is precipitated by neutral salts, but not by acids. These soln. are assumed to contain the acid, $S(SnS.OH)_2$, whilst the composition of the original precipitate is regarded as $HO.SnS.S.SnS.ONH_4$; and that of the oxysulphide, which is soluble in ammonium carbonate as

$$S:Sn{<}^{S}_{O}{>}Sn:S$$
W. Skey said that stannic sulphide is not soluble in **water;** but O. Weigel found the solubility of stannic sulphide in water to be $1·13 \times 10^{-6}$ mol per litre

at 18°. P. de Clermont and J. Frommel, and A. Classen and O. Bauer found that **hydrogen dioxide** forms stannic oxide and sulphuric acid. H. Rose showed that when stannic sulphide is treated at ordinary temp. with **chlorine,** a brown liquid is formed which solidifies to yellow crystals of $SnCl_4.2SCl_4$. W. T. Casselmann obtained a similar result. E. R. Schneider found that with **iodine,** stannic disulpho-tetraiodide, SnS_2I_4, is formed. J. Kelley and E. F. Smith found that **hydrogen chloride or bromide** converts heated stannic sulphide into the stannic halide which volatilizes. H. Rose said that crystallized stannic sulphide is not attacked by conc. **hydrochloric acid ;** the amorphous sulphide is insoluble in dil. acids, but is dissolved by the hot acid ; W. R. Lang and C. M. Carson also found that the amorphous sulphide is dissolved by the hot acid of sp. gr. 1·16. W. T. Casselmann found that at a red heat stannic sulphide reacts with **phosphorus pentachloride,** producing stannic chloride and sulphophosphide, and phosphorus sulphide and sulphochloride. O. Ruff showed that **sulphuryl chloride** converts stannic sulphide into stannic chloride and sulphur—the presence of aluminium chloride accelerates the reaction. A. Guéront said that stannic sulphide is dissolved with difficulty by **sulphurous acid.** H. Rose found stannic sulphide is not dissolved by **nitric acid,** but boiling aqua regia converts it into sulphuric acid and stannic oxide. H. Rose said that stannic sulphide is dissolved by aq. **ammonia** only with difficulty. Aq. soln. of **alkali hydroxides** dissolve stannic sulphide, forming stannates and sulphostannates ; with alkali carbonates, a similar result is obtained, but carbon dioxide is at the same time evolved. O. Materne also showed that precipitated stannic sulphide is soluble in a soln. of sodium carbonate ; and sparingly soluble in one of sodium hydroxide. Soln. of **alkali sulphides** and of **ammonium sulphide** dissolve stannic sulphide, forming sulphostannates—*vide infra.* According to A. Classen and O. Bauer, the dissolution with sodium sulphide is faster than with ammonium sulphide. P. de Clermont showed that when stannic sulphide is boiled with soln. of **ammonium salts,** it forms stannic oxide ; and F. W. Schmidt showed that under certain conditions it is slightly soluble in soln. of **ammonium carbonate.** F. Raschig showed that with a soln. of **cuprous chloride** in one of sodium chloride, cuprous sulphide and stannic chloride are formed. J. B. Cammerer found that with a soln. of **ferric chloride,** stannic and ferrous chlorides are formed. H. Rose found that fused **potassium nitrate** converts stannic sulphide into potassium sulphate and stannate ; fused **lead oxide** converts it into stannic oxide and lead sulphide ; and molten **potassium cyanide** forms a sulphostannate. O. Materne found stannic sulphide to be insoluble in a cold soln. of **borax,** but soluble in a hot soln. C. Pertusi found that when stannic sulphide is suspended in water and mixed with an excess of powdered **magnesium,** it is reduced to tin and to stannous sulphide with the evolution of hydrogen sulphide.

The *sulphochlorides* have been discussed in connection with stannic chloride. E. R. Schneider [3] obtained **stannic sulphoiodide,** SnS_2I_4, by crystallization from the brown liquid obtained by melting together a mol of stannic sulphide and two mols of iodine, and subliming the product in a current of carbon dioxide. While mosaic gold does not dissolve in a soln. of iodine in carbon disulphide, dry precipitated stannic sulphide dissolves slowly in the liquid, and on evaporating the soln., crystals of the sulphoiodide are formed. The crystals are coloured like potassium dichromate, and they are probably rhombic. Water decomposes the compound into sulphur, stannic oxide, and hydriodic acid. The salt is decomposed by hydrochloric acid with the separation of sulphur, iodine and tin passing into soln. Aqua regia acts similarly ; and nitric acid forms sulphur, iodine, stannic oxide and some soluble stannic nitrate. A cold soln. of potassium hydroxide forms stannic oxide and sulphur ; the iodine passes into soln. ; a boiling soln. of the lye dissolves the compound completely ; soln. of sodium carbonate and ammonia act likewise but more slowly. Ammonia gas is absorbed, forming a white powder. Stannic sulphoiodide is soluble in carbon disulphide, or chloroform ; alcohol separates sulphur, and the tin and iodine dissolve as stannic iodide.

§ 24. The Sulphostannates or Thiostannates

J. J. Berzelius [1] showed that stannic sulphide unites with the more basic sulphides of the other elements, forming a series of **sulphostannates** or **thiostannates.** These salts can usually be referred to **sulphometastannic acid,** H_2SnS_3 ; and sometimes to **sulphorthostannic acid,** H_4SnS_4. O. B. Kuhn reported the formation of the former, as an olive-green precipitate, when a conc. soln. of sodium thiostannate is decomposed by hydrochloric or acetic acid. L. Storch was unable to obtain anything other than a mixture of the acid with tin sulphide by this process. He added various acids to a soln. of sodium thiostannate, prepared by saturating a soln. of sodium stannate with hydrogen sulphide. Hydrochloric, sulphuric, and dichloracetic acids cause an immediate precipitation of yellow stannic sulphide, but oxalic, phosphoric, monochloracetic, tartaric, citric, succinic, and acetic acids produced brownish-yellow soln., from which reddish-brown precipitates separated more or less slowly. These results showed that this reaction was dependent on the affinity (avidity) of the acid. The brown precipitates contained only slightly more sulphur than corresponded with the formula SnS_2, and did not appear to be homogeneous. Attempts to isolate the compound formed proved unavailing. When a dil. soln. of oxalic acid is added to a soln. of sodium thiostannate in quantity only just sufficient to neutralize the sodium, a deep yellow soln. is produced which gradually changes to reddish-brown, but remains clear for hours, and may be partially conc. before separation of the reddish-brown precipitate occurs. Acetic and oxalic acids produce no immediate precipitates from this soln. Ammonia and potash gradually decolorize it, as do sodium and ammonium carbonates, ammonium chloride, and

sodium acetate, although more slowly. Many salts and strong acids cause precipitation. As the substance formed could not be isolated, the author estimated the ratio of sulphur to tin in this soln. after the free hydrogen sulphide had been removed by a current of air. The result showed the presence of three atoms of sulphur to one of tin. Hence, it is probable that sulphostannic acid, H_2SnS_3, is present in this soln. It is also probably present in small quantities in the brown precipitate.

The general methods of preparing the sulphostannates are as follow : A. Berg melted a mixture of metallic tin and 6 to 8 times its weight of a mixture of equal parts of sulphur and sodium carbonate at a dark red heat. H. Rose used stannic oxide in place of tin ; and A. Höring used stannous sulphide. A. Ditte melted tin with the alkali or ammonium polysulphides ; and he dissolved stannic sulphide in soln. of the sulphides of the alkalies, alkaline earths, or ammonium sulphide. Precipitated stannic sulphide dissolves more readily when in the amorphous state, and requires a boiling liquid for complete soln. A. Ditte also dissolved stannous sulphide in a soln. of a polysulphide. J. Milbauer melted stannic oxide with potassium thiocyanate. R. F. Weinland and A. Gutmann made the sulphorthostannates by the action of a thiosulphate on alkali stannite. The sulphostannates of the heavy metals are precipitated when a soln. of a salt of the heavy metal is treated with potassium sulphostannate.

As L. Storch has shown, the analytical separation of tin from copper, mercury, and cadmium rests on the formation of the sulphostannates. The sulphostannates are well-defined compounds which can usually be obtained in a crystalline form. The sulphostannates of ammonium, the alkalies, and alkaline earths are colourless or yellow ; and readily soluble in water. The alkali salts are stable at a dull red heat. Mineral acids precipitate stannic sulphide from the soln. A. Classen and O. Bauer showed that the soln. is oxidized by hydrogen dioxide, and when the soln. is boiled, A. Kolb found that stannic hydroxide is precipitated.

V. Stanek reported **trihydrated ammonium sulphostannate**, $(NH_4)_2SnS_3.3H_2O$, in thin yellow plates, by saturating a soln. of colourless ammonium sulphide with stannic sulphide, diluting the soln. with an equal vol. of ammonium sulphide, and adding alcohol. He also obtained **heptahydrated ammonium sulphostannate**, $(NH_4)_2SnS_3.7H_2O$, if alcohol be added to the preceding soln. until a small precipitate appears, the soln. filtered, and alcohol be poured over the filtrate. Long needle-like crystals are formed. E. Priwoznik obtained what was regarded as **ammonium heptasulphotristannate**, $(NH_4)_2Sn_3S_7.6H_2O$, by the action of ammonium sulphide on metallic tin. A. Ditte made it by dissolving tin-foil in yellow ammonium sulphide ; in the cold the reaction is slow and ceases before the ammonium sulphide has all reacted ; if the soln. be warmed much ammonium sulphide is volatilized. If the soln. be evaporated over sulphuric acid and potassium hydroxide in vacuo, yellow plates are produced which readily decompose. When exposed to air, the crystals lose water and become superficially violet. When treated with a large proportion of water, or acids, stannic sulphide is precipitated. When the temp. is gradually raised, water is given off, then ammonium sulphide, then sulphur, and finally stannous sulphide is formed.

O. B. Kuhn melted a mixture of sodium sulphide, stannous sulphide and sulphur, and obtained a black crystalline mass which gave a dark soln. with hot water. On cooling, the soln. deposited colourless monoclinic crystals of **sodium sulphorthostannate**, $Na_4SnS_4.12H_2O$—when dried over sulphuric acid ; before drying $15H_2O$ are present. The salt is precipitated from its aq. soln. by alcohol. R. F. Weinland and A. Gutmann obtained it by the action of sodium thiosulphate on sodium stannite, or of sodium tetrathionate on a soln. of sodium stannite. Stannous sulphide is first deposited, and on evaporation sodium stannite separates out, and finally the salt in question. The yield is small. The yellow monoclinic prisms were found by H. Zirngiebl to have the axial ratios $a : b : c = 0.9030 : 1 : 0.3652$, and $\beta = 92° 5'$. O. B. Kuhn said that when the salt is heated, it melts in its water of

crystallization. R. F. Weinland and A. Gutmann prepared **potassium sulphortho-stannate**, $K_4SnS_4.12H_2O$, in a similar manner. They represented the crystals as monoclinic prisms with the axial ratios $a : b : c = 0.90304 : 1 : 0.36520$, and $\beta = 92°\ 5'$. O. B. Kuhn obtained dihydrated **sodium sulphometastannate**, $Na_2SnS_3.2H_2O$, by the action of tin on molten sodium pentasulphide. When the product is extracted with water, tin and stannous sulphide remain undissolved; and the soln. deposits yellow octahedral crystals of the salt. The crystals become matted when exposed to air; and melt at a temp. approaching redness. A. Höring made it by the action of tin on a molten mixture of sodium carbonate and sulphide, sulphur, and carbon; extracting the product with water; and evaporating the soln., when dirty white needles of sodium and stannic sulphides first separate, and finally colourless, octahedral crystals of the sulphometastannate. The aq. soln. is pale green, and on evaporation furnishes a mixture of sodium and stannic sulphides. A. Ditte made this salt and also **potassium sulphometastannate**, $K_2SnS_3.3H_2O$, by analogous processes. Both these salts were made by J. J. Berzelius. As indicated in connection with stannous sulphide, A. Ditte found that the reaction between stannous sulphide and 20 per cent. potassium sulphide can be represented: $2SnS + K_2S = Sn + K_2SnS_3$; and with a very conc. soln. of potassium sulphide, the metallic tin is attacked, forming potassium sulphostannate and hydroxide, and hydrogen: $Sn + 3K_2S + 4H_2O = K_2SnS_3 + 4KOH + 2H_2$. The evolution of hydrogen also takes place when tin is heated with potassium sulphide. In the presence of air, potassium sulphide is decomposed with the formation of potassium hydroxide, the sulphur uniting with the stannous sulphide, forming stannic sulphide, which is dissolved by the potassium sulphide. Stannous oxide is also formed by the action of potassium hydroxide on the stannous sulphide. In conc. soln., the stannous sulphide is decomposed, with the formation of potassium sulphostannate and tin, whilst the potassium hydroxide formed holds the stannous oxide in soln. as potassium stannate; but the presence of a sufficient quantity of potassium sulphide prevents the formation of stannous oxide. A soln. of stannous sulphide in one of potassium poly sulphide, or of tin in a boiling conc. soln. of potassium sulphide, furnishes, on evaporation, colourless transparent prisms of this salt. If evaporated in vacuo, the soln. becomes supersaturated, and finally congeals to a crystalline mass. The salt is sparingly soluble in water, and a strongly diluted soln. is decomposed with the precipitation of stannic sulphide; this substance is also precipitated by acids. When the yellow soln. is treated with alcohol, a conc. soln. of the sulphostannate is precipitated as a yellow liquid, which, according to O. B. Kuhn, has the composition $K_2SnS_3 + 9$ or $10H_2O$.

P. Niggli and K. Faesy,[2] J. T. Singewald, W. Davy, G. M. Schwartz, W. Lindgren, C. Hartwell, A. Knopf, etc., studied the complex mineral sulphides. W. Guertler and K. L. Meissner made a partial study of the ternary system Cu–Sn–S, and found two sulphides of tin, and three intermetallic compounds. In 1787, M. H. Klaproth analyzed a mineral from Cornwall which he stated to be *das erstes und bisher einziges Bespiel eines naturlichen geschwefelten Zinnerzes;* and A. G. Werner named it *Zinnkies;* A. Breithaupt, *Zinnkupferglanz;* R. Kirwan, *tin-pyrites;* R. J. Haüy, *étain sulfuré;* F. S. Beudant, *stannin;* and J. D. Dana, **stannite.** It was at first obtained from Wheal Rock, and Carn Brea, Cornwall, where there is an extended vein. It has since been found in several other localities. The colour of the mineral is steel-grey to iron-black. In some parts it has the appearance of bronze or bell-metal, and is then called *bell-metal ore.* Analyses have been reported by M. H. Klaproth, J. Kudernatsch, C. F. Rammelsberg, L. J. Spencer, H. T. de la Beche, J. W. Mallet, J. B. Adger, I. Domeyko, A. Stelzner, W. P. Headden, etc. J. Kudernatsch represented its composition by the formula $2FeS.SnS_2 + 2Cu_2S.SnS_2$; C. F. Rammelsberg, by $(RS.Cu_2S).SnS_2$; and L. J. Spencer, $CuFeS_2.CuSnS_3$, **cuprous ferrous stannic sulphide,** in agreement with the crystallographic analogies of the mineral with copper pyrites. G. A. Kenngott and G. Delafosse also favoured a formula showing its analogy with copper pyrites.

S. Reïnheimer regarded tin pyrites as a mixture of $mCu_2FeSn_4 + nCu_2ZnSnS_4$. Observations on the crystals were made by R. J. Häuy, W. Haidinger, A. Breithaupt, G. vom Rath, and A. Stelzner. L. J. Spencer showed that the crystals are tetragonal, sphenoidal, but pseudocubic owing to twinning. The axial ratios $a : c = 1 : 0.98270$. The twinning is always interpenetrating. The microscopic structure, and the corrosion figures, were examined by H. Schneiderhöhn, G. M. Schwartz, and S. Reïnheimer. The sp. gr. given by A. Breithaupt is 4·371–4·454; M. H. Klaproth gave 4·350; J. W. Mallet, 4·522; J. B. Adger, 4·46; A. Stelzner, 4·495; and L. J. Spencer, 4·45–4·52. The hardness is 3 to 4. A. Sella gave 0·1088 for the sp. ht. A. de Gramont examined the spark spectrum of the mineral. It is decomposed by nitric acid with the separation of sulphur and stannic oxide.

According to T. Ulke, a greenish earthy mass from Dakota is an alteration product of stannite with the composition $4SnO_2.Cu_2Sn.(OH)_2$, and he called it *cuprocassiterite*. W. P. Headden showed that the composition is very variable. A. Daubrée obtained a substance, with a composition approaching that of stannite, as an incrustation on an old bronze coin found in a sulphate spring in Corsica.

J. J. Berzelius [3] prepared **calcium sulphometastannate** by adding potassium sulphostannate to a soln. of calcium chloride. A. Ditte prepared **calcium sulphorthostannate**, $Ca_2SnS_4.14H_2O$, by boiling milk of lime with sulphur and tin. As the soln. cools, sulphur and calcium sulphide are deposited, and when the filtrate is evaporated in vacuo, the given salt is obtained; it can be purified by repeated crystallization from water. The lemon-yellow crystals are very soluble in water; and acids precipitate stannic sulphide from the aq. soln. A. Ditte obtained **strontium sulphometastannate**, $SrSnS_3.12H_2O$, in thick colourless prisms by the action of a soln. of sulphur on one of strontium sulphide, and evaporating the liquor in vacuo. J. J. Berzelius obtained it by adding a soln. of potassium sulpho-metastannate to one of strontium chloride; he also obtained **barium sulphometastannate** in a similar way; and A. Ditte prepared this salt, $BaSnS_3.8H_2O$, by a process analogous to that employed for the strontium salt. The lemon-yellow crystals dissolve in cold water without decomposition.

According to L. F. Hawley, **thallous sulphorthostannate**, Tl_2SnS_4, is quantitatively precipitated by adding sodium sulphostannate to a hot, slightly acid soln. of a thallous or thallic salt, and then adding a soln. of sodium sulphide until the liquid is more than neutralized. The mixture is boiled for about 5 mins., diluted with water, and allowed to stand. J. Loczka showed that when thallium sulphide and stannic sulphide are precipitated together, a solid is obtained which is only partially soluble in either dil. acids or alkaline sulphides, and which varies in colour from an orange-yellow when rich in stannic sulphide through a bright red to a very dark red when rich in thallium sulphide. L. F. Hawley examined the precipitates and found that over the range of conc. from thallous sulphide to a point corresponding to thallous sulphorthostannate, Tl_4SnS_4, there were distinguishable two phases, a black and a red, both with a tendency toward crystalline structure and both opaque; at the point thallous sulphorthostannate, $2Tl_2S.SnS_2$, only one phase was present, the red crystalline opaque phase. From this point to 76 mol. per cent. stannic sulphide two phases were present, the red crystalline opaque phase and an orange-yellow amorphous translucent phase; from 76 mol. per cent. stannic sulphide to pure stannic sulphide the solid is entirely homogeneous and changes gradually in colour from orange-yellow to the light yellow of pure stannic sulphide. These observations show that besides the pure components two other phases are present in the series, a compound thallous sulphorthostannate and a series of solid soln. running from 76 per cent. stannic sulphide to pure stannic sulphide. Another indication of the formation of the compound thallous sulphorthostannate occurs when precipitates containing an excess of stannic sulphide are treated with sodium sulphide soln. Stannic sulphide is dissolved until the residue has the composition thallous sulphorthostannide, and then no more will be dissolved even on increasing the conc. of sodium

sulphate to 4 mols. per litre and boiling. The compound thallous sulphortho-stannate is decomposed, however, by a boiling soln. of sodium sulphide when the conc. of the latter is about 5 mols. per litre.

G. T. Prior [4] described a greyish-black mineral, which, according to R. Köchlin, came from Santa Rosa, Bolivia. It was called teallite—after J. J. H. Teall. The analysis corresponds with lead sulphometastannate, $PbS.SnS_2$, or $PbSnS_3$. The thin flexible folia belong to the rhombic system having the axial ratios $a : b : c$ $=0.93 : 1 : 1.31$. The (001)-cleavage is perfect. G. T. Prior compared the analogies between teallite, franckeite, and cylindrite. The hardness is 1 to 2 ; and the sp. gr. 6.36. It is readily decomposed by hot hydrochloric or nitric acid. M. Ahlfeld reported a related mineral, *pufahlite*, from Oruro, Bolivia. Its sp. gr. is 5.4 ; and its composition: Sn, 41.9 ; Sb, 37.4 ; Zn, 6.3 ; and S, 13.5 per cent.

§ 25. The Tin Sulphates

The action of sulphuric acid on tin has been previously discussed, one product of the action of this acid or of pyrosulphuric acid on the metal is **stannous sulphate,** $SnSO_4$. J. J. Berzelius [1] obtained the anhydrous sulphate by heating a mixture of stannous sulphide and mercuric oxide : or a mixture of stannous chloride and

sulphuric acid. J. P. Bouquet obtained it as a white pulverulent precipitate by adding sulphuric acid or ammonium sulphate to a conc. soln. of stannous chloride. Freshly precipitated stannous hydroxide readily dissolves in dil. sulphuric acid, and when the soln. is filtered and evaporated over sulphuric acid, J. P. Bouquet, A. Longi, J. C. G. de Marignac, and A. Ditte found that the crystalline sulphate is formed. J. C. G. de Marignac could not prepare the crystals by cooling a boiling sat. soln. as recommended by J. P. Bouquet. According to R. G. Durrant, when stannous chloride is heated with sulphuric acid at temp. between 20° and 90°, stannous sulphate is formed, and hydrogen chloride liberated: $SnCl_2 + H_2SO_4 = SnSO_4 + 2HCl$; if the temp. rises between 130° and 200°, stannic sulphate is formed and sulphur dioxide is evolved: $SnSO_4 + 2H_2SO_4 = Sn(SO_4)_2 + 2H_2O + SO_2$. If the sulphuric acid is dil., some hydrogen sulphide is evolved before the sulphur dioxide appears; the hydrogen sulphide is formed by the reduction of the sulphur dioxide, which, along with hydrogen chloride, is dissolved in the liquid. J. P. Bouquet was unable to measure the crystallographic constants of the crystals obtained by evaporating the aq. soln. in vacuo. A. B. Berthollet said that the crystals are acicular. According to J. J. Berzelius, the salt could be heated to dark redness without decomposition, but at a higher temp. it forms stannic oxide. J. L. Gay Lussac, and J. P. Bouquet obtained similar results. J. A. Arfvedson said that when heated in hydrogen, some sulphur and stannous sulphide are formed. J. C. G. de Marignac found that 100 parts of water at 19° dissolve 18·8 parts of salt; and 100 parts of a boiling soln., 18·2 parts. The difference is too small to enable crystals to be prepared by cooling a hot sat. soln. A. Longi said that a clear soln. is produced with a small proportion of water, and a turbid soln., with a large proportion. The aq. soln. was found by J. P. Bouquet, and A. Ditte to be soon hydrolyzed with the deposition of a basic salt. The turbid soln. clears when sulphuric acid is added. According to E. Divers and T. Haga, stannous sulphate in the presence of sulphuric acid does not reduce nitric acid to ammonia or to hydroxylamine. *Vide* the action of sulphuric acid on stannous chloride: $SnSO_4 + 2H_2SO_4 = Sn(SO_4)_2 + 2H_2O + SO_2$. R. G. Durrant said that when stannic sulphate is heated alone, sulphur dioxide is given off between 360° and dull redness: $SnSO_4 = SnO_2 + SO_2$.

A. B. Berthollet said that a basic salt is precipitated when a soln. of the normal salt is treated with alkali. As just indicated, an aq. soln. of the normal sulphate slowly deposits a basic sulphate in the cold, and rapidly when heated; according to A. Ditte, its composition corresponds with **stannous dioxysulphate**, $3SnO.SO_3.\frac{3}{2}H_2O$, $SnSO_4.2SnO.3H_2O$, or $2Sn_3O_2.SO_4.3H_2O$. He also made this compound by the action of hot dil. sulphuric acid on stannous oxide; some stannous sulphate simultaneously passes into soln.—the amount depends on the conc. of the acid. Cold water does not alter this basic salt, but when heated with water, a pale red crystalline powder of the anhydrous salt is formed. It is easily soluble in hot water. C. M. Carson found that by gradually adding sodium hydroxide to a soln. of stannous sulphate at 100°, the composition of the precipitates in two regions remained fairly constant. The one corresponds with **stannous oxysulphate**, $SnSO_4.SnO$; and the other with A. Ditte's stannous dioxysulphate, $SnSO_4.2SnO.nH_2O$.

J. P. Bouquet prepared **ammonium sulphostannite**, by the union of the component sulphates in aq. soln., and A. Longi, by the action of ammonia on stannous sulphate; the composition of the product was not constant. J. P. Bouquet prepared **potassium sulphostannite** by the union of the component sulphates, and J. C. G. de Marignac found the analyses of two preparations obtained by evaporating mixed soln. of potassium and stannous sulphates to be $K_2Sn_2(SO_4)_3$, and $K_2Sn(SO_4)_2$. A warm conc. soln. of potassium sulphate and stannous chloride gave J. C. G. de Marignac, and C. F. Rammelsberg hexagonal prisms of **potassium chlorosulphatostannite**, $4K_2Sn(SO_4)_2.SnCl_2$, with axial ratios $a : c = 1 : 0.7485$.

H. Rose found that when stannic oxide is digested with hot conc. sulphuric

acid, the syrupy liquid deposits stannic hydroxide when diluted with water; a similar product was obtained when a soln. of stannic oxide in fused potassium hydrosulphate was diluted with water. J. J. Berzelius made a soln. of **stannic sulphate** by dissolving stannic hydroxide in dil. sulphuric acid; and J. von Kraskowitz, by heating tin with an excess of conc. or fuming sulphuric acid. According to A. Ditte, stannic hydroxide produced by the action of alkalies on a soln. of stannic chloride, dissolves readily in warm dil. sulphuric acid (1 : 8), forming a limpid soln., which when conc. until it contains not more than 3 or 4 vols. of water to 1 vol. of sulphuric acid, deposits at first colourless, radiating needles, then rhombohedral lamellæ, and eventually hexagonal prisms with two parallel faces largely developed; and corresponded with **dihydrated stannic sulphate,** $SnO_2.2H_2SO_4$, or $Sn(SO_4)_2.2H_2O$. The same compound is obtained by the action of sulphuric acid of suitable conc. on the hard, vitreous hydroxide, $Sn(OH)_4$, obtained by dissolving gelatinous stannic hydroxide in ammonia, and evaporating the liquid; on metastannic acid obtained by treating the metal by nitric acid; and on strongly heated anhydrous stannic oxide. In the last case, the rate of soln. is very slow. The form of the crystals varies with the relative proportions of acid and water in the liquid, as just indicated. The crystals are decomposed by water, but the stannic oxide is kept in soln. by the sulphuric acid which is liberated, and a precipitate is only obtained when water is added in such quantity that the liquid does not contain more than about 43 grms. of sulphuric acid per litre. The crystals are very deliquescent, and form a colourless, transparent liquid when exposed to the air; this soln. does not crystallize on evaporation, but forms a hard, vitreous mass. If, however, some sulphuric acid is added to the liquid, crystals of the dihydrate are readily obtained. They dissolve readily in dil. sulphuric acid, especially on heating, are not affected by ether, but are decomposed by alcohol with removal of sulphuric acid. If the sulphuric acid is not in large excess but has dissolved a considerable proportion of stannic oxide, it forms a transparent jelly on cooling, which is sometimes opalescent. This liquefies when heated, but gelatinizes again when cooled. The jelly is strongly acid, and does not become crystalline even after several weeks. If, however, it is mixed with an excess of ether, it yields a precipitate of slender, white needles of **stannic dihydroxy-sulphate,** $SnO_2.H_2SO_4$, or $Sn(OH)_2SO_4$. This compound dissolves in cold water, and the soln. is at first limpid, but soon becomes turbid, owing to the separation of gelatinous stannic hydroxide.

J. G. F. Druce made the potassium salt from a soln. of potassium chlorostannate and sulphuric acid. R. F. Weinland and H. Kühl reported **potassium sulphatostannate,** $K_2Sn(SO_4)_3$, to be formed in needle-like crystals by evaporating a soln. of a mol of α-stannic acid and 1 to 1·5 mols of potassium sulphate in conc. sulphuric acid; they prepared in a similar manner six-sided leaflets of **rubidium sulphatostannate,** $Rb_2Sn(SO_4)_3$; slender needles of **silver sulphatostannate,** $Ag_2Sn(SO_4)_3.3H_2O$; colourless cubes of **calcium sulphatostannate,** $CaSn(SO_4)_3.3H_2O$; J. G. F. Druce also made this salt by the method he used for the potassium salt. R. F. Weinland and H. Kühl made **strontium sulphatostannate,** $SrSn(SO_4)_3.3H_2O$; **barium sulphatostannate,** $BaSn(SO_4)_3.3H_2O$; **lead sulphatostannate,** $PbSn(SO_4)_3.3H_2O$; **cerium hydrosulphatostannate,** $CeHSn(SO_4)_4$, as a colourless, microcrystalline powder; **lanthanum hydrosulphatostannate,** $LaHSn(SO_4)_4$, in small six-sided plates; **yttrium sulphatostannate,** $Y_2Sn(SO_4)_3.6$, as a microcrystalline powder; **thorium sulphatostannate,** $ThSn(SO_4)_4.2H_2O$, in slender needles; and **bismuth hydroxysulphatostannate,** $Bi(OH)Sn(SO_4)_3$, in rhombic leaflets. J. G. F. Druce made aniline, m-phenylenediamine, and quinoline sulphatostannates.

§ 26. Tin Carbonates

According to K. Seubert and M. Elten,[1] when a soln. of sodium carbonate is poured into one of stannous chloride, carbon dioxide is evolved, and stannous hydroxide precipitated—*vide* analytical reactions of tin. H. St. C. Deville, left a conc. soln. of sodium hydrocarbonate and crystals of stannous chloride in a corked flask for some days, and obtained a crystalline powder of **stannous oxycarbonate**, Sn_2OCO_3, or $SnO.SnCO_3$, which decomposed rapidly, becoming black under a soln. of sodium hydrocarbonate, and yellow in air. G. C. Wittstein found that a boiling soln. of ammonium carbonate dissolves stannous hydroxide ; and H. St. C. Deville left a conc. soln. of ammonium hydrocarbonate and crystals of stannous chloride in a corked flask, and in 24 hrs. obtained white, hexagonal prisms of **ammonium carbonatostannite**, $(NH_4)_2Sn_2(CO_3)_3.3H_2O$. The salt is decomposed by water, forming black stannous oxide ; and when rapidly heated, it furnishes olive-green stannous oxide. White needles of **potassium carbonatostannite**, $K_2Sn_2(CO_3)_3.2H_2O$, were prepared in a similar manner. T. Leykauf reported a *sodium carbonato-stannite* to be formed by adding an excess of sodium carbonate to a soln. of stannous chloride because the washed precipitate effervesced with acids. The phenomenon may have been due to the adsorbed alkali carbonate.

§ 27. Tin Nitrates

J. L. Proust[1] found that at ordinary temp. dil. nitric acid dissolves tin, and the reaction is attended not with the evolution of nitrous gases, but with the formation of ammonia, and of a soln. of **stannous nitrate**. The action of nitric acid on tin has been previously discussed. J. J. Berzelius added that the salt obtained by the action of dil. nitric acid on stannous hydroxide is free from ammonium nitrate. N. W. Fischer added lead nitrate to a soln. of stannous chloride and filtered off the lead chloride. R. Weber obtained stannous nitrate, $Sn(NO_3)_2.20H_2O$, by adding freshly prepared stannous hydroxide to nitric acid of sp. gr. 1·20, so long as the liquid remains clear ; when the soln. is cooled to −20°, the salt is deposited in thin, trans-parent, colourless leaflets, resembling potassium chlorate. The crystals melt very quickly after their removal from the cold liquid. J. J. Berzelius, J. L. Proust, and R. Weber found that the soln. of stannous nitrate soon decomposes and deposits hydrated stannous oxide ; and if heated with fresh acid it deposits all the tin as β-stannic acid. A. Ditte said that when the soln. is evaporated, there is a sudden evolution of nitrous gases, and the deposition of basic stannic nitrate.

According to R. Weber, **stannous oxynitrate**, $Sn_2O(NO_3)_2$, or $SnO.Sn(NO_3)_2$, is formed (i) when a soln. of stannous hydroxide in nitric acid of sp. gr. 1·20 is mixed with excess of the oxide at 30°–35°, the basic salt is deposited as a greyish-white coherent crystalline mass, which is dried in the air and recrystallized from water ;

prepared in this way, however, it is generally mixed with oxide. (ii) It can be obtained pure by adding sodium carbonate, with constant shaking, to the freshly-made nitric acid soln. of stannous oxide ; the precipitate of the basic salt thus obtained forms snow-white granular aggregations of rectangular prisms. (iii) When nitric acid, sp. gr. 1·20, is spread over sheets of tin-foil or of an alloy of tin and lead by means of a spray producer, the metallic surface becomes coated with this basic salt, which, when dry, burns with scintillation, or explodes when struck. (iv) It is also formed when tin acts on metallic nitrates, e.g., tin-foil and copper nitrate react ; the tin speedily becomes covered with a mixture of precipitated copper and the basic salt ; the final product, when dry, burns with scintillation, or, when suddenly heated or struck, explodes. The basic nitrate is partially decomposed by water, and gradually oxidizes and changes in the air. It can be heated to 100° ; at a higher temp. it is decomposed with explosion, the product being nitrous fumes and finely-divided stannic oxide. It also detonates strongly either by concussion or friction. R. Weber attributed some explosions which have occurred during the mixing and pressing of the damp constituents of gunpowder to the formation of this nitrate by the action of the nitre and sulphur of the gunpowder on the solder of the rollers. He reproduced the conditions by placing a piece of tin-foil in a dish with a damp mixture of nitre and sulphur, which was covered by a piece of copper, so that only a thin film of the mixture was between the two metals ; in a short time a considerable quantity of the basic tin nitrate had formed. The use of tin in rollers for gunpowder mills at Spandau was therefore abandoned.

According to J. J. Berzelius, stannic hydroxide dissolves copiously in nitric acid, and neutralizes it completely, forming a soln. which, if conc., deposits silky needles of **stannic nitrate.** At 50°, nearly all the stannic oxide is deposited in the hydrated β-form ; at ordinary temp., the soln. deposits stannic hydroxide which redissolves in the presence of ammonium nitrate. Possibly *ammonium nitratostannate* is formed, which is more stable than stannic nitrate. J. B. A. Dumas said that the first action of cold conc. nitric acid on tin is the production of a basic nitrate. A. Ditte obtained **stannic trioxydinitrate,** $Sn_2S_3(NO_3)_2.6H_2O$, by the evaporation of an aq. soln. of stannous nitrate—*vide supra*. V. Thomas poured a chloroform soln. of nitrogen peroxide into a dil. chloroform soln. of stannic iodide, and obtained a violet precipitate, which, when washed with chloroform, became white. The composition $Sn_5N_2O_{17}.4H_2O$ is represented as β-**stannic dinitrate,** $Sn_5(NO_3)_2O_{11}.4H_2O$, analogous with $Sn_5K_2O_{11}.4H_2O$—*vide* β-stannic chlorides.

§ 28. The Tin Phosphates

E. Lenssen [1] found that when a neutral soln. of stannous chloride is added to a conc. soln. of sodium hydrosulphate, acidified with acetic acid, a white, voluminous precipitate is produced which soon becomes crystalline. It appears to be a **stannous tetraphosphate,** $5SnO.2P_2O_5.4H_2O$, or **stannous dihydrotetraphosphate,** $Sn_5H_2(PO_4)_4.3H_2O$. If the soln. of sodium hydrophosphate be added to the stannous chloride soln., the precipitate contains a chloride. The stannous hydrophosphate is insoluble in water ; it is not changed at 100° ; and when ignited, it forms stannic oxide and metallic tin. K. Jablczynsky and W. Wieckowsky prepared **stannous orthophosphate,** $Sn_3(PO_4)_2$, by pouring a ten per cent. soln. of sodium hydrophosphate into a sat. soln. of stannous sulphate (1 : 10), acidified with sulphuric

acid, with constant stirring. The precipitate was washed with hot water; boiled with water; washed with alcohol, and ether; and dried over phosphorous pent-oxide. If stannous chloride be used, the precipitate always contains a chloride. If the stannous sulphate soln. be poured into the hydrophosphate soln., a yellow basic salt is formed owing to hydrolysis. Stannous orthophosphate is a white amorphous solid with a sp. gr. 3·823 at 17·4°/4°. It is stable in air; insoluble in water, but soluble in dil. mineral acids and alkali-lyes. By dissolving 5 grms. of tin in 22 c.c. of warm phosphoric acid of sp. gr. 1·23, and adding water from time to time so that the soln. is not too viscid, and slowly cooling the result-ing liquid, there are deposited six-sided plates of **stannous hydrophosphate,** $SnHPO_4$, of sp. gr. 3·476 at 15·5°/4°. If 13 grms. of tin be dissolved in 35 c.c. of warm phosphoric acid, and 15 c.c. of hot water be added to the hot soln., the hydrophosphate is precipitated in narrow, pointed crystals. If 10 grms. of the hydrophosphate be dissolved in 10 grms. of phosphoric acid of sp. gr. 1·7, heated to 140°, and the liquid cooled slowly in a desiccator with phosphorous pentoxide, rhombic crystals of **stannous dihydrophosphate,** $Sn(H_2PO_4)_2$, are formed. Their sp. gr. is 3·167 at 22·8°/4°. By heating the hydrophosphate to 350°–400°, in an atm. of carbon dioxide, **stannous pyrophosphate,** $Sn_2P_2O_7$, is formed as an amor-phous powder, of sp. gr. 4·009 at 16·4°/4°. If the dihydrophosphate be similarly heated, **stannous metaphosphate,** $Sn(PO_3)_2$, is formed as an amorphous, glassy mass of sp. gr. 3·380 at 22·8°/4°. These phosphates resemble those of lead except that lead orthophosphate is not altered by dil. phosphoric acid, while stannous orthophosphate forms the hydrophosphate; that lead hydrophosphate in boiling water easily forms the orthophosphate but not so with the tin salt; and that lead dihydrophosphate is fairly stable in air, but not so with the tin salt. The stannous salts are more readily hydrolyzed than the lead salts.

According to E. Haeffely, when stannic oxide is treated with phosphoric acid. **stannic oxydiphosphate,** $Sn_2O(PO_4)_2.10H_2O$, or $2SnO_2.P_2O_5.10H_2O$, is formed; P. Hautefeuille and J. Margottet found that orthophosphoric acid, at a temp. below that at which water is given off, dissolves stannic hydroxide, and on cooling furnishes octahedral crystals of the anhydrous salt $Sn_2O(PO_4)_2$; and H. Kopp melted stannic oxide with microcosmic salt, and obtained two kinds of crystals, *viz.,* pyramidal crystals of the oxydiphosphate, and cubic crystals of **stannic pyrophos-phate,** SnP_2O_7. L. Ouvrard obtained the pyrophosphate but not the oxydiphos-phate by fusing stannic oxide with sodium metaphosphate. G. Bornemann obtained a precipitate of variable composition: 22·21–29·53 per cent. P_2O_5 and 70·47–77·8 per cent. SnO_2, by adding an excess of sodium phosphate to a soln. of a sodium stannate; and W. T. Casselmann obtained a gelatinous mass of stannic phosphate by the decomposition of $2SnCl_4.PCl_5$ with an excess of water. The very sparing solubility of stannic phosphate in dil. nitric acid was utilized by A. Reynoso, W. Reissig, and A. Girard for the determination of phosphoric acid in nitric acid soln. free from chlorine. U. Antony and G. H. Mondolfo examined the insoluble compound obtained by adding a phosphate to a metastannic acid. P. Heermann, and H. Silbermann used stannic phosphate as a filling for silk.

L. Ouvrard fused stannic oxide with a large excess of potassium metaphosphate, and obtained **potassium triphosphatostannate,** $K_2O.4SnO_2.3P_2O_5$, or $KSn(PO_4)_3$, isomorphous with the corresponding titanium salt; no cassiterite was formed. If potassium pyro- or ortho-phosphate be employed, **potassium oxyphosphatostannate,** $K_2O.2SnO_2.P_2O_5$, or $KSnOPO_4$, analogous with the corresponding titanium com-pound, is formed. According to G. Wunder, when a mixture of stannic oxide, microcosmic salt, and borax or sodium pyroborate is fused in a crucible; the clear molten liquid poured into another crucible and slowly cooled; the product washed with dil. hydrochloric acid; and the residue separated by elutriation, the tetragonal prisms, resembling anatase, which are obtained have the composition $Na_2Sn(PO_4)_2$, or **sodium diphosphatostannate;** and the rhombohedral crystals, almost cubic, have the composition $NaSn_2(PO_4)_2$, or $Na(SnPO_4)_2$, **sodium diphosphatodistannate.**

These salts were also obtained by H. Knop in an analogous manner. L. Ouvrard prepared sodium diphosphatostannate, and **sodium triphosphatostannate,** $Na_2O.4SnO_2.3P_2O_5$, or $NaSn(PO_4)_3$. W. Prandtl and O. Rosenthal mixed sodium phosphate and stannate in alkaline soln., or dissolved stannic phosphate in sodium hydroxide and obtained complex salts or mixed crystals with the composition $Na_2SnO_3.4Na_3PO_4.48H_2O$; $Na_2SnO_3.5Na_3PO_4.60H_2O$; $Na_2SnO_3.6Na_3PO_4.72H_2O$; and $Na_2SnO_3.4Na_3(P,V)O_4.48H_2O$. H. Zocher showed that the alleged complex phosphatostannates are not chemical individuals because they form a continuous series whose composition depends on the stannate conc. of the mother liquid. G. Saring also reported **potassium calcium phosphatostannate,** $Ca_3(PO_4)_2(CaO)_2(K_2O)_2SnO_2$, analogous with the corresponding phosphato-silicate, titanate, zirconate, cerate, thorate, and plumbate.

CHAPTER XLVII

LEAD

§ 1. The History of Lead

THE metal lead is one of the seven metals known to man from the earliest times. The Egyptians must have been familiar with the metal at the time of Rameses III. (1200 B.C.), since lead plates and small statues, chiefly of Osiris and Anubis, have been found in the tombs of that period. M. Berthelot [1] showed that lead was used by the Egyptians in making jewellery, mirrors, etc. ; and R. Lepsius reported that lead is mentioned in Egyptian hieroglyphics, 1515–1461 B.C. The British Museum has a lead figure found in the temple of Osiris at Abydos, and which probably dates from 3000 B.C. Old Egyptian pottery has also been found covered with plumbiferous glazes (**6**. 40, 36). According to Numbers (**31**. 32), lead was included in the spoil taken from the Midianites by the Israelites. The *opheret* of the Hebrews, Phœnicians, and Egyptians was rendered μόλυβδος, *molybdos*, in the earliest Greek translations of the Old Testament, and as *lead* in the English version ; while *bedil* was generally translated κασσίτερος, and later tin (*q.v.*). F. Hoefer's suggestion that the term *opheret* should be rendered *copper* is not generally accepted. According to Ezekiel (**27.** 12), the Carthaginians traded in silver, iron, tin, and lead. The Israelites do not appear to have made a clear distinction between lead and tin, and their *bedil* is sometimes translated *tin*, and sometimes *lead*. Lead is mentioned by Homer. As indicated in connection with tin, Pliny, in his *Historia naturalis* of the first century, distinguished the two metals by calling tin *plumbum candidum*, and lead *plumbum nigrum*. The use of lead among the ancients was discussed by Theophrastus, in his Περὶ Λίθων (**2**. 8, 56) in the third century B.C. ; by Pliny, *Historia naturalis* (**34**. 173), Dioscorides, *De materia medica* (**5**. 100), and Vitruvius, *De architectura* (**7**. 12), all in the first century of our era ; Strabo, *Geographica* (**3**. 148), in the first century B.C. ; and Gahlen, *De simplicium medicamentorum temperamentis* (**9**. 22 ; **12**. 230), in the second century ; and by the later writers : K. B. Hofmann, H. Blümmer, A. Gobantz, C. G. Fiedler, H. Faure, E. O. von Lippmann, A. Rössing, B. Neumann, A. F. von Pauly and G. Wissowa, J. A. Overbeck, A. Baumeister, H. Droysen, G. Bapst, H. Faure, L. Guillaume, and F. X. M. Zippe. Lead was used for sling-bolts, tipping arrows, coffins, tablets, toys, vases, tokens, weights, net-sinkers, plummets, seals, water-pipes, backing glass mirrors, and Pliny (**33**. 19) referred to the use of lead discs for drawing lines on parchment. Several of the literary men—Catullus, Herodotus, Thucydides, and Cicero—made allusions to lead. Cicero, for instance, humorously emphasized the feeble character of a man by saying that he could be slain with a *plumbo gladio,* or leaden sword ; and stupid people were called *plumbei.*

Lead was mined in considerable quantities by the Greeks and Romans. Polybius, in his *Historia*, in the second century B.C., said that the mines at Carthagena employed 40,000 men ; Xenophon, in his treatise on the revenues of Athens—Πόροι ἤ περὶ προσόδων—written in the fourth century B.C., stated that the mines at Laurium were worked in ancient times, and he advocated the better

management of the mines as a means of improving the revenue. For three hundred years these mines were a source of revenue to Athens. The mines at Linares were worked in turn by the Phœnicians, Carthaginians, and Romans. Some old shafts in the neighbourhood are still known as *Los Pozos de Anibal*—Hannibal's Wells. According to Pliny, *Historia naturalis* (**34**. 138, 164), and Strabo, *Geographica* (**3**. 148), the Romans obtained large amounts of lead from South-Eastern Spain. These mines were opened in the twelfth century B.C. The mines in Crete were described by A. Mosso. The early Spanish mines were described by K. B. Hofmann, H. Blümmer, etc., and they form the main lead district in Spain to-day. The Phœnicians bartered earthenware, salt, and copper with Britain in exchange for lead, tin, and hides—*vide* history of tin. Cicero, in his *Epistolæ ad Atticum*, said that there was no silver in Britain; but he must have been misinformed, because Strabo, Pliny, and others mention it. This shows that cupellation must have been in operation, because the only source of the silver was the lead ore. According to Pliny, the Romans also carried on mining operations in various parts of Britain (Somersetshire, Shropshire, Yorkshire, Derbyshire, Durham, Cumberland, Northumberland, and Scotland), and the British mines have been described by G. Chalmers, H. Blümmer, R. I. Murchison, J. Childrey, J. C. Bruce, and K. B. Hofmann. The lead industry in Scotland dates from a very early period. According to G. V. Wilson and J. S. Flett, there is no evidence that the Romans worked lead in Scotland, although J. R. S. Hunter reported the finding of bronze and stone implements in some old surface workings at Leadhills and Wanlockhead, and D. Wilson, the finding of some pigs of Roman lead. According to T. Pennant, the mines of Islay were worked by the Norwegian invaders when they occupied the country. G. V. Irving, R. W. C. Patrick, J. Leslie, and S. Atkinson have referred to the mining of lead during the Middle Ages in Scotland. J. A. Phillips has suggested that the great wall of Hadrian (A.D. 117–138) was built partly with a view of enclosing and protecting the lead mines of Northumberland and Cumberland. There are ingots in existence to-day with the inscription: *Britannicus ad Verum*. A. Way has given a list of known ingots, and they range from the time of Claudius (A.D. 44–48) to the reign of Hadrian (A.D. 117–138). Many examples are in the British Museum. Lead mining in England may have been restricted, but there is nothing to show that it stopped after the Roman withdrawal. Lead coffins of Saxon age are known. There is a reference in the Doomsday Book of the eleventh century to a lead mine at Crice, and there are records of grants to miners dating from the thirteenth century. The furnaces, etc., were described by J. Glanvil, G. Plattes, T. Houghton, R. Watson, J. Martyn, J. Farey, W. Wallace, and P. A. Dufrénoy. The mining in the Mendip Hills probably dates from pre-Roman times, and has been described by R. Hunt, J. McMurtrie, and T. Morgan. The Roman mines in Gaul, along the Rhine from Bâle to Cologne, have been described by A. Daubrée, and H. Blümmer. Blocks of lead have been found with inscriptions: Nero, Hadrian, and Septimus Severus. The Roman mines in Germany have been described by H. Blümner, A. Frantz, T. Haupt, A. Daubrée, and K. B. Hofmann. The mines of Saxony, Silesia, and the Harz Mountains, as well as the Austrian mines, were discovered about A.D. 1000. The history of the German mines has been discussed by G. Agricola, P. Bech, P. Albinus, H. Ermisch, C. Blömeke, etc. Lead was smelted in the United States at the beginning of the seventeenth century, and this subject has been discussed by H. R. Schoolcraft, C. L. Henning, H. Garlichs, W. H. Pulsifer, etc. According to W. Gowland, although galena is common in Japan, the early Japanese rarely used the metal, copper being usually employed where Europeans use lead. In the ninth and tenth centuries, lead or pewter coins were employed. According to W. H. Adolph, in China, lead was used as a substitute for tin from very early times. The Chinese and Japanese bronzes were discussed by H. Morin, P. Christofle and H. Bouilhet, and S. Kalischer.

The alchemists of the Middle Ages represented lead by ♄, the symbol for

Saturn. It has been suggested that this symbolizes the scythe of Saturn—Father Time—but, according to J. Beckmann,[2] the imaginary scythe has been really formed from the first two letters of his name κρόνος, which transcribers, for the sake of dispatch, made more convenient for use, but at the same time less perceptible. In the Latin work, *Summa prefectionis magisterii*, of Geber, probably of the twelfth century, lead is thus described :

Lead is a metal which is livid, dull, and white ; it is heavy ; not sonorous ; extensible under the hammer ; and easily fused. When exposed to the vapour of vinegar, it forms white lead, and when roasted, red lead. Although lead scarcely resembles silver, it can be easily converted into silver *per nostrum artificium*. It does not maintain its weight during calcination, but acquires a new weight by this operation. Lead is employed in cupellation.

§ 2. The Occurrence of Lead

According to the estimates of J. H. L. Vogt,[1] and F. W. Clarke and H. S. Washington, lead is less commonly distributed than some of the elements usually regarded as rarer and scarcer—*e.g.* zirconium, vanadium, cerium, and yttrium. The average composition of the ten-mile crust, the hydrosphere, and atm. is $n \times 10^{-6}$ per cent. lead, according to J. H. L. Vogt; 0·0005 per cent., according to A. E. Fersmann; and 2×10^{-5} per cent., according to F. W. Clarke and H. S. Washington. A. M. Finlayson estimated in British areas an average of 0·0024 per cent. of lead in granite, diabase, shale, and limestone; the granites contained most—0·002–0·004 per cent.; and the limestones least—0·0005–0·0015 per cent. In the workable deposits, however, the lead occurs in a much greater proportion owing to the natural concentration of the material. The presence of lead in the sun has been demonstrated by the spectral observations of J. N. Lockyer,[2] H. Rowland, C. C. Hutchins and E. L. Holden. According to E. Cohen, the occurrence of lead in meteorites has been reported.

Lead occurs chiefly as sulphide, galena, which is one of the most widely distributed of the metal sulphides. Cerussite and anglesite occur in quantities sufficiently large to be mined; and plumbojarosite, a rare mineral, is mined at Utah. Lead ores occur in veins and lodes or in fissures which have served as channels for the circulation of lead-bearing soln. from magmatic and other sources. The general opinion is that galena is usually of hydrochemical origin. G. Bischof [3] mentions its occurrence in stalactitic form, and as an incrustation on fossil bones
Fig. 1.—The Geographical Distribution of the Chief Deposits of Lead Ore.

in an old mine. A. Russell observed its formation from lead and sea-water in contact with charcoal—*vide* lead sulphide. In the so-called metasomatic deposits, the ore has been formed by a replacement of dolomite or limestone by galena, and some of the most important deposits have been produced in this manner. In the contact deposits the ore occurs in the zone of contact of intrusive igneous masses. Ores of lead usually associated with those of copper and vanadium, are sometimes found disseminated in sandstones and shales. Galena occurs in both crystalline and non-crystalline rocks. It is commonly associated with pyrites, sphalerite, chalcopyrite, arsenopyrite, etc., in the gangue of quartz, calcite, barytes, or fluorspar, etc. Many other salts of lead have been formed by the alteration of galena. All galena is more or less argentiferous. The silver follows the metal when lead is

extracted from galena, and many alchemists thought that the processes they used for extracting the silver were veritable transmutations of lead into silver. Lead is also commonly associated with zinc, and their primary or sulphide ores were brought together probably owing to the similarity in the properties of the sulphides. In the zone of oxidation the zinc sulphate is more soluble than lead sulphate, and consequently the alteration products of the zinc sulphide have been frequently leached away, leaving the lead ore practically free from zinc. A general idea of the distribution of the lead ores will be obtained from Fig. 1.

The occurrence of lead ore in **Europe.** The lead ore of the *British Isles* is generally obtained from veins in carboniferous rocks ; and the ore is galena generally associated with some zinc blende, and on the average with about 3 ozs. of silver per ton. About the middle of last century, the industry was very prosperous, over 1,000,000 tons of dressed ore were obtained from about 350 mines. Scarcely one-tenth of this amount is now obtained, and the industry in many counties, formerly big producers, is now almost extinct owing to the exhaustion and impoverishment of the deposits ; and the increase in the mining costs, and transport. Under these circumstances, the ores cannot compete success- fully against richer ores or ores obtained under more favourable conditions. Between 1848 and 1884, Cornwall and Devon had an average yearly output of nearly 1800 tons ; in 1917, it was 2 tons. In England, lead ore occurs in Cheshire, Cornwall, Cumberland, Derbyshire, Durham, Northumberland, Shropshire, Westmoreland, and Yorkshire ; in Wales, in Cardigan, Carmarthen, Carnarvon, Denbigh, Flint, and Montgomery ; in Scotland, in Dumfries and Lanark ; in Ireland, in Sligo and Wicklow ; and in the Isle of Man. In *Austria*, there are large deposits in the Triassic limestones and dolomites of Carinthia. In *Belgium*, the deposit of the Moresnet district extends into Luxembourg and Prussia ; the Vieille Montagne Mine is here worked. There is also ore at Bleyberg, Liège, and Verviers. In *Bulgaria*, there are mines at Blagodal near Kustendil, at Sedmilchi- sleniza, and Roupio. In *Czecho-Slovakia*, there are mines in Bohemia, at Prizibram near Prague ; near Piken ; at Kuttenberg, and at Budeweis. There are also deposits in the north-west which are extensions of the Saxon Erzegebirge. In the past, *Germany* has occupied a foremost place in the production of lead ore. The most productive deposits are in Upper Silesia. These deposits occur in the south-eastern corner of the province, on the borders of Russia and Austria extending across into Galicia and Russian Poland. The mines are at Miechowitz, Beuthen, Scharly, and Dombrowka. The mining is said to date from the sixteenth century. There are deposits in Saxony in the mining region of the Erzegebirge, at Altenberg, Schneeberg, etc. In the Harz Mountains there are deposits at the Clausthal Plateau, Rammelsberg, and at St. Andreasberg. There are the deposits of Ems, and Holzappel in the Lahn Valley, Nassau ; in Westphalia there are deposits near Coblenz, Armsberg, Gladbach, Dusseldorf, Iserlohn, and Brilon. Near Aix-la- Chapelle there are deposits at Commern, and Mechernich. The gypsum beds of Bavaria and Würtemberg contain galena ; also the Voltzia sandstone of Rheinish Prussia and Lorraine ; the assemblage of veins of the Kinzig Valley, the Black Forest, Baden ; and the beds at Munsterthal, and at Wiesloch. The chief deposits of *France* are situated in the meta- morphic and igneous rocks of Auvergne principally in the departments of Puy-de-Dôme, Cantal, and Haute-Loire ; and southwards in the departments of Gard, Lozere, and Lot. The chief mining localities are Malines, Bleymard, Vialas, and Planioles. The lead ores of the Pyrénées, occur in the departments of Ariège, Hautes Pyrénées, and Basses Pyrénées ; and mines at Boulard de Sentein St. Lary, and Girons. There are lodes in the department of Var, Provence ; and in *Brittany* the most important mine is at Pontpéan, Rennes, in the department of Ille-et-Vilaine. There are lodes near Oporto, *Portugal*. Formerly *Spain* was the largest producer in Europe, and ranked second to the United States in the world's production. The chief deposits are near Linares, in the Sierra Morena, and at Ciudad Real ; in the south-east of Province of Murcia, about Carthagena, etc. There are lodes north of Almeria, South Spain ; and at Guadalajara, Central Spain. The chief deposits in *Italy* are in Sardinia—Iglesais, Montevecchio, Monte- poni, Malafatano, etc. It is said that the Romans worked lead-mines in Sardinia which had been opened up by the Phœnicians, and worked by the Carthaginians. In the Cam- piglia Marittima district of Tuscany the lodes are mined at Bottino. There are many lead and zinc veins near Trent, Pfundererberg, and other places in the Tyrol. The silver- lead mines of the Laurium, *Greece*, were worked before 560 B.C., and flourished one hundred years later ; they were supposed to have been worked out by the beginning of our era, but were re-opened in 1863. Argentiferous ores have long been worked in the islands of Milos, Pharos, and Santorin in the Ægean Sea. The volcanic rocks of the Carpathian Mountains, *Hungary*, have mines dating from the eleventh century or earlier. The chief mining districts are those of Schemnitz-Kremnitz, Nagybunya-Felsobanya-Kapnik, and the Transylvanian Erzegebirge. The deposits of *Poland* at Boleslaw, Szakowa, Trzebinia and Olkusz are an extension of those in Upper Silesia. The deposits in *Yugo-Slavia* are represented by mines at Cerveni Brey, Kosmaj, and Babe in Serbia ; in Bosnia ; and at

Laibach in Carniola. In *Russia*, lead ores have been mined in the Caucasus and in Siberia. In *Norway*, lead ores occur near Vefsen and other places; and in *Sweden*, at Sala, Ammeberg, etc.

The occurrence of lead ore in **Asia.** The principal argentiferous lead mines in *Asia Minor* are those of Balia-Karaidin in Brusa, and Bulgar-Maden in Konia of Anatolia. There are veins about Karahussa, Swas; Bulgar-Dagh, Konia; Arden near Sokia; Angora; at Karalar, Kastamuni; and Keban Maden, Mamuret. In *India*, there are many deposits of galena. Those at Bawdwin, Upper Burma, are being worked on a big scale. From 1910–1916, a large quantity of slag worked by the old Chinese was treated for lead. The largest mine in *China* is that of Shui-ko-shan, in the Hunan Province, Central China. According to A. S. Wheler and S. Y. Li,[4] these mines had been worked spasmodically by the Chinese for the past three hundred years before being taken over by a European company in 1902. There are other mines in the same province at Kianghua, Pinghsien, Liangsiang, Kueiyang, Liling, Lingwu, Liuyang, Hengyang, Suikouling, and Chowkiagang. There are also mines in the province of Chi-li. In *Indo-China* there are lead ores in Annam and Tonkin—Bong-Mieu, Quan-Son, Moa-Ha, Trang-Da, Lang-Hit, and Pia-Ka. In *Japan* there is an important deposit at Kamioka, in the province of Hida, at Akita on the Island of Sado, and near Tokyo.

The occurrence of lead ores in **Africa.** In *Egypt*, the ancient mines at Gebel Rosas were reopened by a European company in 1913. Lead ores occur in Jebel Kutum in the Soudan. Lead is mined in several places in *Algeria*, notably at Oued Moziz. There are also important deposits in *Tunis*. In *Nigeria* lead and zinc ores occur in the Abakaliki district. A lode at Alusi Hill, Ifotta, has been worked by the natives. There are deposits at Broken Hill, North-Western *Rhodesia*. In the *South-West Protectorate*, lead ores have been mined in the Otavi Mountains. In the *Union of South Africa* there are pockets of galena in the dolomite rocks of the Transvaal in the Malmani district; at Leeuwkloof, Broederstroom, Dwarfontein, and Roodekrans in the Pretoria district, and at Rhenosterhoek, Witkop, Bokkraal, Buffelshoek, Rietspruit, and Doornhoek, in the Marico district; and Windhuk, in the Pietersburg district. There is a vein of lead ore at Argent, and others in Northern Transvaal, Gordonia, and Potgietersrust. In Cape Province there are deposits near Port Elizabeth; Banghoek; Knysna; Richmond in the Beaufort West, Victoria West, and Van Rhysndorp districts. Deposits are known in Bechuanaland, Damaraland, and in the Caledon and Swellendam districts. In Natal, galena has been found at Umsingi, in Umvoli Country; and in the Mfongosi and Ngobeon Valleys, Zululand.[5]

The occurrence of lead ore in **America.** In the *British West Indies* and in *British Guiana*, there are lead ores which have been worked on a very small scale. Large quantities are mined in Mexico—Sierra Madre, Sierra Mojada, Zimapan, Santa Barbara, Cuatro Cienegas, Santa Eulalia, and Michoacan. The *United States* is the world's largest producer. The Mississippi Valley deposits include : (i) the south-eastern district of Missouri—Potosi, Palmer, Valle, etc. (ii) South-western Missouri, including neighbouring portions of Kansas and Oklahoma or the Joplin district—Aurora, Granby, Webb City, Alba, Neck, Joplin, Galena, Badger, Quapaw, and Miami; and (iii) the Upper Mississippi Valley, including the Wisconsin, Iowa, and Illinois districts—Mineral Point, Platteville, Dubuque, etc. The Atlantic coast deposits include the deposits near Rossie, Guymard, Ellenville, Wurtsboro, and in Wythe Co., Virginia; in New England, North Carolina, and Tennessee. The Rocky Mountains and Pacific Slope deposits—in Arizona—Mowry, Eureka, Castle Dome, Tombstone, and the Hualpai district; in California—Cerro Gordo, Inyo Co., and the Darwin district; in Colorado—Leadville, Aspen, Monarch, Redcliff, Ten Mile, Silver Cliff, and San Juan; in Idaho—Cœur d'Alene, Bunker Hill, Sullivan, Standard-Mammoth, Morning, Hercules, Minnie Moore, Crœsus, Bullion, Red Elephant, and Red Cloud; in Montana—Alta, Elkhorn, etc.; in Nevada—Eureka, Pioche, Yellow Pine, and Cherry Creek; in New Mexico—Magdalena Mine, and the Grant and Cook districts; in Maine[6]— Portland; in Utah—Salt Lake City, Bingham, Park City, Tintic, and Frisco districts, and in Beaver Co. There are several important deposits of lead in *Canada*.[7] In British Columbia— Slocan, East Kootenay, Ainsworth, and the Nelson districts, and in the Yukon territory. In Ontario there are several occurrences in Frontenac Co., and Hastings Co., and near Sault Sainte Marie. In Quebec—Notre-Dame-des-Anges in Portneuf Co., and on Calumet Island, Pontiac Co. In Nova Scotia deposits have been located in Inverness Co. Lead ores have been found in several places in Newfoundland. In Central America there is a small production of lead ore near Guatemala. In South America, *Peru* produces a few thousand tons per annum; there are small quantities of argentiferous galena in the Colquechaca district, *Bolivia;* about 100 or 200 tons of ore are produced per annum in *Chile ;* and in the *Argentine* Andes, there are extensive deposits of galena.

The occurrence of lead ore in **Australasia.** Australia is the largest producer of lead ore in the British Empire. In *New South Wales*, the famous deposit at Broken Hill, discovered in 1883, was first worked for silver, then for silver and lead, and later largely for zinc. In *Queensland*, there are several groups of claims in the Barketown district, and in the Eungella Goldfield. No important deposits have been discovered in *South Australia*, and the occurrences in *Victoria* have not been worked. The chief occurrences in *West Australia* are in the Northampton district. There are several important deposits

in *Tasmania*. The chief deposits are in the Mount Read and Rosebery areas. There are also important deposits in the Zeehan district, the Dundas region, and the Waratah district. In *New Zealand*, lead ores occur in the Hauraki Peninsula.

The World's production [8] of lead in metric tons is :

1867	1877	1887	1897	1907	1917	1924
157,885	322,910	564,194	721,167	1,011,397	1,107,153	1,302,000

The production in 1924, in the different countries is :

Australia	. . . . .	12,843	Italy	21,706
Austria	. . . . .	4,904	Japan	2,500
Belgium	. . . . .	(64,624)	Mexico	132,000
India	. . . . .	51,759	Rhodesia, etc.	6,631
Canada	. . . . .	74,500	Spain	139,569
France	. . . . .	20,500	Sweden and Norway . .	1,208
Germany	. . . . .	49,000	United Kingdom . .	5,303
Greece	. . . . .	5,000	United States	561,058
Czechoslovakia	. . . .	2,229	Tunis	15,483
Jugoslavia	. . . .	11,300	Argentina	8,000
Turkey	. . . .	5,100	Rumania	139,569

For China, the production in 1924 was 1116 metric tons. The extreme prices of soft foreign lead in 1917 were £29 10s. and £30 10s. per ton ; and in 1921, £16 10s. and £26 per ton.

Lead occurs in nature rarely in the metallic form, and when it does, it is always on a secondary formation, having been reduced from some pre-existing lead compound. Many of the reputed occurrences are doubtful. J. J. Nöggerath,[9] in his *Ueber gediegen Blei natürliche Bleiglatte und Mennige*, made a critical study of the evidence. In 1750, J. G. Wallerius mentioned the occurrence of *plumbum nativum*, both massive—*plumbum nativum sodidum*—and granular—*plumbum nativum in granulis*. J. B. L. Romé de l'Isle considered the evidence somewhat problematic ; L. A. Emmerling, and A. Breithaupt also doubted the occurrence ; while A. G. Werner, and A. Estner did not mention it. R. J. Haüy obtained a specimen of native lead from some lava on Madeira, and he called it *plomb natif volcanique amorphe*. J. F. L. Hausmann considered this the only reliable evidence of the occurrence of native lead, but P. A. Dufrénoy regarded the Madeira lead as doubtful, and believed the only reliable find to be that reported by W. Haidinger at Alston Moor, Cumberland. Concerning this, R. P. Greg and W. G. Lettsom say that the Romans worked lead ore in this locality. Other reputed finds in England and Ireland are mentioned by T. Austin, and H. J. Brooke and W. H. Miller. J. J. Nöggerath considered an occurrence reported at Vera Cruz, Mexico, to be satisfactory, but J. D. Dana considered it to be doubtful. The Mexican finds were also considered by G. A. Stein, A. Breithaupt, R. P. Greg and W. G. Lettsom, and J. L. Comte de Bournon. L. J. Igelström described eight occurrences of metallic lead at Pajsberg, Sweden.

The occurrence of metallic lead in Sweden, in addition to those mentioned above, include deposits at Harstigen, Langban, Oerebro, and Sjögrufvan, described by L. J. Igelström, A. Hamberg, G. Flink, and A. W. Tamm. The occurrence of metallic lead in France was discussed by M. de Gensanne and C. Coquebert ; in Italy, by J. J. Nöggerath ; in Hungary, by S. R. I. E. à Born ; in Poland, by J. G. Wallerius ; in Carinthia, by J. G. Wallerius ; in Spain, by J. C. Ullmann, A. Orio, and C. C. von Leonhard ; in Stavonia and Siebenbürgen, by G. Zerrenner ; in Moravia, by C. F. von Reichenbach ; in Bohemia, by S. R. I. E. à Born ; in Silesia, by L. D. Hermann, G. A. Volkmann, J. G. Lehmann, C. C. Bienert, and H. R. Göppert ; in Saxony, by G. Jenzsch ; in Hesse, by G. Gautieri and J. Schaub ; in the Urals, by P. von Jeremejeff, A. Erman, M. von Tscheffkin, G. Zerrenner, N von Kokscharoff, E. S. von Fedoroff, J. J. Nöggerath, O. von Hingenau, and C. C. von Leonhard ; in Dutch East Indies, by R. Ewerwijn ; in Burma, by F. R. Mallet ; in Australia, by A. Liversidge, G. H. F. Ulrich, and W. F. Petterd ; in Chile, by E. Cohen, and R. P. Greg ; in New Zealand, by J. Park ; in Peru, by A. Raimondi, and I. Domeyko ; in Mexico, by C. W. Kempton ; in the United States, Colorado, by J. D. Dana, and R. N. Clark ; Idaho, by W. P. Blake ; Montana, by F. A. Genth ; North Carolina, by F. A. Genth ; New Jersey, by W. M. Foote, S. L. Penfield, and C. W. Kempton ; and New York, by J. D. Dana ; and in Canada, by E. J. Chapman.

The following list includes most of the plumbiferous minerals. Galena, cerussite, anglesite, plumbojarosite, and mimetesite, are of interest as sources of lead. The other minerals may be useful as sources of other elements, but, owing to their sparsity or to their unsuitability for metallurgical purposes, not as sources of lead. Many can be regarded only as mineralogical curiosities.

The **oxides**: Corodanite, $(Pb,Mn'')Mn_3O_7$; hydroplumbite, $3PbO.H_2O$; mennige, Pb_3O_4; miriquidite, $PbO.Fe_2O_3.As_2O_5.P_2O_5.H_2O$; nivenite, $UO_2.UO_3.PbO.ThO_2$, with iodates; phœnicite, $Pb_3Cr_2O_9$; plumboferrite, $(PbO,FeO,CuO)Fe_2O_3$; and uraninite, $(U,Pb)_3(UO_6)_2$; curite, $PbO.5UO_3.4H_2O$; pilbarite, $PbO.UO_3.ThO_2.2SiO_2.2H_2O$; dewindtite, $4PbO.8UO_3.3Pb_2O_5.12H_2O$; plumbocolumbite, a complex plumbiferous mineral, $R''_2Cb_2O_7.R'''(Cb_2O_7)_3$, where $R''_2=Pb$, UO, Fe, or Cu, and $R'''_4=Al$ and rare earth metals. The **chlorides, oxychlorides, and chlorocarbonates**: Phosgenite, or cromfordite, $PbCl_2.PbCO_3$; boleite, $3\{Pb(OH)Cl.Cu(OH)Cl\}AgCl$; chubutite, $Pb_{16}O_{14}Cl_4$; lauriorite, $Pb(OH)Cl$; lorettoite, $Pb_{15}O_{13}Cl_4$; matlockite, Pb_5OCl_2; mendipite, $Pb_2O_4Cl_2$; pseudomendipite, $Pb_5O_6Cl_4$; mimetesite, $Pb_5Cl(AsO_4)_3$; nadorite, $PbClSbO_2$; ochrolite, $Pb_2Cl_4Sb_2O_7$; paralaurionite, $Pb(OH)Cl$; penfieldite, $PbO.2PbCl_2$; percylite, $PbOH.CuOH.Cl$; polysphaerite, $(Ca,Pb)Cl(PO_4)_3$; pseudoboleite, $5PbCl_2.4CuO.6H_2O$; pseudocotunnite, $2KCl.PbCl_2$; rafaelite, $Pb(OH)Cl$; and schwartzembergite, $Pb_3O_2(I,Cl)_2$. The **sulphides, and oxysulphides**: **selenides**, and **tellurides**: Alaskaite, $Bi_2S_3.(Cu_2,Ag_2,Pb)S$; alisonite, $PbS.3Cu_3S$; baumhauerite, $4PbS.3As_2S_3$; beegerite, $Pb_6Bi_2S_9$; bismuthplagionite, $5PbS.4Bi_2S_3$; bjelkite, $Bi_2Pb_2S_5$; nagyagite, $Pb_{10}Au_2Sb_2Te_6S_{15}$ (variable); zinkenite, $PbSb_2S_4$; bismuthoplagionite, $Pb_5Bi_8S_{17}$; galena, PbS; boulangerite, $Pb_5Sb_8S_{11}$; bournonite, $Pb_2Cu_2Sb_2S_6$; brongniartite, $2(Pb,Ag_2)S.Sb_2S_3$; chiviatite, $2PbS.3Bi_2S_3$; cosalite, $2PbS.Bi_2S_3$; domingite, $3PbS.2Sb_2S_3$; dufrenoysite, $Pb_2As_2S_5$; dürfeldite, $3(Pb,Ag_2)S.Sb_2S_3$; embrithite, $Pb_3Sb_2S_6$ or $Pb_{10}Sb_6S_{19}$; epiboulangerite, $Pb_3Sb_2S_6$; teallite, $PbSnS_2$; cylindrite, $3PbSnS_2+SnFeSb_2S_5$; franckeite, $Sn_2Pb_5Sb_2S_{12}$, or $3PbSnS_2+PbFeSb_2S_6$; galenobismuthite, $PbBi_2S_4$; geocronite, $Pb_5Sb_2S_8$; guitermanite, $10PbS.3As_2S_3$; heteromorphite, $Pb_7Sb_8S_{19}$; hutchinsonite, $PbS.As_2O_4$ with $(Tl,Cu,Ag)_2S.As_2S_3$; jamesonite, $Pb_4Sb_2S_5$; jordanite, $Pb_4Sb_2S_7$; kilbrickenite, $Pb_6Sb_2S_9$; kobellite, $2PbS.(Bi,Sb)_2S_3$; cuproplumbite, $2PbS.Cu_2S$; lengenbachite, $6PbS(Cu,Ag)_2S.2As_2S_3$; lillianite, $Pb_3Bi_2S_6$; aikinite, $PbCuBiS_3$; liveingite, $Pb_5As_8S_{17}$; meneghinite, $Pb_4Sb_2S_7$; mullanite, $5PbS.Sb_2S_3$; plagionite, $Pb_5Sb_8S_{17}$; plumbostannite, $Pb_2(Fe,Zn)_2Sn_2Sb_2S_{11}$; plumosite, $Pb_2Sb_2S_5$; plumbostibnite, $Pb_3Sb_2S_6$, see boulangerite; plumbobismuth glance, $Pb_2Bi_2S_5$; polytelite, $(Pb,Ag_2)_4Sb_2S_7$ with $(Zn,Fe)_4Sb_2S_7$; quirogite, $Pb_{23}Sb_6S_{32}$; rathite, or wiltshireite, $3PbS.2As_2S_3$; rezbanyite, $Pb_4Bi_{10}S_{19}$; sartorite, $PbAs_2S_4$; schapbachite, $(Pb,Ag_2)_2Bi_2S_5$; freieslebenite, $(Pb,Ag_2)_2Sb_4S_{11}$; schirmerite, $(Pb,Ag_2)_3Bi_4S_9$; seligmannite, $3(Pb,Cu_2)S.As_2S_3$; semseyite, $Pb_7Sb_8S_{16}$; teallite, $PbSnS_2$; tinder ore, or Zundererz, $Pb_7Sb_8S_{19}$; weibullite, $2PbS.Bi_4S_8Se_3$; clausthalite, PbSe; zorgite, $(Pb,Cu_2)Se$; kerstenite, $PbSeO_4$; lehrbachite, HgSe with $(Pb,Cu_2)Se$; and altaite, PbTe. The **sulphates**: Caledonite, $(Pb,Cu)_2(SO_4)2CO_3$; caracolite, $Na_2Pb(OH)SO_4Cl$; hinsdalite, $3Al_2O_3.2PbO.2SO_3.P_2O_5.6H_2O$; johnstonite, mixture PbS, PbSO_4, and S; lanarkite, Pb_2SO_5; leadhillite, or susannite, $4PbSO_4.2CO_2.H_2O$; linarite, $(Pb,Cu)(OH)_2.(Pb,Cu)SO_4$; palmierite, $K_4Na_2Pb_4(SO_4)_7$; anglesite, $PbSO_4$; and plumbojarosite, $PbFe_6(OH)_{12}(SO_4)_4$. The **carbonates**: Beresowite, $2PbO.PbCO_3.3PbCrO_4$; cerussite, $PbCO_3$; hydrocerussite, $Pb\{(PbOH)_2CO_3\}_2$; iglesiasite isomorphous mixtures of lead and zinc carbonates, plumbonacrite, $2PbO.Pb(OH)_2.PbCO_3$; and roeblingite, $5CaH_2SiO_4.2(Pb,Ca)SO_4$. The **phosphates, arsenates, antimonates, bismuthates,** and **vanadates**: Araeoxene, $(Zn,Pb)_3(V,As)_2O_8$; arsenomelane, $2PbS.As_2O_3$; bayldonite, $(Cu,Pb)AsO_4.CuOH.\frac{1}{2}H_2O$; beudantite, $(AsO_4)(SO_4)Pb\{Fe(OH)_2\}_3$; bindheimite, or bleinière, $PbO.Sb_2O_5.H_2O$; brackebuschite, $(Cu,Pb,Fe,Zn,Mn)_8V_2O_8.H_2O$; cuprodescloizite, $(PbOH)(Pb,Cu,Zn)VO_4$; dechenite, $Pb(VO_3)_2$; descloizite, $(PbOH)(Pb,Zn)VO_4$, and the related pyrobelonite; ecdemite, or ekedemite, $2PbCl_2.Pb_3As_2O_7$; endlichite, $Pb_5Cl\{(As,V)O_4\}_3$; eusynchite, $(Pb,Zn)(VO_4)_2$; ferrazite, $3(Pb,Ba)O.2P_2O_5.8H_2O$; hedyphane, $(Pb,Ca,Ba)Cl(AsO_4)$; hügelite, zinc lead vanadate; kampylite, $Pb_5Cl\{(As,P)O_4\}_3$; carminite, $Pb_2(AsO_4)_2.10FeAsO_4$; karyinite or caryinite, $(Na_2,Ca,Mg,Mn,Pb)_3(AsO_4)_2$; lossenite, $9Pb(FeOH)(AsO_4)_6SO_4.12H_2O$; mimetesite, $PbCl_2.3Pb_3(AsO_4)_2$; mottramite, $5(Pb,Cu)O.V_2O_5.2H_2O$; parsonsite, $2PbO.P_2O_5.UO_2.H_2O$; pyrobenolite, $7MnO.4PbO.2V_2O_5.3H_2O$; stasite, $4PbO.3P_2O_5.8UO_3.12H_2O$; trigonite, $Pb_3MnH(AsO_3)_3$; and vanadinite, $Pb(VO_3)_2$ or $PbCl_2.3Pb_3(VO_4)_2$. The **chromates, molybdates, tungstates,** and **uranates**: Beresowite or beresovite, $Pb_2.2PbO.3CrO_4.CO_3$; chillagite, $Pb(W,Mo)O_4$; wulfenite, $PbMoO_4$; phœnicite, $Pb_3Cr_2O_9$; crocoite, $PbCrO_4$; curite, and dewindite —vide supra, oxides; stolzite, or raspite, $PbWO_4$; and vauquelinite, $2(Pb,Cu)CrO_4.(Pb,Cu)_3(PO_4)_2$. The plumbiferous **silicates** are: Alamosite, $PbSiO_3$; barysilite, $Pb_3Si_2O_7$; ganomalite, $Ca_4Pb_4(PbOH)_2(Si_2O_7)_3$; gummite, $(Pb,Ca,Ba)SiCl_2O_{12}.5H_2O$; hancockite, $(Ca,Pb)_4(Al,Fe)_5H_2Si_8O_{26}$; hyalotekite, barium calcium lead silicate; kasolite, $3PbO.3SiO_2.3UO_3.4H_2O$; kentrolite, $Mn_4Pb_3Si_3O_{15}$; melanotekite, $Pb_3Fe_2Si_3O_{15}$; margarosanite, $PbCa_2Si_3O_9$; molybdophyllite, $PbMgSiO_4.H_2O$; and nasonite, $Ca_4Pb_6Cl_2(Si_2O_7)_3$.

Lead occurs as a more or less accidental impurity in many minerals. C.W. Cross,[10]

W. H. Emmons, R. N. Clark, B. Lotti, J. Strischoff, P. L. Burthe, and A. W. Stelzner and A. Bergeat found it in some auriferous and other alluvial sands ; A. Raimondi, A. d'Achiardi, M. Fort, and A. W. Stelzner and A. Bergeat, in silver ores, and in copper ores ; K. Nenadkewitsch, in zinc ores ; R. Krzizan, in limestone, also in the Jura bone-earths ; H. Lange, in a red fluorspar from Greenland ; A. Piutti and E. Stoppani, and D. Playfair, in pyrites ; A. Lacroix, and F. Zambonini in Vesuvian fumaroles as lead sulphide, and A. Scacchi, in Vesuvian lavas as lead sulphate and basic chloride. The occurrence of lead in uranium minerals was discussed by A. Becker and P. Jannasch, A. L. Davis, M. Muguet, etc.—*vide infra*.

There are reports of *waters* containing plumbiferous salts. Thus, P. Laur, J. A. Phillips, C. F. Becker, and A. W. Stelzner and A. Bergeat, found lead in the sinter from the hot springs of California ; F. A. Quenstedt, in the ochre from a spring at Cannstatt, Stuttgart ; L. Darapsky, in the calcareous tuff of the spring at Cachapoal, Chile ; R. Fresenius, in the spring at Pyrmont ; F. Garrigou, in the springs of Beaucens ; E. Carstens, 0·000011 grm. PbO per litre in the spring-water at Alexandro-Jormoloff, Caucasus ; W. F. Hillebrand, Joplin, Missouri ; L. Dede, in the sinter at Nauheimer Sprudels ; A. Daubrée, and J. Roth, in a spring at Vichy ; and F. J. Malaguti and co-workers, in sea-water.

The ashes of *grasses*, etc., growing on plumbiferous soils were found by E. Lidgey,[11] R. Beck, and G. Hattensaus to contain lead ; and F. Malaguti and co-workers found lead in the ash of some *sea-weeds*. A. Devergie, M. J. B. Orfila, J. Barse, and A. Chevallier regarded lead as normally present in the internal organs of *man*. V. Legrip said that the ash of the liver and milk of human beings contains 0·0818 per cent. of lead ; and the ash of various organs of a cow, 0·0367 per cent. E. Heubel reported 0·18–0·27 part lead in 1000 parts of bone ; 0·17–0·20 in kidneys ; 0·10–0·33 in the liver ; 0·06–0·11 in the spinal cord ; 0·04–0·05 in the brain ; 0·02–0·04 in the muscles ; 0·01–0·02 in the intestines ; and only traces in the spleen, blood, and bile. H. Oidtmann reported 1 mgrm. per kgrm. in the liver of a man fifty-six years of age, and 3 mgrms. per kgrm. in the spleen. N. A. E. Millon also found lead in the blood of soldiers whose food was cooked in metal vessels. A. Béchamp, L. H. F. Melsens, E. Cottereau, and B. du Buisson found no lead in blood ; and H. W. F. Wackenroder said that the presence of a trace of lead in blood is an accidental circumstance, for the lead is derived from contaminated food. E. Heubel found in a dog killed by chronic lead-poisoning 0·018–0·027 per cent. of lead—in the kidneys, 0·017–0·020 ; in the liver, 0·010–0·033 ; spinal cord, 0·006–0·011 ; brain, 0·004–0·005 ; muscles, 0·002–0·004 ; intestine, 0·001–0·002 ; and traces in the spleen, blood, and bile. The presence of lead in the organs of lead-workers, and of *animals* and man poisoned with lead, has been discussed by A. W. Blyth, E. Brumpt, W. Ebstein, W. Ellenberger and V. Hofmeister, H. Greven, L. Hugounenq, H. Oidtmann, H. Legrand and L. Winter, V. Lehmann, L. G. Maillard, A. Marie and P. Requier, G. Meillère, F. Shufflebotham and J. W. Mellor, C. Oppenheimer, K. Stockmann and F. J. Charteris, etc. The general results show that lead is not a natural constituent of the body, but it may be found in healthy persons who have been quite free from symptoms of lead-poisoning. A. Thiergardt found 0·0031–0·0557 per cent. of lead in *fish* poisoned by water containing a soluble lead salt ; and T. W. Hogg found 0·35–0·52 per cent. of lead in the bodies of earth *worms* which lived in the plumbiferous *débris* of a white-lead works.

Lead occurs normally in many industrial products—alloys, enamels, glazes, glasses, paints, etc. J. Boes [12] indicated its presence in rubber goods, where it was used to accelerate vulcanization ; K. Endell, A. Micault, P. Carles, J. Grünwald, G. Giusti, N. P. Marasneff, etc., in the glazes and enamels of cooking vessels ; O. Megger and K. Fuchs, in dolls' tea-services ; and H. Stockmeier, in children's tin soldiers ; A. Vogel, and A. Seyda, lead in tin-foil ; A. Barillé, in the tin fittings of mineral water syphons ; F. M. Litterscheid, in the tinning of copper vessels ; E. Junker, and K. Neukam in preparations—tooth-pastes, etc.—in

metal tubes ; C. H. la Wall, and W. D. Collins and W. F. Clarke, in the zinc oxide of commerce ; S. de Luca, in the platinum sparking tips ; O. F. Lubatti, in cassia oil, E. Rieter, in stearin ; N. T. Fox, in calcium phosphate ; A. Vogel, in red wafers ; A. Classen, A. Carnot, and A. Hilger, in bismuth preparations ; E. Schering, in potassium iodide ; A. Geheel, in formic acid ; E. Klingelhöffer, and R. R. Tatlock and R. T. Thomson, in tartaric and citric acids ; W. Wicke, in filter-paper ; and H. Lührig, and R. Weber, in transfers.

Lead was also reported by A. R. Leeds,[13] R. Roth, A. Cutolo, L. Stefanowicz, M. Klostermann and K. Scholta, E. Spaeth, P. Carles, F. Wirthle and K. Amberger, and P. Schindler, in foodstuffs which had been contained in tinned vessels ; J. A. F. Ballard also found it in extract of meat ; A. F. Canelli, and H. Baum and R. Seeliger, in milk ; H. Roos, beet-sugar ; G. Sonntag, F. Muttelet and F. Touplain, L. Moreau and E. Vinet, L. Nathan and A. Schmidt, A. Hubert and F. Alba, and F. H. Storer, wines, yeast, and beer ; and A. Stadler, in snuff.

§ 3. The Extraction of Lead

Copper and gold and iron were discovered and at the same time weighty silver and the substance of lead when fire with its heat had burnt up vast forests on the great hills, . . . and had thoroughly baked the earth, there would collect in the hollows of the ground a stream of silver and gold as well as of copper and lead.—*Lucretius* (5. 1241).

The available lead ores are divided into *sulphide ores* which include galena generally mixed with more or less pyrites and other sulphides ; and *oxidized ores* which include the carbonates, anglesite, and pyromorphite. They all contain silver, and when that element is present in amounts sufficient to pay for its extraction they are designated *argentiferous*, and if in less quantity, *non-argentiferous*. During the smelting of the ore, the silver follows the lead, although a small proportion may remain with the slag, or in a regulus or speise which accompanies the reduced lead. The lead is usually desilverized to recover the silver. There are many monographs, etc., on the different phases of the metallurgy of lead.[1]

The lead content of the ore as mined varies within wide limits, being upwards of about 5 per cent. Occasionally the sulphide ores are so free from extraneous matters that a preliminary dressing or concentration is unnecessary ; usually, the sulphide ore is crushed and concentrated on jigs and buddles so as to yield a concentrate containing over 70–85 per cent. of lead. J. Percy showed that it is not necessarily true that the fine-grained galenas are richer in silver than the coarse-grained ore ; the more complex sulphide ores, however, are usually richer in silver than simple galena ore. Particular attention is paid to the silver content of the slimes because with some ores the associated argentiferous mineral may be more brittle and more easily crushed than the galena and so accumulate in the slimes. F. Clark discussed the concentration of lead ores by flotation.

When the ore is associated with much zinc blende, the concentration is difficult. At Broken Hill, New South Wales, the ordinary process of concentration is supplemented by the flotation process so as to procure the zinc blende free from

objectionable lead, and the galena free from the objectionable zinc. E. W. Mayer and R. Schön[2] have described the flotation process at Steiermark. The concentration of oxidized ores is more difficult because of the losses of lead and silver with the slime. These ores are usually smelted as they come direct from the mine.

Lead is usually extracted from its ores by dry processes ; the wet processes are more elaborate and their cost too high for successful competition with the dry processes. Lead ores are usually so easily smelted by ordinary furnace methods that the many wet processes which have been suggested have no chance of success. In exceptional cases, lead may be economically extracted from plumbiferous residues by wet processes. Electrolytic methods are not employed in the treatment of the ores, though they may be used to some extent when dealing with certain alloys.

In the first century B.C., the poet Lucretius speculated how lead and other metals were discovered by man. According to R. H. Lamborn, the early settlers in Missouri made lead for their bullets by smelting pieces of galena in a fire built in the hollow of a tree stump. The allusions in Strabo's *Geographica* (**3.** 2), and in Pliny's *Historia naturalis* (**34.** 22), to the ancient lead furnaces give very little information. A reference in Jeremiah (**6.** 29) shows that bellows were probably used in smelting lead. The primitive smelting of lead in Britain appears to have been done in wind-furances—*boles*—built in a favourable position with respect to the prevailing winds. Thus, J. Childrey[3] said :

The lead-stones in the Peak lye but just within the ground next to the upper crust of the earth. They melt the lead upon the top of the hills that lye open to the west ; making their fires to melt it as soon as the west wind begins to blow ; which wind by long experience they find holds longest of all others.

R. Watson described the *boles* of Derbyshire where lead was smelted in former times ; J. Farey gave a list of the sites of the ancient boles ; and A. Barba described similar furnaces used by the Peruvians. W. Forster said that the boles were simply piles of stone placed around a fire and arranged to leave openings for the admission of air and the escape of gaseous products of combustion. These were supplanted by hearth-furnaces built on the plan of a smith's forge as described by J. Martyn, and J. Glanvil. In 1678, G. L. Grandison obtained a patent for the use of coal in place of wood for smelting lead in reverberatory furnaces ; and J. Hodges, a patent for a similar purpose in 1690. J. J. Becher claimed to have introduced coal as a fuel for smelting tin ores in Cornwall, but J. Percy doubted the validity of the claim. According to C. A. Schlüter, the reverberatory furnace for melting lead was invented by a Mr. Wright in co-operation with two others. A. Barba in 1640 described a *hornos de reberberacion* or reverberatory furnace for roasting ores using wood as a fuel. According to J. Farey, cupola, or low-arched reverberatory furnaces were used at Kalstedge, Derbyshire, in 1747 ; and, according to A. P. Dufrénoy, at Alston, Northumberland, in 1810. These furnaces were very similar to those now in use.

The processes for smelting lead may be classified according to the type of furnace —reverberatory, hearth, or shaft furnace—or they may be classified according to the way the lead is obtained from the sulphide :

(1) In the so-called *air reduction process, or the roasting process*, the galena is roasted so as to form a mixture of the sulphide, sulphate, and oxide in approximately definite proportions, and when the temp. is raised, the lead sulphide reacts with the sulphate and oxide, forming sulphur dioxide and lead : $2PbS + PbSO_4 + 2PbO = 5Pb + 3SO_2$.

(2) In the *reduction process*, the galena is roasted until it is all converted into oxide admixed with a little sulphate which is then reduced to lead by carbonaceous matters. The sulphate is either converted into silicate by fusion with silica at the end of the roasting, and the silicate reduced to metal by subsequently smelting with carbon and iron oxide, or it can be reduced to the sulphide.

(3) In the so-called *iron reduction process*, or the *precipitation process*, the galena

is decomposed by heating it with metallic iron, lead is set free, and *lead matte,* a complex of iron and lead sulphides, is formed. The processes may not be kept entirely separate, but combined as when the residues from the first process are reduced with carbon or with iron ; or when the product of the second process is worked up by either of the other two.

Some chemical changes occurring during the reduction of lead sulphide.—Finely divided and precipitated lead sulphide was found by G. F. Rodwell[4] to absorb oxygen at 50°, and to smell of sulphur dioxide at 125°–150° According to E. F. Anthon, lead sulphide precipitated from a soln. of the nitrate by strontium sulphide, and dried between 40° and 50°, takes fire when nearly dry and continues to burn for about an hour, when it is all converted into lead sulphate. When lead sulphide is gently ignited in air, H. V. Collet-Descotils found that the greater part of the sulphur is given off as sulphur dioxide, while about half the contained lead separates as metal, and the remainder is converted into lead sulphate. This is a very curious reaction. F. Dempwolff found that when air is passed over lead sulphide, warmed in a boat at 250°, and not over 450°, almost all is converted into lead sulphate when the surface exposed is sufficiently great ; with a rising temp., the velocity of the reaction increases and likewise also the amount of sulphur dioxide evolved. Some sulphur trioxide is also given off, and at 750° the ratio of the $SO_2 : SO_3$ from the burnt sulphur is 65 : 35. A reaction between the lead oxide and sulphate then begins. The reaction was studied by F. Janda, P. Berthier, and J. B. Hannay. K. Friedrich found that galena resembles the precipitated sulphide in giving evidence of oxidation at a low temp., namely, 90°. The temp. at which galena begins to glow varies with the size of grain and rate of heating. For grains approximating 0·1–0·2 mm. diameter, the initial glow occurred at 847° when the temp. is raised slowly, and at 646° when the temp. is raised quickly from ordinary temp. The glow occurred at 554° when the mineral is put directly into a furnace at that temp. The product of the oxidation of galena in air is a mixture of lead oxide and sulphate. C. F. Rammelsberg supposed that the sulphide is directly oxidized to sulphate, $PbS+2O_2=PbSO_4$; it is, however, possible that during the roasting some of the sulphur dioxide given off is oxidized to sulphur trioxide and that this unites with the lead oxide, forming the sulphate. This agrees with the observation that the factors which favour the oxidation of sulphur dioxide increase the relative proportions of sulphate and oxide in the roasted mass. C. F. Plattner found that in the roasting of a sample of galena, the product contained 66·3 per cent. of oxide and 36·7 per cent. of sulphate, or twice as much oxide as sulphate.

When lead is extracted from galena by roasting in air, the process is not carried to completion ; for at a certain stage the temp. of the partially roasted ore is raised. A new set of reactions is inaugurated between the unaltered lead sulphide and its partially roasted products. The fundamental reactions involve the oxidation of galena to sulphate *viâ* the intermediate formation of sulphur trioxide as indicated above. These processes furnish the summation equation $PbS+2O_2=PbSO_4$. If two-fifths of the galena is converted to oxide : $2PbS+3O_2=2PbO+2SO_2$, the two products, lead oxide and sulphate, react with the unchanged galena, forming the metal $PbS+PbSO_4=2Pb+2SO_2$, and $PbS+2PbO=3Pb+SO_2$. H. C. Jenkins and E. A. Smith showed that these reactions are reversible, and this was established by the work of W. Reinders, and of R. Schenck and fellow-workers. When the conditions are such that sulphur dioxide is continuously removed, A. Lodin showed that these two reactions may be made quantitative ; such a condition is obtained by heating a mixture of the necessary amounts of sulphide and oxide or sulphide and sulphate in a stream of carbon dioxide or nitrogen. The conc. of the sulphur dioxide is thus negligibly small. C. O. Bannister gives 730°–745° for the temp. of the reaction between sulphide and sulphate, and A. Lodin gave 670° for $PbS+PbSO_4=2Pb+2SO_2$; 820° for $PbS+3PbSO_4=4PbO+4SO_2$; and 720° for $PbS+2PbO=3Pb+SO_2$, and C. O. Bannister gives 800°–810° for this reaction. The temp. in any particular case must naturally depend on the conditions. According to

J. W. Döbereiner, lead oxide and sulphide can be melted together without decomposition; but P. Berthier, and J. Percy have shown that the reaction proceeds as just indicated. If the litharge already has another metal sulphide in soln.—e.g. zinc or iron sulphide—the lead sulphide can be dissolved without decomposition. The summation of these equations furnishes: $PbS+O_2=Pb+SO_2$, which shows only the initial and end-products of the remarkable sequence of oxidizing and reducing reactions. In confirmation of the production of lead by a reaction between lead sulphide and oxide, P. Berthier found that lead is obtained by heating galena with strong oxidizing agents like potassium nitrate, or manganese dioxide. J. B. Hannay also obtained a 50 per cent. yield of lead by blowing air through molten galena. The reactions, however, are even more complex than is here indicated. There is no evidence of any appreciable reaction between lead and its sulphide or oxide, but P. Berthier, and J. Percy showed that at a fairly high temp., lead reacts with the sulphate $Pb+PbSO_4=2PbO+SO_2$, so that when this equation is combined with: $PbS+PbSO_4=2Pb+2SO_2$, there remains $PbS+3PbSO_4=4PbO+4SO_2$ to represent the end-products of this side-reaction. There is nothing to show that sulphur dioxide reacts with lead sulphide or sulphate, but when lead oxide is heated in the gas, C. F. Plattner said that it glows, forming lead sulphide and sulphate. D. L. Hammick found that the reaction occurs just below visible redness—400°–500°. This therefore reverses the reaction $Pb+PbSO_4=2PbO+SO_2$, and $PbS+3PbSO_4=4PbO+4SO_2$. Given the three components, lead, sulphur, and oxygen, there may be the gaseous phase, sulphur dioxide, as well as the solid phases lead, lead sulphate, lead sulphide, lead oxide, as well as the three basic sulphates, making three components, and seven possible phases; giving thirteen possible univariant systems each consisting of three solid phases in equilibrium with the gaseous phase. These form three groups. *Group I* has four systems in which lead sulphide is in equilibrium with solid phases containing oxygen: (1) $7PbSO_4+PbS\rightleftharpoons4Pb_2OSO_4+4SO_2$; (2) $10Pb_2OSO_4+PbS\rightleftharpoons7Pb_3O_2SO_4+4SO_2$; (3) $13Pb_3O_2SO_4+PbS\rightleftharpoons10Pb_4O_3SO_4+4SO_2$; and (4) $3Pb_4O_3SO_4+PbS\rightleftharpoons13PbO+4SO_2$. *Group II* has five systems in which lead and lead sulphide are in equilibrium with one solid phase containing oxygen: (5) $PbSO_4+PbS=2Pb+2SO_2$; (6) $2Pb_2OSO_4+3PbS\rightleftharpoons7Pb+5SO_2$; (7) $Pb_3O_2SO_4+2PbS\rightleftharpoons5Pb+3SO_2$; (8) $2Pb_4O_3SO_4+5PbS=13Pb+7SO_2$; and (9) $2PbO+PbS=3Pb+SO_2$. *Group III* has four systems with metallic lead and two solid phases containing oxygen: (10) $3PbSO_4+Pb\rightleftharpoons2Pb_2OSO_4+SO_2$; (11) $4Pb_2OSO_4+Pb\rightleftharpoons3Pb_3O_2SO_4+SO_2$; (12) $5Pb_3O_2SO_4+Pb\rightleftharpoons4Pb_4O_3SO_4+SO_2$; and (13) $Pb_4O_3SO_4+Pb\rightleftharpoons5PbO+SO_2$. The vap. press. of the systems in groups I and II have been investigated.

. For univariant equilibrium in a three component system, four phases are required, and one of these is the gas sulphur dioxide. Measurable equilibria were found to occur with some systems, and the press. of the gas was independent of the direction from which equilibrium was approached. For the system $PbS+PbSO_4\rightleftharpoons2Pb+2SO_2$, the reaction goes appreciably at 550° as shown by the evolution of sulphur dioxide, and measurable press. are attained at 600°.

	600°	615°	635°	665°	695°	713°	723°
Pressure SO_2 .	39	61	98	201	402	590	735 mm.

The sulphide and oxide begin to react: $PbS+2PbO\rightleftharpoons3Pb+SO_2$ at about 650°–660°, and provided the temp. does not exceed 800°, the reaction is reversible.

	692°	712°	733°	751°	776°	800°	824°
Pressure SO_2 .	6	14	23	39	60	99	276 mm

If the mixture of solids be heated to a higher temp., and then cooled, the press. of the sulphur dioxide does not return to its original value, but is much higher than those just indicated. This was traced to the formation of the basic sulphate

PbO.PbSO$_4$, and the system in equilibrium is represented by 2Pb$_2$OSO$_4$+3PbS ⇌7Pb+5SO$_2$, and the partial press. of the sulphur dioxide was :

	681°	716°	759°	780°	795°	821°	830°
Pressure SO$_2$.	16	42	130	217	306	548	710 mm.

These partial press. curves are plotted in Fig. 2 ; and there is also included in the same diagram observations by W. Reinders, and R. Schenck and A. Albers. The curve *Aa* refers to system (1) ; *Bb* to (2) ; *Cc* to (3) ; *Dd* to (4) ; *OA* to (5) ; *AB* to (6) ; *BC* to (7) ; *CD* to (8) ; and *De* to (9). At the invariant point *A*, 567°, the phases PbSO$_4$, Pb$_2$OSO$_4$, PbS, and Pb are in equilibrium with the gas phase ; at *B*, 706°, Pb$_2$OSO$_4$, Pb$_3$O$_2$SO$_4$, PbS, and Pb ; at *C*, 770°, Pb$_3$O$_2$SO$_4$, Pb$_4$O$_3$SO$_4$, PbS, and Pb ; and at *D*, 784°, Pb$_4$O$_3$SO$_4$, PbO, PbS, and Pb. Lead sulphide is a solid phase in all the zones, and in addition PbSO$_4$ in *OAa* ; Pb$_2$OSO$_4$ in *aABb* ; Pb$_3$O$_2$SO$_4$ in *bBCc* ; Pb$_4$O$_3$SO$_4$ in *cCDd* ; PbO in *dDe* ; and finally, below the line *OABCDe* there is metallic lead. The most stable phases are those in group II, where both lead and lead sulphide are present as solid phases, these

Fig. 2.—Partial Pressures of Sulphur Dioxide in Various Systems, PbO, PbS, PbSO$_4$, etc.

systems being in equilibrium with a lower press. of sulphur dioxide than those of group I. The vapour phase always contains lead sulphide. In systems of group III, where lead sulphide is not present as a solid phase, the vapour must be sat. with respect to lead sulphide. A diagram for group III must therefore be in three dimensions, one of which represents the vapour press. of lead sulphide. The systems of group III were found to be too unsuitable to realize experimentally. R. Schenck studied the action of sulphur dioxide on metallic lead in a closed vessel. The press. of the gas diminishes to a constant value representing the equilibrium of sulphate with sulphide and metal as in the field *OAa*, Fig. 2. The values 101 mm. at 653°, and 240 mm. at 690°, fall exactly on the sulphate curve. In all the above systems of equilibria, the metal phase is not really lead, but a soln. of lead sulphide in lead. If the metal is not sat. with sulphide, the system will be bivariant, not univariant, since the press. of the sulphur dioxide will depend on the conc. of the sulphide in the lead. W. Reinders investigated the ternary system with lead, sulphur, and oxygen as components by gradually removing sulphur dioxide from a mixture of lead sulphide and sulphate, and observed the five univariant systems : I. PbS ·PbSO$_4$– Pb$_2$OSO$_4$; II. Pb$_a$–PbS–Pb$_2$OSO$_4$; III. Pb$_b$–Pb$_2$OSO$_4$– Pb$_3$O$_2$SO$_4$; IV. Pb$_c$–Pb$_3$O$_2$SO$_4$–Pb$_4$O$_3$SO$_4$; and V. Pb$_d$–Pb$_4$O$_3$SO$_4$–PbO. The proportion of lead sulphide dissolved in the lead probably varies with the different equilibria, and the amounts are dia-

Fig. 3.—Equilibria in the Ternary Systems: Pb–S–O.

grammatically represented by the points *a*, *b*, *c*, *d*, Fig. 3. The diagram represents the regions corresponding with the five systems just indicated. K. Jänecke applied the phase rule to the roasting of the sulphide ore.

Carbon dioxide exerts a slight oxidizing action on galena, and A. Lodin found that at 860°, sulphur dioxide is formed, and lead remains—being formed, presumably, by the reaction between lead oxide and sulphide. The effect of carbon on the reduction of lead sulphate and sulphide was studied by P. Berthier, J. L. Gay Lussac, J. Fournet, etc. Galena may contain sulphides other than iron pyrites, and the sulphides of copper, silver, zinc, manganese, and bismuth, which are all oxidized during the roasting, and oxides or basic

sulphates are formed. Arsenic and antimony sulphides form volatile oxides. The products of the reactions of the roasting of these sulphides were considered by C. F. Plattner, G. Keppeler, D. L. Hammick, H. Schiff, W. Mostowisch, and J. Uhl. J. Percy, and C. F. Plattner studied the behaviour of the pyrites present during the roasting of galena, while C. O. Bannister studied the effect of silica ; ferric oxide ; calcium oxide, sulphate, hydroxide and carbonate ; magnesia ; and lead oxide. Silica and calcium sulphate were found to act as inactive diluents opening up the ore and allowing a freer penetration of the air ; ferric oxide reduced the temp. at which roasting begins by about 100°, and at the same time reduced the interval of temp. during which roasting is active. The proportion of lead sulphate in the product was augmented presumably by the catalytic oxidation of sulphur dioxide. Strongly basic oxides like litharge, magnesia, and lime cause exothermal reactions—due to the combination of the base with the sulphur oxide gases—evidenced by glowing, when the oxidation of the galena occurs between 500° and 550°; with calcium carbonate the effect is similar between 550° and 600°.

In T. Huntington and F. Heberlein's process of high temp. blast-roasting, a mixture of 6 to 15 parts of alkaline earth per 100 parts of ore, is heated to 700° in a reverberatory furnace with the free admission of air, and the temp. allowed to fall to about 500°, and not below 450°. The hot mass is transferred to converters where it is subjected to an air-blast and the temp. is raised ; sulphur dioxide is copiously evolved, and the mass becomes viscous as the reactions are completed. It is generally admitted that the mechanical effect of the lime is to prevent premature agglomeration of the charge, and, as emphasized by G. Rigg, to ventilate the ore so that there is a rapid circulation of air about the charge. J. Percy, however, showed that the action of lime is not exclusively mechanical, and is distinctly chemical. There are many differences of opinion as to the chemical actions involved. P. Berthier showed that calcium oxide and galena react when strongly heated, forming calcium sulphide and lead oxide. Some metallic lead, and a slag of sulphide and sulphate, are produced, making it probable that the lead oxide is reduced by lead or calcium sulphides with the formation of an equivalent quantity of sulphate. It has not been proved that reactions between calcium oxide and lead sulphate ; calcium sulphate and lead oxide ; calcium sulphide and lead sulphate ; or calcium sulphate and lead sulphide, if they occur at all, have any influence on the roasting process. T. Huntington and F. Heberlein assumed that the action of the lime is catalytic involving the cyclic formation and reduction of calcium dioxide : $4CaO_2+PbS$ $=PbSO_4+4CaO$; while the reactions in the converter were assumed to be PbS $+3PbSO_4=4PbO+4SO_2$ and $PbS+PbSO_4+O_2=2PbO+2SO_2$. W. Borchers, W. M. Hutchings, F. Richter, and C. Guillemain doubt if calcium dioxide is formed under the conditions which obtain in the furnace, although W. Borchers believes that a calcium plumbite or plumbate, $CaPbO_3$, is produced by the action of air and lime on the litharge produced from the lead sulphide, and that the oxidation of the galena involves the cyclic formation and reduction of calcium plumbate : $3CaPbO_3$ $+PbS=4PbO+3CaO+SO_2$. D. Clark, W. Borchers, and A. D. Carmichael found calcium plumbate among the products of the action, but T. Richter found none, and he believed that although a little may be produced, it plays only a secondary part in the roasting process. W. M. Hutchings suggested that calcium sulphate is formed by the action of sulphur dioxide and oxygen on lime, and this product is the catalytic agent ; indeed, in A. D. Carmichael's modification, calcium sulphate is employed in place of lime. H. F. Collins pointed out that as emphasized by W. C. Roberts-Austen, the reaction $PbS+CaSO_4=PbSO_4+CaS-28$ cals., being endothermal, is probably impossible in a neutral atm., but may be possible if the calcium sulphate can be oxidized by air : $CaS+2O_2=CaSO_4+226·4$ cals., for the calcium sulphate can give up oxygen to lead sulphide, forming calcium sulphide, which is reoxidized in the act of being formed, so that the net result is the exothermal reaction : $PbS+CaSO_4$ $+2O_2=PbSO_4+CaSO_4+198·4$ cals. It therefore seems probable, added H. F. Collins, that the addition of lime to the converter charge does facilitate the oxidation of lead

sulphide, yet, as pointed out by C. Guillemain, the addition is by no means essential and the result of eliminating the sulphur and converting the lead into oxide can be obtained by a combination of the exo- and endo-thermal reactions : $2PbS + 3O_2 = 2PbO + 2SO_2 + 199.6$ cals., and $PbS + 3PbSO_4 = 4PbO + 4SO_2 - 187$ cals.; and the premature sintering of the charge prevented by the addition of fine iron flux, quartz ore, or other inert substance. Arguments are frequently based on the thermo-chemical data obtained at comparatively low temp., but it is probable the data are quite inapplicable at higher temp., and the conclusions are therefore *non sequitur*.

P. Weiller represents the reaction $PbS + 2O_2 = PbSO_4$; $2PbS + 2O_2 = 2PbO + 2SO_2$; $PbS + CaO = CaS + PbO$; and $CaS + PbSO_4 = CaSO_4 + PbS$, and the latter reacts with oxygen as before. D. Clark, A. D. Carmichael, F. O. Doeltz, W. Mostowisch, W. M. Hutchings, C. Guillemain, and F. Richter have also studied these reactions. R. Tandler represents the main reaction as involving the oxidation of lead sulphide to sulphate by the irreversible reaction : $PbS + 2O_2 = PbSO_4$; and the balanced reaction $PbSO_4 + CaO \rightleftharpoons CaSO_4 + PbO$. The important part played by silica in the reactions in the formation of slag in the converter has been emphasized by A. Savelsberg, W. M. Hutchings, etc. According to P. Richter, the silica acts by decomposing the objectionable sulphates, forming a readily fusible silicate. According to H. O. Hofmann and W. Mostowisch, the silica begins to decompose calcium sulphate at about 1000°, and decomposition is complete at 1250°. C. Dörschel studied the effect of zinc blende and of barytes on the roasting of galena.

Dry processes for the extraction of lead.—G. Agricola, in his *De re metallica* (Basel, 1556), gave a description of the methods of smelting lead ores in vogue among the Saxons, Poles, and Westphalians in the sixteenth century. Alternate layers of fuel (wood) and ore were piled on a " hearth of bricks—four feet high—with sloping sides," so as to form a kind of basin. When the fuel burnt, the ore was reduced, and the resulting metal collected in the basin of the hearth. The lead basin was either tipped like a crucible, or the lead was allowed to flow over the edge at one corner. The extraction of lead from the rich galenas by partially roasting the ore followed by the reduction through the interaction of the products of oxidation is generally con-ducted in **reverberatory furnaces** of the type of the so-called *Flintshire furnace.*[5]

The hearth of the furnace is built over a vault to avoid the loss of lead in the foundations. The modification of the Flintshire furnace used at Couëron, Loire Inférieure, France, is illustrated by the longitudinal section, Fig. 4. Here A represents the fireplace; the hearth, B, is trapezoidal in shape, and is about 100 sq. ft. in area, sloping towards the tapping-hole C. The working doors are shown at D; the feeding hopper at E. The working-bed B is made of grey slag from the smelting. The slag is broken into pieces, thrown into the red-hot furnace, and, when melted, is worked by rabbles over the firebrick bottom into the required shape. About 30 cwts. of ore are spread on the bottom of the red-hot furnace; it is then stirred and worked over with rabbles at a temp. as high as possible without sintering the ore. The sul-phide is partly oxidized to sulphate and oxide. The temp. is then raised, and reduced lead accumulates in the well, from which it is tapped at inter-

FIG. 4.—Flintshire Reverberatory Lead Furnace.

vals. Lime is then thrown in to thicken the slag. The unreduced ore floats on the surface, and the operations of roasting and smelting are repeated until the flow of lead slackens. The residual slags are raked out, and the lead is tapped again. The skimmings from the lead pot are returned to the furnace. Three charges are worked off in about 24 hrs., and each charge yields about a ton of lead. The metal is cast in ingots or pigs—*pig-lead*.

There are several modifications of the process arranged to suit peculiarities in the local ores. The *Silesian process* is similar in principle to the above, but the furnace is larger, and the temp. is lower. Oxidizing materials—works residues,

consisting of lead, etc.—are added to assist the reaction with unoxidized sulphide. The *Corinthian process* was formerly worked at Bleiberg, Corinthia, and in some other countries—Belgium, Missouri, etc. The *French process*, or *le procédé breton* —*Brittany process*—of this process was formerly used at Poullaouen, Brittany, and in other parts of France and in other countries. The *Cornish process*, or *flowing furnace process*, was once used for impure galenas in Cornwall. Here the lead is partially reduced by the Flintshire process, and partly by iron and culm (small coal or anthracite). This process is also used for recovering lead from slags and other refuse in the Flintshire process. The product is called *slag lead*, and is contaminated with more antimony, copper, and other impurities than is the case with the lead from the Flintshire process.

The method of smelting in the **ore hearth** or **ore-hearth furnace** preceded the use of the reverberatory furnace. The ore hearth is really a small rectangular blast-furnace of a primitive type. Early in the eighteenth century, nearly all the lead-smelting in Derbyshire was conducted in the ore hearth, charcoal or dried wood being used as a fuel, and the blast was supplied by bellows worked with a water-wheel. Towards the end of the eighteenth century, said R. Watson,[6] there were only one or two such furnaces in the whole country. The ore hearth is still considered to be useful for ores rich in lead, and the residues and slags with a high lead-content require separate treatment in a flowing furnace or in a cupola. The illustration, Fig. 5, resembles in a general way one employed by Keld Head Co., Yorkshire. In the ore hearth the charge of ore, mixed with fuel A, Fig. 5, floats on a bath of molten lead, B, in a sump or cast-iron dish set in masonry. The air is supplied by a blast C. The reduced lead trickles through the charge into the bath and overflows down a sloping plate, D, into an iron pot, E, outside the furnace. The lumps of slag are picked out and removed as they are formed, and fresh quantities of ore and fuel added in small charges as required. The reactions are similar to those in the reverberatory furnace process, but the oxidation and reduction stages occur simultaneously; the air reduction, however, is here supplemented by the carbon reduction. The loss of silver, etc., by volatilization necessitates the introduction of an efficient fume collector, F. The fume collector is indispensable for protecting the workmen from the injurious action of lead vapour and sulphur dioxide fumes which ascend copiously from the hearth. There are many modifications. In the simple *Scotch hearth*, the furnace gets very hot in about 6 hrs., and it is then allowed to cool for about the same time. In the *Rossie furnace*, the hearth is cooled by air; in another type at Missouri, described by C. P. Williams, and G. C. Broadhead, the hearth is cooled by water; in the *Moffet hearth* or *Jumbo furnace*, the double hearth is partly cooled by water and partly by air.

FIG. 5.—Ore Hearth.

The different varieties of **blast furnace** [7] or **shaft furnace** used for the reductions of the roasted ores, can be regarded as a highly developed form of hearth furnace. Smelting in reverberatories and hearths is confined to ores and concentrates with over 60 per cent. of lead and less than 5 per cent. of silica. Ores with a lower proportion of lead, plumbiferous slags, roasted matters, and furnace products rich in lead are smelted in blast furnaces. Ores free from sulphur can be heated in blast furnaces after being mixed with lime, silica, or other fluxes so as to form a slag with the gangue of the ore, and the ash of the fuel. The carbonaceous matters in the fuel reduce the lead.

Sulphide ores are subjected to a preliminary roasting. There may be the simple heap roasting for ores in lumps, and roasting in reverberatory furnaces suitable for powdered ore. In sinter roasting, the charge is heated sufficiently to agglomerate or sinter the ore into masses which are afterwards broken up for the blast furnace. Ores which do not

sinter well may be made into briquettes with a suitable bond—milk of lime, or clay—and afterwards roasted. In lime roasting, the ore is mixed with limestone, or silica and limestone and roasted in the usual way. This process was used by T. Huntington and F. Heberlein; in the A. D. Carmichael process the ore is mixed with calcium sulphate and roasted. L. S. Austin used a specially designed pot for roasting. There are roasting furnaces with fixed hearths and immovable rabbles—e.g. the furnace of Wethey, A. von der Ropp, and E. Keller; in another type, the hearth rotates and the rabble is fixed—e.g. the furnaces of Brunton, F. Heberlein, etc. Some roasting is also done in shaft furnaces.

There are many types of blast furnace, and in the earlier types, the furnace linings were so quickly destroyed by the corrosive action of the plumbiferous slags, etc., that they were not a commercial success. It was only after B. Pilz had designed the water-jacketing of these furnaces in 1863, that blast furnace processes for lead smelting became a practical success. The many types now used are either circular—e.g. the *Pilz furnace*—or rectangular—e.g. the *Raschette furnace*. A furnace used at Freiberg, Fig. 6, illustrates the circular type. There is a wrought-iron water-cooled jacket in the tuyère zone. This is arranged in segments. Cold water enters at the bottom of each segment and flows away in a pipe leading from the top. The lead is tapped from N into the basin O; and the slag is tapped from M into P; T, T represent tuyères. The furnace may or may not be fitted with automatic charging devices. The blast, hot or cold, is delivered near the base of the furnace through tuyères. The products obtained are (i) the *lead* or *base bullion*; (ii) the *matte*, or *Bleistein*, or regulus, which is a mixture of sulphides of copper, nickel, zinc, iron, etc. The proportion of matte depends on the proportion of sulphur left in the roasted ore. If the matte is cupriferous, it may be used by the copper smelter; if not, it is roasted, and returned to the lead smelting furnace. Analyses of mattes were reported by H. Weidmann, R. Vambera, A. Streng, A. Schertel, A. Zdrahal, N. von Jossa and N. S. von Kurnakoff, etc. (iii) Ores carrying arsenic furnish a *speiss* which is essentially an iron arsenide, and if nickel is also present, nickel arsenide. If the speiss contains enough lead to be worth retreatment, it is roasted and returned to the furnace; if not, it is thrown away. Analyses were reported by C. Guillemain, A. Schertel, F. A. Hübner, etc. (iv) The *slag* is a complex silicate of iron, calcium, etc. It is usually black and should not contain enough lead to be of value—usually 1–2 per cent. is present. The slag is usually thrown away on the slag-tip. Analyses of the slags were reported by C. F. Plattner, C. Mann, P. Heberdey, A. Zdrahal, A. Schertel, R. Vambera, F. von Lipp, C. Ernst, N. von Jossa and N. S. von Kurnakoff, L. Dietz. (v) Much lead is volatilized during the smelting, and some material is carried away mechanically by blast or draught. The material recovered is called *flue-dust* or *fume*. Formerly no effort was made to collect the finely divided material carried along with the waste gases from the smelting furnaces. Much valuable material was lost, and damage done to the vegetation, etc., in the surrounding country owing to the poisonous nature of the *smelter's smoke*. The fume is condensed in settling chambers or settling flues just as suggested by R. Watson in 1778; [8] by washing with water as suggested by R. Watson and applied by J. D. Stagg; by allowing the coarser dust to settle in chambers, and then collecting the finer dust in filtering bags as first suggested by J. Percy; and by passing an electric discharge through the fume as applied by F. G. Cotterell. The fume collected from blast furnaces in bags is usually combustible and is ignited on the floor of the bag-house and returned to the furnace with the flue-dust collected by the other methods. Analyses of flue-dust and fume were reported by M. A. Fallize, F. Moldenhauer, J. Hannay, K. Friedrich, C. Schiffner,

FIG. 6.—Blast Furnace.

B. Kosmann, N. W. Iles. E. F. Côte and P. R. Pierron tried the so-called electro-thermal process for reducing galena by iron and fluxes.

Wet processes for the extraction of lead.—In the treatment of lead sulphide ores containing zinc, the zinc may be volatilized, as in Bartlett's process ; or else it is slagged by treatment with suitable fluxes, as in *H. E. Fry's process* with alkaline fluxes. In the wet processes for the treatment of these ores, the ore is roasted so as to convert the zinc into oxide or sulphate as in the processes of E. A. Parnell,[9] E. A. Ashcroft, E. Ellershausen, W. West, and C. F. Croselmere ; or the zinc may be roasted with salt—*chloridizing roast*, so as to convert it into a mixture of chloride and sulphate as in E. H. Russell's process. In each case the zinc is converted into a soluble salt ; the product is leached ; the iron and other metals removed if necessary ; and the zinc precipitated, and smelted for zinc, or employed in other ways. In E. W. von Siemens and J. G. Halske's process, the unroasted ore is treated with chlorine, and leached. The insoluble residues are smelted for lead, and the soln. electrolyzed for zinc. The chlorine which is liberated is used over again. The lead residues are treated for metal. N. C. Christensen, H. and P. Faivre, and F. E. Elmore treated the ore with a chloride soln., and electrolyzed the soln. A. Nathansohn also extracted the lead with chlorine or hypochlorites in the presence of dissolved chlorides ; H. Hey, with hydrogen chloride gas. Lead is a by-product in the extraction of vanadium from vanadite at Santa Marta, Spain.

The purification of lead.—The lead received from the smelting operations is called *base-bullion*—the *work-lead* or *Werkblei* of the Germans, and the *stannous* of Pliny's *Historiæ naturalis* (**34**. 47, c. 77 A.D.). Base-bullion is generally so contaminated with antimony, arsenic, sulphur, copper, tin, etc., that it is unsuitable for treatment by the desilverization processes, and it is also too hard and deficient in malleability to admit of its application to various manufacturing operations. Hence its name *hard lead*. The first process of purification is intended to separate those constituents, chiefly antimony, which make the lead hard. The quality of the base-bullion, said J. Percy, depends less on the mode of smelting than on the nature of the ore from which it is derived. Analyses of work-lead and of hard lead have been reported by A. Streng and E. Overbeck,[10] W. Hampe. H. Jäger, A. Schertel, S. Mitteregger, L. Schneider, E. Priwoznik, F. Moldenhauer, E. Dietz, L. F. Emmons, W. Mrazek, C. Balling, H. Dietrich, F. von Lill, etc. Analyses of impure lead derived from drosses, slags, etc., were reported by F. Reich,[11] H. Jäger, A. D. Machatti, etc. The **softening of lead** may involve two operations—liquation, and oxidation. In the **liquation of lead,** the metals and their compounds held in soln. by the lead are separated when the metal is melted slowly at a low temp. The *dross* consists of a mixture of lead, copper, sulphur, arsenic, etc. Analyses before and after liquation have been made by W. Hampe,[12] A. Schertel, etc. *E.g.*

	Pb	Ag	Cu	Bi	Sb	As	Sn	Fe	S	Ni+Co
Before	96·667	0·549	0·940	0·066	0·820	0·449	0·212	0·027	0·200	0·055
After	97·830	0·536	0·042	0·066	0·771	0·333	0·210	0·006	0·180	0·001

In some cases the liquated lead is desilverized, in other cases, a further softening is needed. This is effected by exposing the molten metal to an oxidation process —say, by melting it on the bed of a reverberatory furnace exposed to a current of atm. air. The dross is skimmed off from time to time, until the residual lead, on trial, has the required degree of softness. The rapidity of the operation depends on exposing fresh surfaces to oxidation. W. Hall found that in the process of making red-lead, the residual lead becomes soft. The softening has also been conducted in kettles or cast-iron dishes holding, say, 15 tons of lead. Steam may or may not be blown through the molten metal. The reverberatory furnace process is slower, but cheaper. Oxidizing agents of various kinds have been suggested by E. A. Pontifex and C. Glassford, T. Richardson, A. H. Johnson, H. Harris, A. Warner, B. George, American Metal Co., and W. Baker. A com-

bined liquation and poling process was described by H. W. Kachelmann. Analyses of softened and purified lead were reported by R. Fresenius,[13] H. Jäger, F. von Lill, E. Dietz, A. Eschka, P. Beck, A. Mosso, American Metal Co., O. Herting, P. N. Degens, F. Mylius, L. Schneider, E. Priwoznik, A. Zdrahal, A. Exeli, etc.

The desilverization of lead.—Lead obtained by smelting contains variable proportions of silver and gold, and the separation of these metals is usually economically profitable. The desilverization of lead [14] has been considered in connection with silver—3. 22, 4. There are (i) *Pattinson's process* and L. Rozan's *modification* in which steam under press. is forced into the molten argentiferous lead, so as to promote uniformity of temp. in the crystallizing metal, and prevent the formation of crusts. This gives small crystals of lead which can be readily drained from the mother-liquor. Analyses of *pattinized lead* were made by A. Streng, W. Mrazek, H. Hahn, etc. (ii) *Parkes's process* based on the discovery of C. J. B. Karsten that zinc extracts silver from molten argentiferous alloys. Analyses of *parkesized lead* were made by W. Mrazek, etc. The silver and gold are separated from the products of Pattinson's or Parkes' process by *cupellation*—a process known to Biblical writers, and frequently mentioned in the Bible in order to accentuate moral lessons.

Electrolytic process for the purification of lead.—A. C. Becquerel [15] made some early observations on the electrodeposition of lead, and N. S. Keith tried to refine base-bullion by using as electrolyte a soln. of lead sulphate in one of sodium acetate, using anodes of the base-bullion. D. Tommasi tried a modification of this process, but neither was a commercial success. A. G. Betts employed as electrolyte a soln. of lead fluosilicate which is free from polarization effects due to the formation of lead dioxide on the anode. The anode is placed in bags to collect the slimes. When about 0·1 grm. of galena is present per litre of electrolyte, the lead deposited on the cathode is smooth, lustrous, and so coherent as to permit bending without breaking. E. W. von Siemens and J. G. Halske consider that a soln. of lead perchlorate with some free perchloric acid gives even better results than the fluosilicate. R. Saxon found poor deposits of lead were obtained by the electrolysis of galena in various salt soln. or in hydrochloric or nitric acid. The following analyses illustrate the results obtained with A. G. Betts's process :

	Pb	Ag	Au	Cu	Fe	Sn	Sb	As
Hard lead	98·1014	0·8934	0·0122	0·1800	0·0140	0·0289	0·6076	0·1693
Refined	—	0·0009	—	0·0066	0·0012	0·0059	0·0043	0·0001

G. Titschak examined the electrodeposition of lead from soln. of lead chloride in magnesium chloride dissolved in dil. hydrochloric acid ; and from soln. containing α-naphthalenemonosulphonic acid or hydrofluotitanic acid. Analyses of electrolytic lead have also been reported by N. S. Keith, W. Hampe, K. Pietrusky, C. F. Mathers, E. W. von Siemens and J. G. Halske, etc.

There are many grades of lead on the market. The basis of most transactions on the London Metal Exchange is soft-foreign lead ; but there is *double-refined lead*, *super-refined lead*, *chemical-assay lead*, or *granulated lead*. The so-called *soft lead* is the product of a non-argentiferous ore which has been refined in the ordinary way, or else softened lead ; it is less pure than the so-called *desilvered lead*. The *chemical hard lead* contains a rather higher proportion of copper and antimony than ordinary soft-lead, and owing to its higher resistance to corrosion by acids is preferred more in chemical industries. The so-called *antimonial lead*, or *hard-lead*, is really an alloy with 15–20 per cent. of antimony. The composition of some varieties is indicated in Tables I and II. The ordinary English brand had 0·0026 per cent. of cadmium and no tin ; the best English brand had no cadmium, no tin, and no nickel, but the ordinary English and the chemical lead had traces of nickel, the electrolytic tin had 0·0025 per cent. of arsenic, the good chemical lead had a trace of arsenic, and the two brands of English lead had no arsenic, no manganese, and no cobalt. F. Mylius found the purest obtainable commercial samples of lead

contained 0·0006 per cent. of iron, 0·001 per cent. of copper, and a trace of oxide. W. Stahl said that the best refined lead made by the dry process contains 0·001–0·0015 per cent. of tin derived from the original ores, the fluxes used in smelting, or from the zinc used in desilverization.

The metallic precipitation of lead.—T. Bergman [16] was not right in stating that the metals precipitate one another after a certain order, which is the same in nearly all acid menstrua ; in spite of some anomalous circumstances the order is constant, and never inverted. Zinc prevails over iron ; iron over lead ; lead over tin ; tin over copper; copper over silver; silver over mercury; etc. Rather did O. Sackur show that tin is precipitated by lead from soln. of tin in nitric acid ; and, on the other hand, that lead is precipitated by tin from soln. of lead acetate—vide infra. C. A. Kraus and H. F. Kurtz found salts of lead dissolved in liquid ammonia are reduced by **sodium** and **calcium.** H. Reinsch found that **copper** precipitates lead as a black powder from soln. of lead acetate acidified with hydrochloric acid provided air has free access to the soln. ; if air be excluded, no precipitation of lead occurs. According to A. Roussin, **magnesium** precipitates lead from soln. of its salts, and, according to H. Mouraour, and E. G. Bryant, the reaction is accompanied by the evolution of hydrogen. S. Kern said that if a soln. of lead nitrate is used, the finely divided lead is covered by a film of lead hydroxide ; and A. Commaille showed that with lead chloride gas is evolved and some lead oxychloride is formed. Lead is precipitated by **zinc** from soln. of lead nitrate, and, according to N. W. Fischer, if a zinc rod be suspended in a soln. containing one part of a lead salt, 1½ parts of acetic acid, and 100 parts of water, the so-called arbor saturni is formed ; A. Simon also found that the lead-tree is formed if the zinc is suspended in silicic hydrogel containing some lead acetate. E. Giurgea obtained lead crystals by placing a porous pot containing a zinc rod in a soln. of lead acetate. The crystals of lead appear on the outside of the pot. H. N. Warren also obtained octahedral crystals by wrapping asbestos paper about a zinc rod which was then dipped in a soln. of lead salt. Neither N. W. Fischer, nor A. M. Pleischl obtained a deposition of lead when zinc is placed in an alcoholic soln. of lead acetate. The precipitation of lead by zinc was examined from an analytical point of view by F. Stolba, A. Gawlowsky, L. T. Merrill, A. Eckenroth, F. Mohr, and C. Rössler. L. T. M. Gray,

and H. Freundlich and J. Fischer examined the effect of gelatin, gum, and glue on the precipitation of lead from soln. of its salts by zinc and found that finer deposits are obtained with special conc. of the colloid. Both N. W. Fischer, and A. M. Pleischl found that **cadmium** precipitates lead rapidly and quantitatively from soln. of lead salts—*vide* lead chloride. A. M. Pleischl observed no deposition of lead when a **tin** rod is placed in a soln. of a lead salt, but O. Sackur found that while no lead is obtained from neutral and acid soln. of lead nitrate, with a sat. soln. of lead sulphate in sulphuric acid, or of lead chloride in hydrochloric acid, tin passes into soln. as a stannous salt, and lead is deposited. A state of equilibrium is established between the lead, tin, and the salts of these metals. The equilibrium ratio Sn : Pb in dil. soln. of the two chlorides in the presence of solid tin and lead : $Sn+PbCl_2 \rightleftharpoons Pb+SnCl_2$ at 25° varies from 3·09 to 3·45 when the acidity ranges from N- to $0·2N$-HCl. The results were affected by hydrolytic phenomena. The conditions agree with those deduced from the law of mass action and the theory of soln. press. It was also found that lead is almost completely precipitated by tin from soln. of lead acetate, and this the more rapidly the greater the acidity of the soln. O. Sackur explains the behaviour of tin and lead towards different acids on the assumption that lead has a greater soln. tension than tin, and that the stannous salts, with the exception of the nitrate, are only very slightly dissociated into ions. Measurements of the *E.M.F.* of a voltaic element of the form Pb | $Pb(NO_3)_2$ | $Sn(NO_3)_2$ | Sn showed that the electrolytic soln. tension of lead is about 17·2 times as great as that of tin. A. A. Noyes and K. Toabe found that lead is precipitated by tin from soln. of lead perchlorate in dil. perchloric acid ; they found that the equilibrium ratio of Sn : Pb in dil. soln. of lead and tin perchlorates ranged from 3·080 : 1 with soln. containing $0·475N$-$HClO_4$ to 3·011 : 1 with $0·959N$-$HClO_4$ at 25°. The reaction $Sn+PbCl_2 \rightleftharpoons Pb+SnCl_2$ was studied by R. Lorenz and co-workers ; F. Wöhler found that a **lead** rod in a soln. of lead nitrate or acetate forms crystals of lead ; J. B. Senderens found the same thing with neutral soln. of lead nitrate with the exclusion of air, and basic lead nitrite is formed—*vide infra*, allotropic lead. According to G. von Hevesy, the measurement of the rate of exchange between lead and the lead in a soln. of lead nitrate was made possible by adding a trace of thorium-B to the latter. He found the rate of exchange at the surface of metallic lead in contact with such a soln. of lead nitrate is of such magnitude as to suggest that the exchange is not solely due to thermodynamic equilibrium, but rather to the action of local currents. At some points lead passes into soln., at others lead is precipitated. A. Cossa found that **aluminium** readily precipitates lead from soln. of its salts, and A. H. Low, and J. E. Williams employed the reaction in analytical work. W. C. Reid showed that **thallium** precipitates lead from soln. of its salts. N. W. Fischer found that **manganese** precipitates lead from soln. of lead acetate as a brown powder, and O. Prelinger found that lead is also precipitated from (previously warm) soln. of lead salts. N. W. Fischer, and A. Payen found that **iron** slowly precipitates lead from soln. of lead acetate in the presence of air ; and from soln. of lead nitrate by a process analogous to that used by E. Giurgea—*vide supra*.

For the electrodeposition of lead, *vide infra*, the electrical properties of lead. G. Shimazu [17] described the preparation of reactive *powdered lead*. B. de Rostaing prepared powdered lead by pouring the molten metal on a sieve rotating in a horizontal plane 2000 revolutions per minute. The rain of lead is received into a vessel of water. L. Creveling and others obtained finely divided lead by driving a blast of warm air or superheated steam on to a fine stream of molten lead. J. Ohshima electrolyzed a dil. soln. of lead benzene sulphonate or lead naphthalene sulphonate, and pulverized the deposited lead. Pulverulent lead was made by P. Schützenberger, A. Thiel, H. Luggin, G. Bredig, and W. A. Tichomiroff and P. Lidoff. O. Ohmann [18] made *lead-wool ;* V. G. Yourieff, and O. W. Brown and A. R. Nees, *spongy-lead ;* H. I. Hannover, and L. Höpfner, *porous lead ;* G. F. Taylor, *lead-filaments ;* and F. Paneth and O. Nörring, and P. Schützenberger,

lead-films. H. N. Ridyard described the deposition of lead-films on glass, porcelain, etc., so that joints can be soldered.

Lead of a high degree of purity.—Lead of a high degree of purity can be obtained in many ways. The following process was employed by J. S. Stas : [19]

A soln. of lead acetate was digested with lead-foil at 40°–50° in order to precipitate copper and silver. The soln. was filtered into sulphuric acid, and the lead sulphate was washed and digested in an ammoniacal soln. of ammonium carbonate ; and the resulting carbonate washed free from ammonium salts. To eliminate iron, part of the carbonate was heated in a platinum dish to convert it into oxide, and the remainder was converted into neutral nitrate. The latter was dissolved in boiling water, and the oxide added in small portions at a time. The iron was thus precipitated as hydroxide, and the soln. of basic lead nitrate was filtered into a soln. of ammonium carbonate. The precipitated carbonate was washed, dried, and reduced to lead by adding it to molten potassium cyanide contained in an unglazed porcelain crucible. The button of lead was remelted under fused cyanide, and if the metal is free from traces of sulphate or oxide it furnishes a convex button resembling mercury.

B. Lambert and H. E. Cullis distilled in vacuo at 1200° the lead prepared by J. S. Stas' process, using quartz tubes divided into three compartments by constrictions. The first fraction was collected in the 1st compartment ; the middle fraction in the 2nd compartment ; and the residue remained in the 3rd compartment. They found that the globules of lead obtained in this way adhered very closely on the under side to the quartz, producing a very fine reflecting surface. It was found that if the distilled lead was exposed to air a short time after distillation, but when quite cold, the brilliant surface was quickly dimmed by a film of oxide. If, however, the metal was kept in the vacuous tube for several months, exposure to the air did not then cause any appreciable decrease in its brilliant lustre for several days. The purification of lead by the repeated crystallization of the nitrate, and the subsequent reduction of the nitrate to metallic lead, has been discussed by G. P. Baxter and F. L. Grover, and T. W. Richards and C. Wadsworth.

Colloidal lead.—According to G. Bredig and F. Haber,[20] and R. Lorenz and co-workers, when dil. mineral acids are electrolyzed with a bright lead plate or wire as cathode, and a platinum anode, with a current at 24–72 volts, a momentary pulverization of the lead occurs, and a fine, metallic powder of **colloidal lead** or **lead hydrosol** falls through the liquid. This takes place at isolated spots on the surface of the metal, bright indentations being left with rounded edges. A similar phenomenon takes place in alkaline soln., but in this case is continuous and much more energetic. The metallic lead thrown down is peculiarly susceptible to chemical change, and can readily be converted into white lead by the simultaneous action of air and carbonic anhydride. The addition of small quantities of a chromate or chromium salt prevents the occurrence of the phenomenon. Colloidal lead was also made by T. Svedberg, and S. Bodforss and P. Frölich by forming a direct current arc, or a high frequency arc, or an oscillatory Leyden jar discharge between lead electrodes under a given medium. A. Gutbier made the colloid by reducing a cold dil. soln. of lead chloride with hydrazine ; and R. Furth, by dusting the metals in air by means of the electric arc. E. F. Burton gave for the rate of migration of the particles in an electric field towards the negative pole was $12 \cdot 0 \times 10^{-5}$ for a fall of potential of 1 volt per cm. at 18°. The potential difference between the lead particles and water was 0·018 volt. J. Billitzer obtained the colloidal metal in a similar manner ; he found that the action is facilitated by using a roughened surface, and a loose superficial aggregation. C. J. Reed obtained the colloid by cathodic spluttering in a borax soln. D. Zavrieff, and G. Börjeson and T. Svedberg studied the production of colloidal lead by the oscillatory discharge. F. Bayer used caoutchouc as a protective colloid. O. Ruff and R. Wallstein made colloidal lead by the action of zirconium trichloride on a soln. of lead chloride ; and L. Gurvich, by shaking the powder in a liquid for a few hours. H. Nordenson, and F. Haber doubted if the colloid is really metallic lead—it may be a hydroxide or hydride.

According to T. Svedberg, when a clean surface of lead is placed in a flat dish covered with a dispersion medium, and exposed to ultra-violet light, a colloidal soln. of lead is produced. With water, the particles are probably those of the colloidal hydroxide; with methyl alcohol, ethyl alcohol, isobutyl alcohol, ethyl ether, acetone, and ethyl or amyl acetate as dispersion media, the size and number of the particles vary very much; and the disintegration of the lead depends on the nature of the dispersion medium. E. F. Burton, and T. Svedberg prepared **lead methylalcosol,** which was deep brown in transmitted light, and bluish-black in reflected light. They also made **lead ethylalcosol,** and **lead isobutylalcosol** in an analogous way. C. H. Hall [21] found that suspensions of finely divided lead in lubricating oil are not precipitated by alternating or direct currents at 10^4 to 2×10^5 volts.

§ 4. The Physical Properties of Lead

Lead belongs to the white metals, but ordinary lead has a decided bluish-grey **colour** ; and the term lead-grey is used to indicate a specific colour. Lead has a much darker colour than tin, and this was emphasized when Pliny, in his *Historiœ naturalis* (**35**. 16, c. 77 A.D.), called lead *plumbum nigrum*, and tin, *plumbum album*. The colour of lead of a high degree of purity, distilled in vacuo, resembles that of mercury or silver, and B. Lambert and H. E. Cullis [1] found the bluish tint, usually associated with lead, to be entirely absent. According to M. Faraday, a very thin layer of lead appears brown by transmitted light, and after the film had been pressed with agate it appeared blue ; according to A. W. Wright, thin films of lead are brown or olive-green. W. L. Dudley found that the vapour of lead is blue. W. Spring and C. van Aubel, and F. Mylius and O. Fromm obtained *black lead* by dissolving zinc containing lead in an acid. They said that the black substance may be finely divided lead or an allotropic modification of lead. If zinc be rubbed with this lead-black by means of a spatula, it becomes more soluble in acids. Mercury amalgamates and dissolves the lead-black, and this is probably the reason why amalgamated zinc is not soluble in acids. F. Wöhler showed that if a soln. of lead nitrate is electrolyzed the tabular crystals which deposit on the cathode are coloured *copper-red*. F. Stolba attributed the colour to a surface film of a foreign substance. The **lustre** of a freshly cut surface of lead is bright, but it quickly tarnishes on exposure to air.

According to J. B. L. Romé de l'Isle,[2] R. J. Haüy, L. L. Pajot, G. R. Levi, J. A. Mongez, H. Behrens, and J. Braunsdorf, lead crystallizes from the molten state in octahedral **crystals.** C. M. Marx showed that on allowing molten lead to cool slowly and partially to solidify without being disturbed, when a hole is made in the surface crust and the still liquid portion is poured off, the remaining solid portion will be found in skeleton octahedral crystals belonging to the cubic system. The fern-like forms were said to recall those formed when ammonium chloride crystallizes. Fig. 7 shows the appearances of some well-developed dendritic forms reported by W. Campbell.

F. Stolba obtained crystals, 4 mm. long, by pouring lead into one corner of a tilted cardboard box, and as soon as solidification began tilting the box so that the still molten metal ran to another corner. F. M. Ihle found distinct octahedral crystals of lead in a cavity in a pig of lead, and crystals in furnace products have been reported by J. J. Nöggerath, J. Percy, F. Sandberger, J. F. L. Hausmann, and C. C. von Leonhard. G. W. A. Kahlbaum and co-workers found that when lead condenses from the vaporous state, cubes and octahedra are formed. The formation of lead crystals was also described by R. Gross, A. Thiel, J. B. Senderens, E. Giurgea, O. Rothe, J. H. Bowman, A. Stock and F. Gomolka, P. Schützenberger, E. Cohen and W. D. Heldermann, etc. H. A. Miers acted on lead for 24–48 hrs. with 5–10 per cent. nitric acid, and obtained small crystals. J. Durocher prepared small crystals by reducing lead chloride at a red heat with hydrogen sulphide. F. Wöhler poured water into a vessel to form a layer above the surface of a soln. of lead nitrate or acetate, and a piece of lead was dipped in both liquids. Small crystals

of lead were formed.   J. B. Senderens made a similar observation with neutral soln. of lead nitrate when air is excluded—*vide supra*, metallic precipitation of lead. The subject was also discussed by G. von Hevesy, and A. Thiel.   The production of the lead-tree—*arbor saturni*—was discussed by R. Lüpke.   O. Lehmann considers that the electrolytic formation of crystals may be compared with ordinary crystallization on the assumption that the metal which separates out at first remains dissolved in the electrolyte, and that, when the latter becomes sat., it crystallizes out in the ordinary manner.   When the strength of the current is increased until

FIG. 7.—Dendritic Crystals of Lead.

the metal no longer forms a uniform deposit on the surface of the electrode, the crystals that are deposited arrange themselves into a skeleton-like structure, and that further increase in the current strength will only alter the mass of the structure, but not its form.   Lead is an exception, because with a weak current it separates out in leafy crystals which appear to belong to the monoclinic system, and are similar to those forming the ordinary lead-tree ; whilst with a strong current the crystals obtained are those of the cubic system and, under favourable circumstances, well-formed octahedra.   He assumes that the rate at which the lead-atoms separate out being far less in the first than in the second case, different mol. are formed in the soln., and that since the metal separates out from the soln. in crystalline form, the one set of mols. will form crystals which are distinct from those of the other. The lead-tree, said J. Schildowsky, always grows towards the anode.   E. Cohen and K. Inouye's measurements of the e.m.f. of the supposed monoclinic and cubic forms of lead showed that the crystals are identical, and not allotropic forms. According to C. Elbs and F. W. Rixon, lead is sometimes deposited in large shining plates, and sometimes in the form of a sponge, the difference is due to the presence or absence of a plumbic salt in the electrolyte ; if present, a spongy deposit is always obtained.   F. Haber found that a layer of spongy lead is formed on the cathode during the electrolysis of sulphuric acid with lead electrodes.   B. Wäser and R. Kühnel, P. K. Frölich and co-workers, and V. Kohlschütter and F. Uebersax investigated the cathode deposits of lead obtained under different conditions. A. Günther-Schulze examined the rate of growth of the deposit and the current strength.   In the growth of the lead-tree which occurs when a rod of zinc is

immersed in a soln. of lead acetate or nitrate, the separation of the plates is frequently followed by a spongy deposit. H. N. Warren found that when litharge or lead sulphate is introduced into canvas bags, through which is inserted a lead sheet, and the bags immersed in dil. sulphuric acid, then when the lead is connected with sheets of iron, immersed in the acid, the sulphate or other lead compound contained therein is speedily and completely reduced to the spongy metal— *vide* the metallic precipitation of lead. N. A. Puschin obtained crystals of lead from amalgams rich in lead. As in the case of tin, I. V. Obreimoff and L. V. Shubnikoff prepared large single crystals of lead.

Like most metals, lead crystallizes in the cubic system. Octahedral crystals occur in nature (*vide supra*), and they are produced when the metal crystallizes in Pattinson's desilverization process, and by the methods indicated above. The etching of the surface of lead shows that the octahedral crystals are sometimes in combination with the cube. A. Hamberg, and G. Flink examined crystals of native lead (*q.v.*). L. Vegard's **X-radiogram** shows that the space-lattice is a face-centred cube, with the edge of length $a=4.91$ A.; E. C. Bain gave 4.92×10^{-8} cm.; W. P. Davey, $a=4.920\pm0.005$ A.; W. C. Phebus and F. C. Blake, $a=4.92$ A.; and M. Levi, 4.93 A. R. Vogel, and E. A. Owen and G. D. Preston also examined the X-radiogram of lead; and K. Weissenberg, the structure of the crystals. P. Scherrer said that the crystals are isomorphous with those of aluminium, copper, silver, and gold. R. J. Anderson and J. T. Norton examined the effect of cold work on the X-radiogram of lead; and A. E. van Arkel found that the lattice of the stressed metal could suffer a maximum distortion of 0.15 per cent. According

FIG. 8.—Lead etched with Acetic Acid ($\times$ 33).

to J. C. W. Humfrey, the **corrosion figures** produced by 5 per cent. nitric acid are of the cubo-octahedral form. J. Czochralsky gave the **velocity of crystallization** of lead as 140 at 320° when that of tin at 232° is 90, and of zinc at 416°, 100. A. Günther-Schulze studied the speed at which lead crystals grow during electro-deposition; V. Kohlschütter and F. Uerbersax examined this subject. J. Czochralsky found the velocities of crystallization of tin, lead, and zinc to be related as 90 : 140 : 100. N. I. Nikitin showed that finely divided lead prepared by reduction at 125° is non-pyrophoric because the metal crystallizes at this low temp.

Ordinary lead usually presents no evidence of a crystalline structure to the eye, although it is certain that the metal is an aggregate of polyhedral crystals. The crystalline structure is usually shown on the surface of pigs (ingots) of market lead. According to R. Vogel, N. S. von Kurnakoff and N. A. Puschin, F. Robin, etc., the crystalline structure appears on the surface of lead cast on a smooth surface—say glass. G. Cartaud etched the polished surface with a soln. of picric acid in acetone. If ordinary rolled sheet lead be etched, the structure appears like Fig. 8, which W. Campbell obtained by etching the metal with acetic acid. After annealing for a week at 200°, a coarse, irregular, crystalline structure was developed. A crystal 2·5 cms. long and 1·25 cms. broad was grown in 5 days at 180°. Some of the crystals show twinning. E. Cohen and K. Inouye said that if lead with the crystalline surface exposed by etching be pressed against rolled lead at or about 100°, the strained metal is rendered crystalline by contact. A. L. Norbury studied the spontaneous annealing of lead. H. Baucke found the crystallization at ordinary temp. of cold-worked lead is accelerated by the presence of an electrolyte—say dil. acid. Figs. 9 and 10, by J. A. Ewing and
FIGS. 9 and 10.—Slip-bands in Lead Crystals (×100 and ×1000 respectively).

W. Rosenhain, show the development of **slip-bands** which occur when a crystal is strained. These slips occur along the gliding planes of the crystal. Those shown in the diagrams were obtained by allowing molten lead to solidify on a smooth glass plate, and straining the metal by bending. The slip-bands with lead are particularly straight even under extreme magnification, as shown in Fig. 10. P. Gaubert observed no twinning of the crystals to be produced by press. J. C. W. Humfrey found that lead tends to slip along planes perpendicular to the octahedral axes of the crystals. Some slight differences of orientation of the slip lines may occur after a single crystal has been strained, but this is not due to recrystallization, but to the fact that the strain was not homogeneous; when a slip has occurred in a certain part, it tends to go on there rather than in other parts of the crystal. After straining, the lead recrystallizes, and the recrystallization is not a direct and instantaneous effect of the strain, but severe strain and high temp. both tend to increase the subsequent rate of change of structure. The patches of new orientation probably start from a cleavage plane, and this gives rise to the formation of twin crystals.

According to J. A. Ewing and W. Rosenhain, although twinned crystals are

rarely, if ever, found in cast metal, they are frequently developed by strain, and are commonly found in metal which has been annealed after severe strain. This is explained as follows :

When the metal solidifies from the liquid state, it does so by the formation of skeleton crystals, starting from a great number of centres, and the arms of these skeletons continue to grow until arrested by meeting with other growths. From these arms, other arms again shoot out, and so on until the entire metal is solidified ; but each crystalline element as it settles into place on any of these arms must assume the proper orientation to enable it to fit in, and in the process of filling space by means of such a system of many meeting and interlacing arms, the formation of a twin would be almost impossible. But when the metal recrystallizes after severe strain, it does so by the growth of skeleton arms that must often start from a cleavage plane of an actual solid crystal, and probably the new elements deposited upon such a plane would find it as easy to assume the twin orientation as the normal. The idea that twin crystals are formed in annealed metal by growth starting from cleavage planes which have been sheared across in the process of compression is suggested by the very straight boundaries observed as a characteristic feature of twin lamellæ.

J. A. Ewing and W. Rosenhain made observations between 100° and 300°, and concluded :

In lead which has been severely strained, recrystallization goes on at all temp. from that of an ordinary room up to the m.p. The higher the temp. the more rapid are the changes in the crystalline structure. The rate of change varies with different specimens, probably depending upon the nature and quantity of impurities present, and upon the severity of the strain to which the metal has been subjected. The size of the crystals ultimately produced does not vary appreciably between 100° and 300°. In lead annealed at the temp. of the air, very large crystals have not yet been obtained, but this is probably only a question of time. The phenomena of growth of crystals occur in lead only when the metal has previously been subjected to severe plastic strain. The structure of a cast specimen remains unaltered at temp. which cause a strained specimen to show rapid change. By casting in a mould arranged to cause rapid cooling, specimens of lead can be obtained having a minute crystalline structure, whose scale is not very different from that of severely crushed lead ; such a specimen was exposed to 200° for nearly seven days, but no visible change of structure occurred. A piece of this specimen was then strained by severe crushing, and on further exposure to 200° vigorous growth took place. The rate at which a lead specimen is cooled down to ordinary temp. has no visible effect on the structure. Even " quenching " in liquid air has no visible effect ; quenching in water, cooling in air, and slow cooling in the oven, were all tried on a number of specimens without in any way affecting them. Lead is mechanically hardened to a small extent by severe strain, and the subsequent effect of annealing in restoring softness is correspondingly small. In one of the experiments a specimen of lead was crushed under a given load in the testing machine, and the load was left on until no further creeping occurred. The specimen was then annealed and again placed under the same load, when a distinct amount of further crushing was seen to take place.

F. C. Thompson and W. E. Millington found that with cast and slowly cooled lead, slip-bands appear at 25 kgrms. per sq. cm. when the elastic limit is 102 kgrms. per sq. cm. R. S. Dean and W. E. Hudson found the velocity, V, of grain growth in lead with 1 per cent. antimony is represented by $V = ae^{b/T}$, where a and b are constants. G. Tammann said that after cold working, annealing begins at 45°, and at 150°, the new crystals formed are rather small. The annealing of mechanically worked lead, even at ordinary temp., is illustrated by the gradual loss in the mechanical hardening occasioned by rolling ; and to coarse crystalline character of old roofing lead. Unlike tin, lead does not emit a *cry* when bent. G. T. Beilby showed that during hammering lead is converted from the crystalline to the amorphous state. The recrystallization of lead during annealing was also studied by H. Baucke, R. Vogel, G. Tammann and co-workers, O. Bauer, F. Robin, W. Rosenhain and S. L. Archbutt, M. Cook and U. R. Evans, etc.

There are passages in Theophrastus' Περὶ Πυρός, in the third century before our era, and in Plutarch's *Symposiaka* (**6.** 8), towards the end of the first century of this era, which refer to the change which occurs in lead and tin during the cold of the wintry season. It must be remembered that at this time the distinction between lead and tin was not clearly marked. H. St. C. Deville [3] showed that the sp. gr.

of lead is affected by the thermal history of the metal, and U. J. J. le Verrier found that the same thing applied to the sp. ht. As indicated above, the dimorphic forms of lead reported by O. Lehmann were shown by E. Cohen and K. Inouye, to be the same thing. According to C. Jeantaud, when a soln. of mixed alkali plumbate and plumbite is electrolyzed, using a current density not less than 2 amps. per sq. dcm. of cathode surface, dull grey crystals of lead are obtained which have a smaller electrochemical eq. than ordinary lead, and give an e.m.f. about 5 per cent. higher than ordinary lead, and have double the capacity of the ordinary metal. G. Rosset, and C. Jeantaud claimed special advantages for this form of lead in the construction of accumulators, but this has been denied.

E. Cohen and W. D. Helderman inferred that lead furnishes at least two **allotropic forms,** for, as shown by H. Heller, when the metal is suspended in a 40 per cent. soln. of lead acetate containing 10 per cent. of nitric acid of sp. gr. 1·16, the metal shows marked signs of structural change ; the surface becomes wrinkled, and in three weeks this becomes so pronounced as to suggest complete disintegration of the metal as when white tin passes into grey tin. H. J. M. Creighton confirmed H. Heller's experiment by the following experiment :

A current of 2 amps. at 6 volts was passed through an electrolyte consisting of nitric acid, sp. gr. 1·42, using as cathode a piece of sheet lead 2 cms. wide, 2 mm. thick, and 10 cms. long, and a thin piece of platinum foil as anode. At the end of 8 hrs., the cathode had increased slightly in vol., its colour had changed to grey ; it lost its former malleability and firmness ; and when the lower part was rubbed between the fingers, it furnished small particles which could easily be rubbed to a fine powder, or pressed into a soft mass.

F. H. Getman found the potential of lead to be 0·4121 volt against the normal calomel electrode, whether the lead be cast in sticks, electrolytically deposited, or used as an amalgam. Lead which has been immersed in a soln. of lead acetate and nitric acid gives higher values, which increase with the time of immersion ; the lead at the same time becomes brittle. E. Cohen and W. D. Helderman found that the sp. gr. of the metal changed from 11·3299 at 25°/4° to respectively 11·3415, 11·3283, and 11·3129 when kept for some time at 15°, 25°, and 50°, in the soln. just indicated. They estimate that the **transition temperature** is near 50°, above which lead is stable without a tendency to disintegration. E. Jänecke measured the pressure-temperature cooling and heating curves of the metal and found evidence of a break or transition point between 59° and 62°. E. Cohen and A. L. T. Moesveld say that the failure of P. W. Bridgman to find polymorphic forms is due to his use of compact masses of metal. The changes are so slow that it is necessary to accelerate the change by working with finely-powdered metals in a soln. of an electrolyte. B. Lambert and H. E. Cullis inferred that the corrosion of pure lead is due to electrolytic action between electrically different parts of the mass of lead. P. W. Bridgman observed no signs of allotropism in his observations of the thermo-electric properties of lead. The assumed physical heterogeneity is due to the presence of different allotropes in the mass of metal causing parts to be electrically different from other parts ; these differences persist for a long time after the metal has been prepared. On the other hand, A. Thiel concluded that the phenomenon observed by H. Heller is not due to an allotropic change but is an effect of chemical action. The disintegration is observed only with a soln. containing nitrates, and does not occur with lead acetate and acetic acid ; lead chloride and hydrochloric acid ; lead fluosilicate and hydrofluosilicic acid ; or lead perchlorate and perchloric acid. Disintegration which has started in H. Heller's soln. is arrested when the metal is transferred to a soln. free from nitrates. The metal is slowly attacked by Heller's soln. with the evolution of nitrogen and nitric oxide, and much is dissolved before disintegration occurs. The metal is similarly attacked by soln. of nitrates free from lead, but the reaction is faster if a trace of lead nitrate or nitrite is present. The disintegrated metal has not the appearance to be expected if an allotrope were formed consisting, as it does, of irregular, polyhedral grains, with more or less rounded edges, and free from small crystals. The lead supposed to be

stable above 50°–60° readily disintegrates under soln. containing nitrates at 100°, though unaffected by soln. free from nitrates. There is only a very slight difference of potential between compact and disintegrated lead immersed in a soln. of lead perchlorate. A. Thiel explains what he calls the *disglomeration of lead* in the following manner :

Compact lead is composed of crystallites, the crevices of which are filled by a finely granular eutectic, which is present even in " pure " metals (a similar structure must be assumed for all metals which have solidified from the molten state). This eutectic is more readily attacked by the suitable agent when the impurities are more chemically active than the metal itself ; in consequence, cavities are formed around the crystallites, which finally become so deep that the latter are completely detached from the main mass.

The disintegration can be effected by other agents—*e.g.* when a lead anode slowly dissolves in a soln. of perchloric acid. Copper can be similarly disintegrated in an ammoniacal soln. of persulphate.

Lead is the densest of the common base metals. The Arabic manuscript of Abu-r-Rarhan, *The Book of the Best Things*, written about the tenth century, and described by H. C. Bolton,[4] and J. J. C. Mullet, gave 11·33 for the **specific gravity** of lead, and this value is very near that accepted to-day ; and in the Arabian manuscript, *Book of the Balance of Wisdom* of Al-Khazini, written about 1122 A.D., and described by H. C. Bolton, and N. Khanikoff, 11·32 is given for the sp. gr. of lead. D. G. Fahrenheit gave 11·35 ; R. Boyle, 11·325 ; P. van Muschenbrock, 11·445 ; and L. B. Guyton de Morveau, 11·358 to 11·388. Collections of data were made by R. Böttger,[5] and F. W. Clarke. J. J. Berzelius gave 11·445 for the best representative value ; 11·35 is perhaps nearer the mark. M. J. Brisson gave 11·352 ; R. Böttger, 11·207 ; A. T. Kupffer, 11·3338 at 14°, 11·3299 at 15°, and 11·3303 at 17° ; J. Crichton, 11·346 at 15·5° ; A. Baudrimont, 11·3775 ; W. Herapath, 11·352 ; C. J. B. Karsten, 11·3888 ; G. Timoféeff, 11·349 at 15°/4°, and 11·331 at 25°/4° ; H. Tomlinson, 11·193 at 20°/4° ; L. H. Adams and co-workers, 11·336 at 20° ; J. J. van Laar, 11·4 at 0° ; A. Streng, 11·395 at 4° ; A. Hamberg, 11·372 at 15°/18° ; A. Matthiessen and M. Holzmann, 11·376 at 14°/0° ; P. Schweitzer found 11·344 at 4° and 11·352 at 23° for a sample cut from the end of a cast ingot, and 11·358 at 4°, 11·359 at 18°, and 11·366 at 23° for a piece cut from the middle of the bar. W. Herz calculated the sp. gr. at absolute zero to be 12·880, and the at. vol. 16·09. C. J. St. C. Deville found that when lead is slowly cooled from a fused state, the sp. gr. is 11·254, and when rapidly cooled 11·363 ; and that electrolytic lead has a sp. gr. 11·542, and if fused and cooled quickly, 11·225. W. Herz estimated that the sp. gr. of lead at absolute zero is 12·88. E. Cohen and W. D. Heldermann's observations on the sp. gr. of the allotropic forms of lead are indicated above.

The differences in the results of different observers in what appears to be one of the simplest of observations are somewhat remarkable, and emphasize how little reliance can be placed in the agreement or disagreement of determinations on different samples. J. Percy observed that the sp. gr. of lead is usually diminished if sensible proportions of the usual impurities are present, so that other things being equal, the greater the purity the higher the sp. gr. of lead. C. J. B. Karsten's sample was reduced from the nitrate by carbon. A. Streng's sample was stated to be the purest pattinsonized lead, but it was really somewhat impure and contained 0·02 per cent. of copper and 0·04 per cent. of antimony. F. Reich gave for the cast lead 11·352 at 0°/4°, and 11·372 at 24°/24° ; for rolled lead, 11·358–11·365 at 0°/4°, and 11·376–11·383 at 24°/24°. The sp. gr. of pattinsonized lead with less than 0·1 per cent. of copper and iron was 11·363–11·374 at 0°/4° ; lead prepared from the acetate with 0·007 per cent. of iron had a sp. gr. 11·3683–11·3695 at 0°/4°, and after hammering between paper and the surface cleaned, 11·3675 at 0°/4°. F. Kick examined the sp. gr. in different parts of a lead cylinder. J. Percy reported a sample of highly purified lead, after melting under-potassium cyanide, to have a sp. gr. 11·358 at 15·5° ; a piece chiselled out from the pig had a sp. gr. 11·382, and, after

hammering, a sp. gr. of 11·387. F. Reich found the sp. gr. of lead after rolling into thin sheet rose from 11·354 to 11·356 ; and L. Knab found that rolling cast lead raised the sp. gr. from 11·352 to 11·358. G. W. A. Kahlbaum found the sp. gr. of lead distilled in vacuo was 11·3415 at 20°/4° ; and after compression at 10,000 atm., 11·3470. W. Spring said that like all bodies which expand during fusion, lead expands when subjected to high press., for the sp. gr. of cast lead was 11·3351, rolled lead 11·3348, and drawn lead 11·3410—the presence of gas inclusions interfere with the results. He also found that lead with a sp. gr. 11·350 at 14° had a sp. gr. 11·501 at 14° after pressing at 20,000 atm., and 11·492 at 16° after another treat-ment at 20,000 atm. press. G. Spezia obtained a decrease in the sp. gr. at high press., but regarded this as an effect of the elasticity of the metal. F. W. Clarke, and S. P. Howell reported that the sp. gr. of lead is materially decreased when distorted quickly as by an explosion—the latter observed a drop from 11·403 to 10·996, and from 11·376 to 11·156 ; and the former from 11·510 to 11·268. T. M. Lowry and R. G. Parker found the density of lead *en masse* to be 11·3368, and of the same sample as filings, 11·3337. The annealing of lead at 100°, produced an expansion. F. Nies and A. Winkelmann said that the sp. gr. of lead must be increased during fusion because solid lead floats on molten lead, but E. Wiedemann said that this is a mistaken inference, for the result is an effect of convection in the molten metal—lead expands on melting. R. Hoffmann and W. Stahl gave for 99·98 per cent. lead, 11·371 at 0°/4° ; 11·379· at 4°/4° ; 11·364 at 20°/4° ; and 11·358 at 600°/4°. W. C. Roberts-Austen and R. Wrightson found the sp. gr. of solid lead at the m.p. to be 11·40, and that of the liquid, 10·37 ; G. Vicentini and D. Omedei gave 11·359 for the sp. gr. at 0° ; 11·005 for the sp. gr. of the solid at 325°, and 10·645 for the liquid. L. Playfair and J. P. Joule gave 11·231 at 4° and 10·509 for the molten metal ; G. Quincke gave 11·335 at 0° and 10·952 for the molten metal ; R. Hoffmann and W. Stahl, 10·358 at 600°/4° ; M. Plüss, 10·896 at 340° ; C. E. Fawsitt found 10·65 at 330° and 10·63 at 347°. C. Benedicks also measured the sp. gr. of molten lead. A. L. Day and co-workers found at

	327°	350°	450°	550°	650°	750°	850°
Sp. gr. . .	10·686	10·658	10·536	10·418	10·302	10·188	10·078

P. Pascal and J. Jouniaux obtained rather higher values, namely, 10·875 at the m.p. ; 10·85 at 400° ; 10·71 at 600° ; 10·49 at 800° ; and 10·15 at 1000°, so that there is a 4·3 per cent. increase in vol. when lead at 20° is converted into liquid at the m.p. M. Toepler found 3·7 per cent. expansion during melting. H. Endo found a change in vol. of 3·44 per cent. during the melting of lead. R. Arpi, and C. Cat-taneo measured the effect of temp. on the sp. gr. of lead. T. R. Hogness gave 10·65 for the sp. gr. of molten lead at 366° ; 10·55 at 444° ; and 10·44 at 522° ; and he represented the sp. gr. of molten lead at $\theta°$ by $10·71—0·00139(\theta—327)$. For the sp. gr. of lead from radioactive sources, *vide* at. wt. of lead ; A. C. Egerton and W. B. Lee gave 11·3437 for the sp. gr. of ordinary lead at 20°, and 11·2960 for that of uranium-lead at 16° ; and B. Perrette obtained respectively 11·3363 and 11·2784 at 0°. The at. vol. of the isotopes are the same. T. W. Richards and C. Wadsworth prepared samples of lead of a very high degree of purity from different sources, and found that while ordinary lead has a sp. gr. 11·337 at 20°/4° (at. wt. 207·2), that derived from a radioactive Australian one had a sp. gr. 11·288 (at. wt. 206·3), and that from Norwegian cleveite, 11·273 (at. wt. 206·09). F. Soddy observed no appreciable difference in the at. vol. of the two forms of lead. J. Joly and J. H. J. Poole did not get any appreciable separation by centrifuging molten lead. W. L. Bragg calculated the **atomic radius** to be 1·90 A. A. Groh and G. von Hevesy computed the radius of the lead-ions to be three times as great as that of the atoms. W. P. Davey, and W. J. Sollas made calculations on the dimensions of the atoms of lead. J. J. van Laar calculated b of J. D. van der Waals' equation to be $b=0·00320$; for a, $\sqrt{a}=0·11$;

and for the valency attraction A, $\sqrt{A}=40$. H. H. Potter compared the gravitational attraction of brass and lead but detected no difference.

Lead is the softest of the common base metals—thallium, calcium, potassium, and sodium are softer than lead. It can be easily cut with a knife, and scratched with the finger nail. It makes a grey streak on paper, and was formerly used as a pencil for writing on paper.[6] Lead clogs an ordinary file, but it can be worked with a rasp. P. Nicolardot[7] showed that lead is hardened by hammering. J. R. Rydberg gave for the **hardness** of lead on Moh's scale 1·5, when that of tin is 2·5 ; zinc, 6 ; and copper, 8. The softness of the metal is utilized in modelling for artistic purposes, as described by W. R. Lethaby, and L. Weaver. For lead containing less than one per cent. of silver, copper, and antimony, F. Auerbach represented what he called the absolute hardness by 10, which is nearly the same as that of gypsum (14)—the value obtained for cast tin was 11, gold 97, and the diamond 2500. F. C. Calvert and R. Johnson gave 16 when that of iron is 1000 ; H. Gollner gave 3 for the hardness of hard-lead when that of tin is 2 ; T. Turner gave 1·0 when that of copper is 8·0 ; and C. A. Edwards, 6·95 when that of copper is 53. H. J. Coe gave 11·355 for Brinell's hardness of cast lead. F. Sauerwald and K. Knehans gave 7·44 for Brinell's hardness at 25° ; 6·93 at 73° ; 6·62 at 122° ; 5·68 at 170° ; 4·93 at 219° ; and 4·24 at 267°. K. Ito, and A. L. Norbury also measured the hardness of lead at different temp. G. Coriolis found that after repeated melting in air, lead becomes harder and more brittle owing to the formation of the oxide which mixes with the metal. The effect of impurities was examined by C. O. Thieme, A. Bencke, and P. Ludwik. W. Baker showed that the hardness of lead is largely conditioned by the proportion of sulphur, antimony, arsenic, copper, and iron it contains. P. Duhem, S. Bottone, and A. Kürth made some observations on the hardness of lead. K. Honda and R. Yamada measured the abrasive hardness of lead. P. Ludwik measured Brinell's hardness of lead with loads continuous for 5 and 300 secs., and the results are plotted in Fig. 11. A. Kürth measured the effect of temp. on the hardness. A. L. Norbury found the results for the Brinell's hardness depend on the time of application of the load ; tests were also made by J. Okubo. Tests on the effect of cold-work on hardness showed that lead is hardened by cold-work to an extent depending on the amount of work done ; and that the metal is annealed spontaneously at room temp. at a rate which increases with the amount of deformation. In severely cold-worked specimens, this annealing is so rapid that 20 secs. after hammering the metal is dead soft. Related observations were made by T. K. Rose, P. Nicolardot, N. S. von Kurnakoff and S. F. Schemtschuschny, M. Levi-Malvano and O. Ceccarelli, A. Saphoshnikoff and J. Kaniewsky, G. Moreau, W. Herold, and M. Hanriot. P. P. Lazareff discussed the relation between the hardness and other physical properties of lead ; and K. Ito, the relation between the temp. coeff. and the m.p. C. A. Edwards and A. M. Herbert gave 3·2 for the **plasticity** number of lead when that of copper is 49·3. The flowing press. of lead was measured by N. S. von Kurnakoff and S. F. Schemtschuschny, A. Geller, and D. Saito and K. Hayashi. G. Subrahmanian measured the **viscosity** of lead ; and E. E. Walker, the resistance offered by powdered lead to compression.

FIG. 11.—The Effect of Temperature on the Hardness of Lead.

The **surface tension,** σ, of lead at the m.p., 327°, found by G. Quincke[8] is 535·9 dynes per cm. ; by H. Siedentopf, 509·5 dynes per cm. ; by L. L. Grünmach, 482 mgrms. per mm. ; by S. W. Smith, 424·5 dynes per cm. ; and T. R. Hogness, 444 dynes per cm. G. Tammann, and W. Hagemann made observations on this subject. T. R. Hogness also gave :

	327°	350°	400°	450°	500°
Surface tension . .	444	442	438	438	431 dynes per cm.

and at θ, for molten lead, $\sigma=444-0.077(\theta-327)$. For the capillary constant, a^2, G. Quincke gave 9.98 ; H. Siedentopf, 9.778 ; L. L. Grünmach, 9.060 ; G. Tammann, 9.778 ; S. W. Smith, 8.12–8.36. R. Lorenz and A. Liebmann observed that the surface tension of molten lead in contact with molten lead chloride increases if potassium chloride is present, and this the more the higher the temp. T. K. Rose found that tellurium lowers the surface tension of gold so that the bead of gold is flattened during cupellation, and absorbed by the cupel. Hence the loss of telluriferous gold on cupellation. I. Traube gave for the **internal pressure** of lead 51,500 megabars or $51,500\times10^{-6}$ dynes per sq. cm. ; and T. W. Richards, 53,000 megabars. J. H. Hildebrand and co-workers calculated relative values for the internal press. of the metals. J. J. van Laar showed that the mol. attraction is probably very strong. M. von Wogau [9] found the coeff. of **diffusion** of lead in mercury at 9.4° to be 1.50 per sq. cm. per day, and at 99.2°, 1.92 per sq. cm. per day ; G. Meyer gave 1.37 per sq. cm. per day at 15.6° ; and R. Kremann and A. Hrasovec made some observations on this subject. W. C. Roberts-Austen gave for lead in tin at 500°, 3.18 per sq. cm. per day ; for gold in lead, 490°, 3.03, and at 500°, 3.19 per sq. cm. per day ; for platinum in lead at 490°, 1.69 per sq. cm. per day, and for rhodium in lead at 500°, 3.04 per sq. cm. per day ; and G. von Hevesy and co-workers gave 2.22 per sq. cm. per day for the diffusion of thorium-B in lead at 343°. According to W. C. Roberts-Austen, gold diffused in a cylinder of lead to a height of 7.65 cm. in 4 years at 18° ; and C. S. van Orstrand and F. P. Dewey found that while the diffusion of gold into lead (both solid) could be traced a distance of 2.4 cm., that of lead into gold did not exceed 0.2 mm. G. von Hevesy and A. Obrutsheva calculated that the rate of self-diffusion of lead increased from 6×10^{-7} sq. cm. per day at 260° to 1.4×10^{-4} sq. cm. per day at 324°.

Lead emits a peculiar odour when rubbed between the fingers ; the smell is probably not due to the metal, but to the organic substances—the fingers, for example, which come in contact with it. According to J. Percy,[10] lead is feebly elastic or sonorous, and it furnishes a dull sound when struck with a hard substance ; and the dullness of the sound, the " leaden-ring," is proportionate to the purity of the metal. R. A. F. de Réaumur reported that in 1726, L. Lemery discovered *par un pur hazard*, that if lead be cast into the shape of a segment of a sphere—*i.e.* mushroom-shaped—it has the novel and remarkable property of emitting sharp notes when struck with another piece of lead. The sonorous lead is rendered dull by hammering. C. Neumann also stated that lead cast into the form of a hollow spherical or elliptical segment, is very sonorous. R. A. F. de Réaumur attributed the sonorous quality to the shape of the grains and to the way they touch one another. If the rounded grains are flattened by hammering, the elongated grains fill the interstitial spaces, and the particles are no longer free to vibrate, and the lead then emits a dull sound when struck. The **velocity of sound** in lead, according to G. Wertheim, is 1320 metres per second ; and, according to A. Masson, and W. Herz, in soft-lead at 15°–20°, 1227.4 metres per second.

D. Saito and K. Hayashi [11] measured the fluidity of molten lead. According to C. E. Fawsitt, molten lead is about three times as viscous as water ; at 330°, the viscosity of lead was 0.0320, and at 347°, 0.0293. A. Mesnager obtained 0.029 for the viscosity. M. Plüss made observations on some alloys of lead. R. Arpi found the **viscosity,** η, of molten lead, in an atm. of hydrogen, to be

	340°	376°	419°	470°	550°
Viscosity	0.0189	0.0167	0.0160	0.0144	0.0144

The **malleability** of lead at ordinary temp. is large, and the metal may be rolled into thin sheets. Sheet-lead was formerly made by casting, but the resulting sheets were often defective owing to blow-holes, sand-holes, and uneven thickness. The manufacture of sheet-lead by rolling dates from about 1670, and was not adopted without strong opposition. Lead is flexible and pliable. It becomes harder with

mechanical work—rolling, hammering, etc.—but acquires its original softness by annealing. H. S. Rawdon [12] and co-workers examined the brittleness of lead produced by stress and corrosion. As shown by J. Percy, Z. Jeffries, P. Ludwick, and G. W. A. Kahlbaum and E. Sturm, the **ductibility** of lead is not so marked as its malleability, and it cannot be drawn into fine wire, although lead wire about $\frac{1}{18}''$ diameter is manufactured and used by gardeners in fixing trees to walls, etc. When at the right temp. lead may be worked in the same way as macaroni and squeezed into solid or hollow cylinders. Lead-piping, for instance, is made by squirting, a process in which lead is forced by hydraulic press. through the annular space between a die and a mandrel.[13] If the temp. be near the m.p. of lead, the metal becomes brittle, and an ingot can be broken to pieces by striking with a hammer. The fracture is then columnar.

J. Percy [14] reported the accidental formation of a fine hair-like mass of lead—*lead-moss* or *lead-wool*—on the outside of a pot of lead when the lead after desilverization was left to solidify. The liquid lead appeared to have been forced through a minute hole in the pot.

When two plane and clean surfaces of lead are pressed together, they adhere with great tenacity. Such surfaces are produced by cutting, say, a leaden bullet in half with a knife, and pressing, with a screwing or twisting movement, the halves together on their cut surfaces. In T. Dobbs' patent,[15] adhesion is effected between tin and lead by passing superimposed ingots of these metals through a rolling machine. J. Fournet considers this kind of cohesion as true welding, being dependent on the softness of the metal at ordinary temp. As indicated by J. Percy, the requisite softness for welding iron is induced only at a high temp.; so that the heat acts on iron by producing the necessary softness which in the case of lead exists at ordinary temp. According to P. A. Bolley, lead in a fine state of sub-division can by press. be made into a solid mass. W. Spring also claimed that at 2000 atm. press., plates of lead form a compact mass. On the contrary, W. Hallock said that not the slightest change occurs even at 6000 atm. press., and no signs of melting were observed. The increase in vol. which occurs when lead is melted is cited in evidence that lead cannot be liquefied simply by increasing the press. (**1**, 9, 4; and **1.** 13, 18)); but the m.p. of a solid is always lowered when the press. acts on the solid, but not on the liquid. W. Rosenhain and P. A. Tucker could obtain only a conglomeration of tin and lead by compression at 35 tons per sq. in. H. S. Rawdon studied the intercrystalline brittleness of lead.

In 1830, G. Coriolis [16] gave an account of some *expériences sur la résistance du plomb à l'écrasement* made with the quaint object of finding if the resistance which lead offers to crushing under pressure could be utilized to make a simple machine to act as a substitute for the weigh-bridge used for weighing carts, waggons, etc. The great influence of the duration of the press. on the resistance of the lead showed the idea to be impracticable. T. W. Richards and co-workers gave $2\cdot33\times10^{-6}$ for the coeff. of **compressibility** of lead at 20°, between 100 and 500 megabars press. when that of mercury is $3\cdot95\times10^{-6}$. L. H. Adams and co-workers gave $2\cdot21\times10^{-6}$ at 0 megabar and at 10,000 megabars $2\cdot16\times10^{-6}$, corresponding with a 2 per cent. decrease of compressibility when the press. changes from 0 to 10,000 megabars; and for the volume change δv when the press. changes $p-p_0$, $\delta v=0\cdot8\times10^{-4}+2\cdot202\times10^{-6}(p-p_0)+0\cdot24\times10^{-11}(p-p_0)^2$. P. W. Bridgman found rather higher values for the coeff. of compressibility; and gave for $\delta v/v$, for cast rods, $-10^{-7}(23\cdot73-17\cdot25\times10^{-5}p)p$ at 30°, and $-10^{-7}(24\cdot33-17\cdot7\times10^{-5}p)p$ at 75°; while for an extruded sample, $-10^{-7}(23\cdot05-12\cdot3\times10^{-5}p)p$ at 30°, and $-10^{-7}(23\cdot63-12\cdot3\times10^{-5}p)p$ at 75°. E. H. Amagat gave $2\cdot761\times10^{-6}$ for the compressibility coeff. H. J. Coe found the break-down press. of lead to be $1\cdot12$-$1\cdot17$ tons per sq. in., and the elastic limit $0\cdot05$ ton per sq. in. Observations were also made by J. Johnston. E. Grüneisen measured the compressibility between the temp. of liquid air and 165°. W. Hallock found no flow of the metal under a press. of 6000 atm.

B. B. Lera found lead agreed with the relation $\frac{4}{3}aD/\beta A$ =constant, where a denotes the coeff. of expansion, β the coeff. of compressibility, D the density, and A the at. wt. of the metal.

The **tensile strength** of lead is small. J. J. Berzelius [17] found the breaking load to be 14·75 kgrms. for a wire 0·3 mm. diam. ; P. Berthier gave 9 kgrms. with a wire 0·2 mm. diam. ; A. Baudrimont, 6·5 kgrms. with a wire 1·8755 mm. diam. G. Wertheim, working with lead reduced from the nitrate, found that, between 15° and 20°, cast lead broke with a load of 1·25 kgrms. per sq. mm. when applied slowly, and with 2·21 kgrms. per sq. mm. when applied quickly ; for drawn lead, 2·07 kgrms. per sq. mm. when applied slowly, and 2·36 kgrms. per sq. mm. when applied quickly ; and for annealed lead, 1·80 kgrms. per sq. mm. when applied slowly, and 2·04 kgrms. per sq. mm. when applied quickly. At 100°, annealed lead broke with a load of 0·54 kgrm. per sq. mm. C. Bach found 0·635–1·26 kgrm. per sq. mm. for cast lead ; 0·835–2·735 for rolled lead ; and 2·13–2·325 for lead wire. H. J. Coe found the maximum load in tension for lead annealed at 100° to be 1·17 tons per sq. in. ; the elastic limit, 0·05 ton per sq. in. ; and the elongation in length, 67·3 per cent. ; and the metal was reduced to a point. G. Lunge and E. Schmid said that the presence of 0·02 per cent. of copper raised the tenacity of lead. K. Karmarsch found that lead elongates considerably before it breaks. Thus a wire 42·15 cms. long and 1·6 mm. diameter extended to 213·1 cms. before it broke. Much, however, depends on the time during which rupture is effected. According to J. Dewar, cast lead rods, 0·2 in. in diameter, broke under a load of 77 lbs. at 15°, and 172 lbs. at −182°. Thus, the cooling raised the tenacity to twice its usual value. The elongation at −182° was found to be equal to that at 15°. P. Ludwik, and D. H. Ingall studied the relation between tensile strength and temp. P. Ludwik investigated the action of alternating stresses on the mechanical properties of lead. G. Respondek used X-rays to detect pores and flaws in the metal. H. S. Rawdon and co-workers found that the metal under tension is more easily attacked by acids. Observations were made by H. S. Rawdon, L. Archbutt, and Z. Jeffries. H. L. Heathcote and co-workers found the **tearing test** is 220 lbs. per linear inch on a thickness 0·075 in., meaning the load required to tear the metal apart. R. H. Greaves and J. A. Jones measured the notched bar **impact test**— *vide* Fig. 14, **7**. 46, 4.

According to P. Lagerhjelm, the **elasticity** of lead is about one-tenth that of wrought iron. J. Thoulet made some observations by means of pendulums. J. Dewar found that the elasticity of the metals cooled to −182° is markedly greater than at ordinary temp. The flattened surface produced by dropping a leaden sphere at −182° on an iron anvil is one-third the diameter of that produced under similar conditions with a leaden sphere at 15°. G. Wertheim found the **modulus of elasticity, or Young's modulus,** for cast lead is 1803 kgrms. per sq. mm., and for annealed lead, 1727 kgrms. per sq. mm. E. H. Amagat gave 1556 ; C. Schäfer, 1493 ; E. Grüneisen, 1656–1786 ; and A. H. Stuart, 1800 kgrms. per sq. mm. G. Wertheim found the elastic modulus of annealed lead fell from 1727 to 1630 kgrms. per sq. mm. by raising the temp. from 15° to 1000°. W. Sutherland gave 1900 (extremes 1490–2550) kgrms. per sq. mm. at 0°, and estimated 2700 kgrms. per sq. mm. at −273°, absolute zero. A. Mallock gave 1·80 for the ratio of Young's modulus at −273° to that at 0°. A. Kürth, A. Mallock, and C. Schäfer measured the effect of temp. on the elasticity of lead ; and K. R. Koch and C. Dannecker found a steady fall in the elasticity as the temp rises to 220°. G. Wertheim gave 2500 kgrms. per sq. mm. for the **elastic limit** of drawn lead, and 2000 kgrms. per sq. mm. for annealed lead. O. Faust and G. Tammann gave 2500 kgrms. per sq. mm. for drawn lead ; and they measured the elastic limit as evidenced by the appearance of slip-bands in the crystals. K. R. Koch and R. Dieterle found for the elastic modulus, in kgrms. per sq. mm. :

	13°	89°	150°	195°	250°
Elastic modulus . . .	2010	1930	1790	1685	1560

T. Kikuta measured the logarithmic decrement of wires of the metal. For **Poisson's ratio,** A. Mallock gave 0·375 ; E. H. Amagat, 0·428 ; and C. Schäfer, 0·431. H. Shoji studied the elastic after-effect. For the **rigidity** or **torsion modulus,** C. Schäfer gave 550 ; H. Tomlinson, 740 ; W. Sutherland, 840 ; and F. Horton, 814 kgrms. per sq. mm. ; K. R. Koch and C. Dannecker gave for the torsion modulus in kgrms. per sq. mm. :

	20°	50°	100°	150°	200°	235°
Torsion modulus . . .	780	743	667	597	539	244

For the temp. coeff., C. Schäfer gave 78·7, and N. Katzenelsohn, 80. W. Sutherland gave 0·773 for the ratio of the rigidity at 100° to that at zero ; T. Kikuta found the rigidity of lead at 12·5° is 7·098 × 10^10, and remains constant up to 100° ; at 122°, 5·64 × 10^10 ; at 253°, 3·485 × 10^10, and it continues decreasing until it vanishes at the m.p., 327°. P. P. Lazareff discussed the relation between the elastic constants and the hardness of lead.

The linear coeff. of **thermal expansion** of lead was determined by P. S. Laplace and A. L. Lavoisier,[18] who gave $0·0_42848$; A. Matthiessen gave $0·0_42799$ between 0° and 100° ; F. C. Calvert and R. Johnson, $0·0_33005$; P. Glatzel, $0·0_42936$ between 16° and 100° ; H. Fizeau, $0·0_42924$ at 40°, and $0·0_42918$ at 50° ; and G. Vicentini and D. Omodei, $0·0_4295$ at about 320°. E. Grüneisen gave $0·0_4293$ between 17° and 100°, and $0·0_4270$ between −190° and 17° ; J. N. Friend and H. Vallance gave $0·0_4295$ between 10° and 100° ; and R. Hoffmann and W. Stahl, 0·000168 (cubic) between 0° and 600°. C. H. Lindemann found between 19° and −190°, $0·0_4265$; between −83° and −190°, $0·0_4196$; and between −192° and −253°, $0·0_4188$. H. Kopp found the coeff. of cubical expansion between 0° and 100° to be $0·0_589$; and A. Matthiessen gave for the vol., v at θ, $v = v_0(1 + 0·0_481177\theta + 0·0_52220\theta^2)$, where v_0 represents the vol. at 0°. G. Vicentini and D. Omodei gave for the coeff. of cubical expansion of liquid tin between 325° and 357°, $0·0_3129$. P. W. Bridgman found the proportional change of the coeff. of linear expansion, a, with press., p, to be $−da/adp = 1·51 × 10^{−5}$ for cast lead, and $1·46 × 10^{−5}$ for extruded lead. The relations between the coeff. of thermal expansion and other physical properties have been discussed by H. Buff, E. M. Lémeray, P. Frenchen and V. Poulsen, T. Carnelley, E. Grüneisen, J. Kleiber, and C. H. Lindemann. H. Buff calculated what he called the heat of expansion from the relation for that of expansion $= DSa/\beta$, where D denotes the sp. gr. ; S, the sp. ht. ; a, the coeff. of linear expansion ; and β, the coeff. of cubical expansion.

According to C. M. Despretz,[19] if the **thermal conductivity** of silver be 100, that of lead is 14 ; G. Wiedemann and R. Franz gave 8·1 ; and F. C. Calvert and R. Johnson, 28·7. R. Schott working with commercial and purified samples obtained with the former respectively 0·114 cal. per cm. per sec. at −252·6° ; 0·108 at −246·8° ; 0·095 at −187·3°, and 0·079 at 0° ; and with the latter, 0·138 at −252·4° ; 0·117 at −247·1° ; 0·092 at −187° ; and 0·089 at 0°. The first, and the last two of the following determinations are by W. Meissner, and the others are by P. Macchia :

	−252·8°	−183°	−12°	25°	43°	80°	100°	200°
Conductivity .	0·116	0·1080	0·0921	0·0825	0·0795	0·0782	0·084	0·084

Other determinations were made by C. H. Lees, H. Lorenz, H. F. Weber, G. Kirchhoff and G. Hansemann, T. Peczalsky, A. Berget, C. D. Bidwell, M. F. Angell, and W. Jäger and H. Diesselhorst. M. O'Day gave 0·0877 at 0° ; 0·0920 at 26·5° ; and 0·0955 at 53·1°. G. Glage gave 0·244 for the temp. coeff. of the conductivity at 40°. M. Jakob gave 0·095 at −180° ; 0·085 at 0° ; 0·080 at 100° and at 200° ; and 0·075 at 300°. S. Konno's observations over a range beyond the m.p. (327°) are :

	0°	100°	200°	300°	400°	500°	600°	700°
Conductivity . .	0·083	0·081	0·077	0·074	0·038	0·037	0·036	0·036

These results show that the thermal conductivity of lead decreases with a rise of

temp. up to the m.p., and there is an abrupt decrease at the m.p. According to S. Lussana, the thermal conductivity is 2·04 per cent. greater at 1300 atm. press., and 3·60 per cent. greater at 2600 atm. press. than it is at one atm. ; while P. W. Bridgman found a 20·7 per cent. linear increase at a press. of 12,000 kgrms. per sq. cm., and an average press. coeff. of $0·0_4173$; S. Lussana gave for the average press. coeff. $0·0_4134$ at 2600 kgrms. per sq. cm.—the initial value was $0·0_4164$, and the final value $0·0_4116$. C. H. Lees and J. E. Calthorp found the thermal conductivity is decreased by twisting lead wires—approximately proportionally with the twist per unit length.

P. L. Dulong and A. T. Petit [20] gave 0·0293 for the **specific heat** of lead ; H. V. Regnault, 0·0314 ; H. Kopp, 0·0315 between 19° and 48° ; L. Lorenz, 0·0308 at 0° and at 100° ; H. Tomlinson, 0·03151 from 0° to 100° ; H. E. Schmitz, 0·03046 from 20° to 100° ; C. I. Burton and W. Marshall, 0·0320 ; H. Schimpff, 0·0297 ; L. Schütz, 0·03171 ; A. Bartoli and E. Stracciati, 0·030887 ; and W. Spring, 0·03050 from 17° to 108° ; 0·03195 from 13° to 191° ; 0·03437 from 16° to 292°. A. Naccari gave

	15°	50°	100°	150°	200°	250°	300°
Sp. ht.	0·02993	0·03040	0·03108	0·03176	0·03243	0·03312	0·03380

U. J. J. le Verrier, and E. Cohen showed that the sp. ht. depends on the thermal history of the metal ; thus, G. W. A. Kahlbaum and co-workers found the sp. ht. of the unpressed metal to be 0·03033, and of metal which had been exposed to a press. of 10,000 atm., 0·03083. F. Glaser gave 0·031708 for the sp. ht. of hard-lead containing 0·3 per cent. of antimony, and for purified lead, 0·047063. P. Schübel gave 0·0318 between 18° and 200°, and 0·0326 between 18° and 300°. E. Bède represented the effect of temp. by $c=0·0286+0·0000019\theta$; A. Naccari, by $c=0·0297+0·00001358\theta$; and E. H. and E. Griffiths, by $c=0·03020(1+0·0_3400\theta-0·0_8 36\theta^2)$. Low temp. observations were made by W. Nernst and co-workers, U. Behn, H. Barschall, F. Koref, T. W. Richards and F. G. Jackson, E. H. and E. Griffiths, J. Dewar, C. Forch and P. Nordmeyer, etc. A. Eucken and F. Schwers gave for the sp. ht. and the **atomic heat** :

	2·0°	−187·0°	−218·6°	−225·7°	−232·9°	−247·6°	−258·9°
Sp. ht.	0·0307	0·0279	0·0257	0·0248	0·0232	0·0169	0·0075
At. ht.	6·365	5·790	5·333	5·131	4·801	3·510	1·56

The last datum is by W. H. Keesom and H. K. Onnes. For the formulæ relating the sp. ht. with temp. in the vicinity of the absolute zero, vide 1. 13, 15. W. R. Fielding estimated that the sp. ht. is zero at −267°. H. Schimpff found the sp. ht. of lead and bismuth decreases with rise of temp., whilst that of the other metals tried increases. The relation of the sp. ht. to other constants has been discussed by C. H. Lindemann, W. Nernst and co-workers, J. Kleiber, etc. F. Glaser found that whilst the sp. ht. at 18°–198° is 0·0317, that between 18° and 380° is 0·0471 (m.p. 327°) ; W. Spring gave 0·03556 for the sp. ht. at 310°, and 0·04096 at 360°. I. Iitaka found that the sp. ht. of lead decreases during its passage through the liquid state, being 0·0358 at 327° with solid lead, and 0·0340 at 327° with molten lead. W. M. Latimer studied the relation between the sp. ht. and the thermoelectric force ; and F. Michaud compared the ratio of the sp. ht. to the absolute temp. for a number of metals. L. H. Adams calculated the thermal capacity of lead vapour at different press. E. D. Eastman, and G. N. Lewis and co-workers gave 15·53 for the **entropy** of lead at 25° and 1 atm. W. M. Latimer gave 0·03–0·04 for the change of entropy in passing from 200° to 300°. H. Tetrode predicted 41·9 for the entropy of lead vapour at 25° ; and W. H. Rodebush and A. L. Dixon found 41·8. A. L. Bernouilli discussed the relation between the sp. ht. and the elastic constants of lead and some other metals. E. D. Eastman and co-workers made estimates of the thermal energy of the electrons in lead.

Lead is very fusible, and it might be anticipated that the discrepancies, so common in the determination of the **melting points** of the less fusible elements by

the early observers, would not be so marked. The accurate determination of the higher melting-points became possible only with the comparatively recent development of pyrometry. The results with lead are often wide of the mark, and show that sufficient care was not taken to purify the metal under observation. Among the earlier data may be quoted 260° by J. B. Biot [21]; 282° by I. Newton; 296·2° by A. V. Tidblom; 312° by L. B. G. de Morveau; and 322° by J. Dalton, J. F. Daniell, L. B. G. de Morveau, and J. Crichton. F. Rudberg came very near the value accepted at the present day with his 325°, and later 326°, likewise also A. von Riemsdijk with 326°, C. C. Person with 326·2°. The two last-named results are too high, and likewise also A. T. Kupffer with 334°, and G. Brigel with 330°–335°. A large number of determinations have been made in connection with the study of binary and ternary systems of lead with other elements. Thus, K. Friedrich and co-workers, G. J. Petrenko, A. G. C. Gwyer, J. Czochralsky and E. Rassoff, W. E. Barlow, K. Lewkonja, E. Isaac and G. Tammann, N. S. Kurnakoff and N. A. Puschin, E. Jänecke, D. P. Smith, G. Grube, N. S. Kurnakoff and N. J. Stepanoff, G. Voss, R. Ruer, F. Dörinckel, S. Tamaru, and W. Spring and L. Romanoff gave 327°; R. S. Dean, 327·1°; C. H. Mathewson, 326·9°; R. Vogel, A. Stoffel, R. S. Williams, K. Friedrich and A. Leroux, F. Wüst, A. Ledebur, W. Gontermann, and P. N. Degens, 326°; G. Vicentini and D. Omodei, H. Siedentopf, and G. Hindrichs, 325°; A. Stoffel, 321·5°; H. Fay and C. B. Gillson, 322°; and N. Baar, and L. Donsky, 330°. C. T. Heycock and F. H. Neville gave 327·60°; L. J. Dana and P. D. Foote, 327·4°; H. L. Callendar, 327·7°; H. L. Callendar and E. H. Griffiths, 327·69°; W. R. Mott, 327·4°; L. Holborn and A. L. Day, 326·9°; C. W. Waidner and G. K. Burgess, 327·43°; E. H. Griffiths gave 328·78°; H. Tsutsumi, 328·4°; A. L. Day and R. B. Sosman, 327·3°; L. H. Adams and J. Johnston, 327·3°. The best representative value is 327·4°, in agreement with W. Guertler and M. Pirani. C. W. Waidner and G. K. Burgess found evidence of a slight undercooling during the freezing. C. T. Heycock and F. H. Neville measured the effect of small additions of various metals on the f.p. of lead, and applied F. M. Raoult's law to the results. A. Wertheimer, and T. Carnelley found the m.p. of lead, fitted with the application of the periodic law to the m.p. of the elements. G. von Hevesy discussed the break-down of the space-lattice during melting. The effect of press. on the m.p. of lead is in harmony with Clapeyron's equation (1. 9, 4), there is the rise in the m.p. of about 0·008026° per atm. J. Johnston and L. H. Adams found :

Press.	1	150	250	350	500	1000	1490	2000 atm.
M.p.	325·35°	326·53°	327·46°	328·12°	329·26°	333·38°	337·35°	341·38°

The results agree very well with the formula $\theta_m - 327·3 = 0·008026p$, showing that the change is a linear function of the press. The change $\delta\theta$ per 1000 atm. is 8·03°, or $d\theta/dp = 0·00803°$ per atm., in agreement with 0·00832° calculated from C. C. Person's datum for the heat of fusion (5·37 cals. per gram), and G. Vicentini and D. Omodei's value 0·003076 c.c. per gram for the change in vol. on melting. According to E. Hagenbach, lead can be melted by *un choc violent*. W. H. Preece found the melting of a wire d mm. diameter by a current of intensity I, occurs when $I = 10·8d^{1·5}$. A. Jouniaux studied the variation of the mol. wt. of lead with temp. calculated from cryoscopic results.

L. Lewin [22] could detect no vapour at all from lead at 500°–520°. According to J. Percy, when lead is heated in air, fumes of lead monoxide are evolved at a bright red-heat, and appear to have a well-marked odour which can be imitated by shaking finely divided litharge in the air of a room. In the absence of air, lead is not sensibly volatilized below a white heat. Lead boils rapidly before the oxyhydrogen blowpipe, but it cannot be distilled like zinc *per se* in closed vessels. In the extraction of zinc from plumbiferous ores, the vapour of zinc is mixed with that of lead. In the process of smelting and cupelling lead, there is an evaporation of lead or of its compounds. In practice, lead is therefore regarded as a volatile

metal, and K. Sander, C. W. Hixon, etc., have cited cases where large proportions of the lead in a charge passed into the flues—*vide supra*, fume-collectors. H. Engel and V. Froboese found that the volatilization of lead during lead burning, etc., is favoured by an excess of oxygen.

P. Berthier reported that when lead is heated in a brasqued crucible to about 1060° there is a 0·5 per cent. loss in weight, and a 9 per cent. loss when heated to 1400°. J. W. Richards calculated values for the **vapour pressure** of lead from those of mercury. J. Johnston represented the vap. press. of lead at $T°$ K. by log $p=8·05 -9900T^{-1}$. He thence computed :

	620°	710°	820°	960°	1130°	1290°	1360°	1640°
p mm.	0·001	0·01	0·1	1	10	50	100	750

H. von Wartenberg gave $1·05 \times 10^{-4}$ atm. at 808°; $2·30 \times 10^{-3}$ at 996°; and $2·20 \times 10^{-2}$ at 1178°. J. H. Hildebrand gave log $p=7·85-10362T^{-1}+$log 3·3. J. A. M. van Liempt found $\log_{10} p=5·05-9521T^{-1}$; and for the sublimation curve, $\log_{10} p=5·54-10030T^{-1}$; W. H. Rodebush and A. L. Dixon gave log $p=-10100T^{-1} -0·65$ log $T+10·05$ mm. between 600° and 900° K. They also calculated values for the entropy of the vapour. A. C. Egerton gave for the vap. press. of molten lead at temp. ranging from 600° K. to 1200° K. log $p=7·908-9923T^{-1}$, and C. K. Ingold found that an equation of the type $\log_{10} p=4·818 -11160T^{-1} +1·750 \log_{10} T-0·000982T'$ in mm. of mercury, represented the results of his observations up to 1130°, but it diverged more and more as the temp. exceeded this limit; the equation $T_{Pb}/T'_{Hg}=3·244-0·00038T_{Hg}$ gave results in close agreement with observations over the whole range; here, T'_{Hg} refers to the absolute b.p. of mercury when under the same pressure as the lead whose absolute b.p. is T'_{Pb}. The observed results are:

	920°	950°	1000°	1050°	1100°	1150°	1200°	1250°	1300°	1340°
p mm.	0·49	0·86	1·77	3·69	4·87	12·8	23·2	37·5	62·0	90·3

O. Ruff and B. Bergdahl gave 73 mm. at 1275° and 758 mm. at 1555°. W. H. Rode-bush measured the vap. press. between 1118° and 1235°, and W. H. Rodebush and A. L. Dixon gave log $p=-10372T^{-1}-$log $T-11·35$, when the press. are expressed in mm. The **boiling point** of lead deduced from these results is 1619°. J. Johnston computed 1640°; O. Ruff and B. Bergdahl, 1555°; T. Carnelley and W. C. Williams, 1600°; W. R. Mott, 1525°; J. J. van Laar, 1870°; H. von Wartenberg, 1580°±20°; and H. C. Greenwood obtained

	105 mm.	266 mm.	760 mm.	6·3 atm.	12·7 atm.
Boiling point	1315°	1410°	**1525°**	1870°	2100°

L. H. Borgström gave 2870° at 93 atm. press. F. Krafft and co-workers observed at a low press. a reduction of 30° in the b.p. of lead corresponding with a change of 45 mm. mercury press.; and in the vacuum of a cathode light, the b.p. was 1144° at 70 mm. They also found that under these conditions lead is distinctly volatile at 335°. P. Walden calculated the b.p. in the cathode vacuum to be 1140°, and at 760 mm., 1700°. According to W. J. Russell, and C. Zenghelis, lead volatilizes at ordinary temp. because a thin plate of silver hanging in a moist atm. over powdered lead, is perceptibly attacked in 24 hrs. W. N. Hartley mentioned the volatilization of lead in the induction sparks; and R. J. Strutt, in the cathode ray vacuum. A. Schuller, and G. W. A. Kahlbaum and co-workers found that lead distils with difficulty under reduced press., and E. Tiede and F. Fischer showed that although tin melts at a lower temp. than lead, its b.p. is much higher, and it is possible to separate the two elements quantitatively by fractional distillation in a cathode light vacuum with the metal contained in a porcelain boat at a bright red heat. H. Moissan and co-workers also made some observations on this subject—*vide* tin. No trace of tin was carried by the vap. of lead. W. Crookes found the rate of volatilization of tin and lead from a negative electrode in vacuo is as 57 : 75 when

the value for gold is 100. W. G. Duffield measured the velocity of evaporation of molten lead. H. F. Wiebe deduced a relation between the b.p., m.p., at. wt., and coeff. of thermal expansion of a number of metals. W. Herz studied some regularities in the vap. press. of lead and other elements; and E. D. Eastman, the heat capacity of the electrons.

J. J. van Laar estimated the **critical temperature** of lead to be 3000°, and the **critical pressure,** 370 atm. C. M. Guldberg gave 2000° for the critical temp. if that of mercury is 1000°; P. Walden gave 3598°; and W. Herz, 2696°. F. Rudberg gave 5·86 cals. per gram for the latent **heat of fusion;** C. C. Person, and D. Mazzotto, 5·37 cals.; E. Glaser, 4·78 cals; W. Spring, 5·320 cals.; P. W. Robertson, 6·45 cals.; and I. Iitaka, 5·53 cals. per gram. A. C. Egerton gave 47000 ± 1000 cals. for the latent heat of vaporization of solid lead at absolute zero; that of molten lead which varies a little with the temp. up to 1200° is about 45,350 cals. The so-called radioactive lead has a slightly higher value than ordinary lead. H. C. Greenwood gave 45,500 cals. per mol. for the **heat of vaporization** of lead; J. Tate, 175 cals. per gram at 1170°; W. H. Rodebush and A. L. Dixon, 46,300 cals.; and J. A. M. van Liempt, 43,590 cals. per mol. For **Trouton's constant,** the last-named found 23·12. A. Henglein gave 0·174 Cal. for the mol. heat of evaporation. H. von Wartenberg calculated 44,000 cals. for the inner heat of vaporization, and from the **vapour density** he inferred the molecule to be monatomic at 1870°. F. Simon gave 2·66 for the **chemical constant** of lead; and W. H. Rodebush and A. L. Dixon gave $-1·40$ in agreement with $-1·588$ required by the quantam theory.

According to S. Haughton,[23] the **index of refraction** of lead for red light is 2·2; P. Drude gave for rays of wave length $0·589\mu$, 2·01 for the index of refraction; 3·48 for the **absorption index;** and the **reflecting power,** 62 per cent. H. von Wartenberg gave 2·01 for the index of refraction of lead for light of wave-length $0·589\mu$; 3·48 for the absorption coeff.; and 62 per cent. for the reflecting power. A. K. Aster found the index of refraction of molten lead to be 0·415, and the absorption coeff. 1·76; and that both were independent of the temp. L. Austin and H. Starke said that the reflecting power of lead is 63 per cent. of that of copper. M. A. Schirmann studied the polarization of light by the colloidal particles of lead. J. H. Gladstone found the **specific refraction** of lead to be 0·117–0·129; and 24·5–26·7 for the **atomic refraction;** E. Krause and co-workers gave 18·89; and W. J. Pope gave 30·02 for the at. refraction. P. Niggli studied this subject. C. A. Valson examined the refractive power of lead in soln. of its salts; G. Grüttner and E. Krause, the refractive power of quadrivalent lead in the lead tetralkyl compounds; and H. Grossmann, the effect of lead salts on the refractive index of sugar. M. Faraday found thin films of lead depolarized and rotated a ray of polarized light as in the case of thin films of gold.

The ultra-violet **fluorescence** of lead compounds was studied by E. Wiedemann and G. C. Schmidt,[24] and of the vapour by H. Kopfermann; the **cathode ray** luminescence, by P. Schuhknecht; and the effect of lead salts on the luminescence of calcium sulphide, by P. Lenard and V. Klatt. P. Lewis examined the spectrum of the vapour luminescent in the cathode rays; and V. Carlheim-Gyllensköld, the luminescence in the **canal rays.** G. Dima[25] studied the **photoelectric effect** of lead oxide and lead halides. W. Ramsay and J. F. Spencer placed lead after cadmium and before bismuth in the order of their photoelectric effect; K. Herrmann placed it after cadmium and before copper; and R. A. Millikan and G. Winchester placed it after zinc. O. Stuhlmann found 1·12 for the ratio of the photoelectric effect on two sides of a lead film in air. The phenomenon was studied by G. Reboul. The limiting frequency of the photoelectric effect is $\lambda = 2980 \pm 50$. S. Maracineanu reported that lead may be excited by solar radiations and, for a few months, shows slight ionizing properties; causes scintillations on a screen of zinc sulphide; and darkens a photographic plate provided water vapour is present. The subject was discussed by A. Kufferath and W. Merckens, and G. L. Keenan.

A magnetic field, heat, pressure, and friction may also be used to excite lead. N. Piltschikoff found that lead emits positive Moser rays.

J. A. McClelland [26] studied the effect of **radium radiations** on lead; and showed that the intensity of the secondary radiation invoked increases with the at. wt. of the elements. W. H. Bragg measured the stopping powers of various substances for the α-**rays**, and found the stopping power of lead to be 4·27 (air unity). The subject was studied by Y. Tuomikoski, M. Ishino, J. Thibaud, C. D. Ellis, A. H. Compton, H. A. Bumstead and A. G. McGougan, N. R. Campbell, etc. H. R. von Traubenberg gave $24·1 \times 10^{-4}$ cm. for the range of the α-rays in lead. J. A. Crowther found for the ratio of the coeff. of absorption, μ, and the density, for the β-**rays**, $\mu/D = 10·8$ when that of copper is 6·8. Further observations were made by W. Wilson, W. B. Huff, J. S. Latès and G. Fournier, etc. J. Thibaud studied the β-rays of lead. A. S. Russell and F. Soddy found the coeff. of absorption, μ, for the γ-**rays** of radium 0·495 per cm.; γ-rays of uranium, 0·725 per cm.; thorium-D, 0·462 per cm.; and for mesothorium, 0·620 per cm. The subject was studied by Y. Tuomikoski, M. Ishino, J. Thibaud, C. D. Ellis, A. H. Compton, M. Baltruschat and H. Starke, N. Ahmad, B. Keetman, H. Richardson, E. Rutherford and co-workers, etc. The δ-**rays** from lead were studied by N. R. Campbell. A. T. Waterman observed the emission of no characteristic positive ions from heated lead halides. The **radioactivity of lead** was examined by J. Elster and H. Geitel, E. Rutherford, K. A. Hofmann and co-workers, H. Geitel, M. Levin and R. Ruer, J. Danysz, B. B. Boltwood, C. S. Wright, C. Winkler, H. Herchfinkel, A. Debierne, A. Korn and E. Strauss, J. C. McLennan, etc. According to M. Muguet, the radioactivity of lead from the uranium ores of Madagascar increased 12-fold during six months.

The absorption of **X-rays** by lead was studied by T. E. Aurén,[27] W. Duane and co-workers, E. A. Owen and co-workers, K. W. F. Kohlrausch, J. C. Chapman, K. A. Wingardh, D. Hurmuzescu, G. Fournier, H. S. Read, S. J. M. Allen, F. P. Slater, G. Holtsmark, F. K. Richtmyer, L. Benoist, E. Rutherford and co-workers, C. D. Cooksey, G. W. C. Kaye and R. A. Houstoun—*vide* 4. 25, 6. For rays of wave-length λ Angström units, the ratio of absorption coeff., μ, and the density, D, is, according to A. W. Hull and M. Rice, for wave-lengths greater than 0·149 A., the

λ	.	.	0·294	0·245	0·221	0·196	0·184	0·160	0·147
μ/D	.	.	11·10	6·70	4·63	3·40	2·71	1·82	1·50

The absorption is given by $\mu/D = 430\lambda^3 + 0·12$; below 0·149 A., there is a sudden increase in the values of μ/D, owing to the presence of a characteristic absorption band, which was also observed by L. de Broglie. E. Rutherford found that the thickness of lead through which the radiation was measureable increased with the voltage applied, being 3·1 mm. with a voltage of 79,000; 4·6 mm. with a voltage of 10,500; 7·0 mm. with a voltage of 183,000; and 10·0 mm. with a voltage of 196,000. W. E. Williams and B. L. Worksop found the critical frequency for the K-absorption $21·58 \times 10^{18}$ per sec. H. S. Read studied the effect of temp. on the X-ray absorption. G. W. C. Kaye and E. A. Owen examined the absorption of the rays by various substances. Injurious effects—X-ray burns—are produced by the absorption of very soft X-rays by the skin. Most of the protective devices— gloves, aprons, spectacles, etc.—depend on the absorption properties of lead salts. C. G. Barkla and J. G. Dunlop studied the scattering of X-rays by lead, and found for the ratio of the scattering coeff., σ, and the density, D, referred to that for aluminium to be for

σ	.	.	0·63	0·52	0·43	0·316	0·314	0·305

K. E. F. Schmidt studied the refraction of the X-rays by lead; J. Herweg, the polarization of these rays; G. Shearer, the emission of electrons; P. D. Innes, the velocity of the electrons emitted by lead under the influence of X-rays;

W. Seitz, the asymmetry of the X-rays from lead; C. G. Bedreag, electrification by the X-rays; H. A. Blumstead, the heating effects of X-rays; K. W. F. Kohlrausch, and P. Curie and G. Saynac, J. C. Chapman, the secondary radiations from different metals; J. Cluzet and T. Kofman, the effect of lead on the action of X-rays on colloidal metals; and M. Wolfke, the production of X-rays by the action of canal rays on lead.

The **X-ray spectrum** was examined by M. and L. de Broglie,[28] B. B. Ray, E. C. Stoner, D. Coster, H. Robinson, G. Kettmann, P. A. Ross, H. Hirata, G. Réchou, K. Lang, J. Laub, H. Küstner, E. Hjalmar, H. G. J. Moseley, C. G. Barkla, H. Robinson and W. F. Rawlinson, E. Rutherford and co-workers, M. Siegbahn and co-workers, W. Stenström, E. G. Taylor, etc. The K-series were reported on by W. Duane and co-workers, A. Leide, B. R. Stephenson and J. M. Cork, M. Siegbahn and E. Jönsson. M. de Broglie, C. D. and D. Cooksey, D. Coster, W. Duane and co-workers, and M. Siegbahn found for the L-series in Angström units, 10^{-8} cm., $a_2a'=1 \cdot 18352$, $a_1a=1 \cdot 17202$; $\beta_1\beta=0 \cdot 97990$; $\beta_2\gamma=0 \cdot 97990$, $\gamma_1\delta=0 \cdot 83708$; $\epsilon=1 \cdot 34662$; $\eta=10902$; $\beta_6=1 \cdot 0188$; $\beta_7=0 \cdot 9590^2$; $\beta_8=0 \cdot 9735$; $\beta_5\zeta=0 \cdot 9452$; $\gamma_2\theta=0 \cdot 8182$; $\beta_4v=1 \cdot 00469$; $\beta_3\phi=0 \cdot 96602$; $\gamma_5=0 \cdot 8639$; $\gamma_6=0 \cdot 81370$; $\gamma_3\chi=0 \cdot 8379$; and $\gamma_4\psi=0 \cdot 8100$. G. Wentzel, G. Kettmann, F. K. Richtmyer, and M. Siegbahn reported for the K-series, $a_1=5 \cdot 290$; $a'=5 \cdot 287$; $a=5 \cdot 2851$; $\beta=5 \cdot 0648$; $\beta_1=5 \cdot 078$; $\gamma=4 \cdot 6637$; $\gamma_1=4 \cdot 534$; $\gamma_2=4 \cdot 073$. S. J. M. Allen, and F. W. Warburton and F. K. Richtmyer studied the adsorption coeff. for the X-rays.

Lead salts impart to Bunsen's flame a bluish tinge, and give a **flame spectrum** of what is presumably the oxide, and show some bands. The flame spectrum was studied by H. Auerbach,[29] R. Böttger, L. de Boisbaudran, E. Diaçon, J. M. Eder and E. Valenta, A. Gouy, A. Hagenbach and H. Konen, A. Harnack, W. N. Hartley, O. Vogel, and C. de Watteville. The band spectra, and the spectra of lead compounds were examined by G. Ciamician, E. Diaçon, W. N. Hartley and H. Ramage, H. Lamprecht, A. R. Leeds, A. Mitscherlich, and E. Wiedemann.

The spectrum obtained by heating lead in an electric furnace was examined by A. S. King. The **spark spectrum** of lead was examined by C. Wheatstone in 1835. A flame fed with oxygen playing on lead resting on charcoal gave a continuous spectrum. Numerous records of the spark spectrum have been made—D. Alter, A. J. Angström, L. and E. Bloch, W. von Bolton, L. de Boisbaudran, R. Capron, R. J. Lang, E. Demarçay, J. M. Eder and co-workers, F. Exner and E. Haschek, H. Finger, C. E. Gissing, A. de Gramont, A. Hagenbach and H. Konen, W. N. Hartley and co-workers, J. Hartmann, G. A. Hemsalech, A. C. Jones, A. Kalähne, G. Kirchhoff, J. N. Lockyer, O. Lohse, A. Masson, J. C. McLennan and co-workers, W. A. Miller, S. R. Milner, H. W. Morse, J. Parry and A. E. Tucker, J. Plücker and J. W. Hittorf, F. R. Robinson, T. Royds, J. A. Carroll, and J. Wilsing. The most intense lines are 2802·10; 2833·12; 3573·03; 3639·72; 3682·64; 3740·28; 4058·00 (violet) a, Fig. 12; 4167 (violet); 4245·42; 4387·11 (indigo); 5005 (green)β; 5045
FIG. 12.—The Spark Spectrum of Lead.

(green); 5201 δ; 5373 (green) ζ; 5547 (green), 5609·00 (green),γ; and 6002 (orange-yellow). E. O. Hulbert examined the spark spectrum in water and in aq. soln. of lead salts. The **arc spectrum** was examined by A. S. C. Dunstan and B. A. Wooten, J. C. McLennan and co-workers, M. Kimura, J. M. Eder and E. Valenta, K. W. Meissner, F. Exner and E. Haschek, W. Gallenkamp, W. Grotrian, A. Hagenbach and H. Konen, J. Hartmann, A. de Gramont and G. A. Hemsalech,

H. Hertenstein, T. Royds, W. B. Huff, W. Huppers, H. Kayser and C. Runge, H. Köne-
mann, J. C. McLennan and co-workers, N. K. Sur, T. R. Merton, W. R. Mott,
H. A. Rowland, J. Stark and R. Küch, and V. Thorsen. The more intense lines in
the arc spectrum are 2539·92, 2577·39, 2614·39, 2614·26, 2663·27, 2802·10, 2828·31,
2833·21, 2873·48, 3572·95, 3639·72, 3671·80, 3683·52, 3740·20, 4019·80, 4058·00, and
5005·63. B. E. Moore studied the excitation stages in the arc spectrum. The effect of
pressure was examined by W. J. Humphreys; the effect of the *oscillating discharge*, by
P. Joye, G. A. Hemsalech, G. Berndt, and E. Néculcea; the effect of a *magnetic
field*, the **Zeeman effect**, by J. E. Purvis, E. Back, P. A. van der Harst, and
H. Lunelund; the **Stark effect**, by H. Nagaoka and Y. Sugiura; the *reversed
lines*, by A. Cornu; the *enhanced lines*, by M. Kimura and G. Nakamura, and
J. Steinhausen; the *variability* of the spectrum, by L. de Boisbaudran;
and the *sensitiveness*, by F. Brasack, W. N. Hartley and H. W. Moss, and
A. de Gramont. The **ultra-violet spectrum** was investigated by L. and E. Bloch,
R. J. Lang, F. Exner and E. Haschek, J. M. Eder and E. Valenta, G. D. Liveing
and J. Dewar, J. C. McLennan and co-workers, W. A. Miller, A. de Gramont,
R. V. Zumstein, V. Schumann, and G. G. Stokes; and the **ultra-red spectrum,**
by H. Becquerel, A. Bergmann, H. Lehmann, V. P. Lubovich and E. M. Pearen,
R. J. Lang, and H. M. Randall. The structure of the spectrum, or the **series
spectrum,** was studied by R. V. Zumstein, P. G. Nutting, K. W. Meissner,
W. N. Hartley, J. A. Carroll, F. Hund, A. E. Ruark and R. L. Chenault, H. Gieseler
and W. Grotrian, H. Sponer, L. Janicki, V. Thorsen, and H. Lunelund. H. Kayser
and C. Runge found constant difference groups in the spectrum of lead, and these
were verified by F. Klein, and R. Arnolds; otherwise A. Fowler reported that
no typical series have been discovered in the spectral lines of lead. The **absorp-
tion spectrum** of lead vapour was examined by J. N. Lockyer and W. C. Roberts-
Austen, N. K. Sur and R. K. Sharma, J. C. McLennan and co-workers,
W. Grotrian, R. V. Zumstein, E. O. Hulburt, W. Friederichs, J. G. Frayne
and A. W. Smith, A. L. Narayan and K. R. Rao, and H. Geiseler. Both
ends of the spectrum are said to be absorbed. L. Janicki and R. Seliger, and
B. Reismann examined the spectrum of the vapour of lead at the anode of a
discharge tube. Soln. of lead salts are colourless, and give no absorption spec-
trum. They have been examined by C. Schäfer, W. N. Hartley, W. W. Coblentz,
and T. Retschinsky, and absorption bands beyond the visible spectrum have
been observed. T. R. Merton, E. S. Bieler, L. Grebe and H. Konen, and
W. D. Harkins and L. Aronberg compared the spectra of ordinary lead, and
lead from radioactive sources. According to J. Formanek, no characteristic
absorption spectrum is given by a soln. of a lead salt and alkanna. A. P. Weber,
and B. R. Stephenson and J. M. Cork measured the K-series in the **X-ray spectrum**
of lead; and S. J. M. Allen, and F. K. Richtmyer, the L-series. F. L. Mohler
and co-workers found 1·26 volts for the **resonance potential** and 7·93 volts for the
ionization potential of lead vapour. P. A. Ross found the critical potentials of the
M-line $\lambda=5\cdot2751$ to be 2·5 kvolts; the $\lambda=5\cdot0648$ line, 2·7 kvolts; the $\lambda=4\cdot6637$
and 4·073 lines, 3·1 kvolts; and $\lambda=3\cdot94$, and 4·0 kvolts. B. E. Moore examined the
excitation stages in the arc-spectrum of lead. J. E. P. Wagstaff calculated the
vibration frequency of lead to be $1\cdot84\times10^{-12}$. A. Terenin studied the fluorescence
and resonance spectra. A. T. Waterman calculated the conc. of free electrons in
lead to be $1\cdot1\times10^{17}$ per c.c. at 0°, and the value decreases with rise of temp. The
electronic structure with respect to the spectrum of lead was studied by S. Goudsmit.
The cathodic spectrum of lead in a vacuum tube with an aluminium anode was
studied by M. Kimura and G. Nakamura. A. Nodon found that the photogenic
radiations from the sun can penetrate lead, but not metals of lower valency.
H. Könemann examined the spectrum of fluorescent lead vapour; and S. Smith,
that of electrically exploded lead wire.

　　Determinations of the **electrical conductivity** of lead were reported by
A. C. Bequerel,[30] A. Matthiessen and co-workers, J. R. Benoit, A. Arndtsen,

R. Clausius, J. Bergmann and co-workers, H. F. Weber, A. Berget, L. Lorenz, G. Kirchhoff and G. Hansemann, C. Vicentini and D. Omodei, J. Dewar and J. A. Fleming, H. Dickson, L. de la Rive, A. Eucken, etc. The results show that if the conductivity of silver at 0° be 100, that of lead is 8·277 at 0°, 8·245 at 12°, and 5·761 at 100°. J. Dewar and J. A. Fleming, and H. Dickson gave $4·91 \times 10^4$, G. Niccolai, $5·05 \times 10^4$, and J. Bergmann, $5·18 \times 10^4$ mhos at 0°; and W. Jäger and H. Diesselhorst, $4·80 \times 10^4$; W. Meissner, $5·19 \times 10^4$ mhos at 0°, and $4·83 \times 10^4$ mhos at 18°; C. H. Lees gave $5·19 \times 10^4$ mhos at 0°, and $4·84 \times 10^4$ mhos at 18°. G. Kirchhoff and G. Hansemann, and W. Herold traced variations in the conductivity of a lead wire to its heterogeneous structure. The sp. **electrical resistance,** R, given by G. Niccolai is:

	−189°	−150°	−125°	−50°	0°	25°	50°	100°	200°	300°
R . .	6648	9253	10975	16190	19803	22047	23663	27844	38047	49932

A. Schulze gave $0·0_42038$ for the sp. resistance of lead. For the *temperature* coeff. of the resistance, a, in $R=R_0(1+a\theta)$; for temp., $\theta°$, between 0° and 100°, J. Dewar and J. A. Fleming gave 0·0411; W. Jäger and H. Diesselhorst, 0·0428; G. Niccolai, 0·0406; L. Holborn, and F. Henning, 0·0422; C. Cattaneo, −0·00065 between 226·5° and 325°; and P. W. Bridgman, 0·0421; for the molten metal, G. Vicentini and D. Omodei gave $a=0·00052$, and P. Müller gave $a=488$ for the temp. coeff. of the conductivity from 327° to 1000°. S. Konno gave for the sp. resistance R,

	20°	100°	220°	302°	327°	329°	331°	338°	345°	450°	551°	577°
$R \times 10^{-4}$ . .	21·0	25·6	34·1	40·8	43·4	50·8	67·6	81·5	83·0	87·4	91·8	93·0

The change in the electrical resistance of lead on fusion was measured by C. Benedicks, L. de la Rive, A. Schulze, P. Müller, G. Vicentini and D. Omodei, etc. H. Tsutumi found 3·27 for the ratio of the sp. resistance of liquid and solid lead at the m.p. E. F. Northrup and co-workers found the electrical resistance is nearly doubled when the metal melts. The results are graphed in Fig. 13. Expressing the resistance R in microhms per c.c., they found:

R . . .	819°	333°	400°	500°
	50·00	95·00	98·30	102·85
	600°	700°	800°	
	107·25	111·75	116·20	

Fig. 13.—Electrical Resistance of Lead at Different Temperatures.

The curve of the variation of the electrical resistance of lead with temp., Fig. 13, is slightly convex towards the temp. axis; and for the liquid state, a straight line. The highest value for the resistance of the solid before fusion was 49·2 microhms, and 94·7 after fusion. A. Schulze gave 49×10^{-6} for the sp. resistance of the solid at the m.p., and $94·6 \times 10^{-6}$ for that of the liquid. The resistance of lead becomes smaller and smaller as the temp. is reduced; H. K. Onnes and co-workers found the following values referred to lead unity at 0°,

	16·33°	−103·63°	−195·15°	−216·61°	−252·78°	−255·07°	−258·70°
R . .	0·0652	0·59548	0·25257	0·17129	0·03032	0·02314	0·01311

At the temp. of liquid helium, said F. B. Silsbee, or, according to C. A. Crommelin, at 7·3° K., lead becomes a super conductor. W. Tuyn and H. K. Onnes found ordinary lead and radioactive lead behave similarly. Observations at low temp. were also made by E. Grüneisen, H. Schimank, L. Holborn, etc. H. K. Onnes and co-workers stated that the great change in the temp. coeff. exhibited by lead at low temp. in the presence of a small amount of *impurity* must be attributed to the transition of the admixture to a state of solid soln. N. S. Kurnakoff, and S. F. Schemtschuschny found the lowering of the electrical conductivity of lead

by equi-atomic proportions of other metals to be the same. W. Meissner and H. Schimank computed values for the ratio of the resistance at absolute zero to that at $T°$ K. S. Smith measured the electrical resistance of lead vapour. Working with lead containing not more than 1 part of silver and copper in 300,000, and no trace of any other metal, P. W. Bridgman found, for the effect of *pressure* on the electrical resistance,

		0°	25°	50°	75°	100°
Resistance .	. .	1·0000	1·1022	1·2065	1·3127	1·4207
Press. coeff.	0 kgrm.	$-0{\cdot}0_41442$	$-0{\cdot}0_41452$	$+0{\cdot}0_41462$	$-0{\cdot}0_41473$	$-0{\cdot}0_41483$
	12,000 kgrms.	$-0{\cdot}0_41044$	$-0{\cdot}0_41045$	$-0{\cdot}0_41047$	$-0{\cdot}0_41049$	$-0{\cdot}0_41051$
	Average	$-0{\cdot}0_41212$	$-0{\cdot}0_41222$	$-0{\cdot}0_41232$	$-0{\cdot}0_41243$	$-0{\cdot}0_41253$

E. Lisell gave for the press. coeff. at 0°, $-0{\cdot}0_4144$; and W. F. Williams, $-0{\cdot}0_4138$. H. K. Onnes and B. Beckman gave for the press. coeff. at $-183°$, $-0{\cdot}0_4225$, and at $-252{\cdot}7°$, $-0{\cdot}0_4170$. Interpolating the observed values, it was found that the decrease in the resistance per 100 atm. approximates to zero on approaching the absolute zero of temp. E. D. Williamson also studied this subject. Z. A. Epstein examined the relation of the electrical conductivities of the metals to the *periodic law*. H. Tomlinson noted that the resistance of a lead wire was increased when the metal is in *torsion;* L. Guillet and M. Ballay found that cold-hammering raised the resistance very little. C. H. Lees and J. E. Calthrop found the change to be less than in the case of thermal conductivity, but it is approximately proportional to the square of the twist per unit length. O. Chwolson found the resistance increased by *annealing*; and L. L. Grunmach and F. Weidert found a slight increase in the resistance when the metal is transversely *magnetized*. P. W. Bridgman found that the differences in the electrical resistance, and the temp. and press. coeff. of ordinary lead and that from radioactive sources lie within the limits of experimental error. A. Stein discussed the relation between the m.p. and electrical resistance of tin and other metals; and A. T. Waterman, the theory of electrical conduction.

N. A. Hesehus [31] showed that in a closed circuit with hot and cold lead there is no electric current. According to A. Matthiessen, lead stands in the thermoelectric series between magnesium and tin. The **Seebeck effect,** or the **thermoelectric force** of the *platinum-lead* couple at 100°, was found by W. Jäger and H. Diesselhorst to be 0·041 millivolt where the current flows from the lead to the platinum; J. Dewar and J. A. Fleming gave 0·44 millivolt at 100° and 0·21 at $-190°$, and 0·12 at $-100°$; H. Pélabon gave 5·14 microvolts at 100°; K. Noll gave 0·41 millivolt at 100°; and E. Wagner, and E. Rudolfi, 0·46 millivolt. H. Pélabon found the e.m.f. rises linearly with the temp. up to the m.p. of lead. W. M. Latimer studied the thermoelectric force of the *silver-lead couple.* For the *lead-mercury* couple, K. Noll gave 0·41 millivolt at 100°, and 1·03 millivolts at 200°. For the *lead-copper* couple, W. Jäger and H. Diesselhorst gave 2·9 millivolts at 18°, and 3·4 at 100°; E. Wagner gave 3·09 millivolt at 49·2° and 3·23 millivolts at 70·5°. C. Benedicks gave $-2{\cdot}8$ microvolts. H. K. Onnes and G. Holst gave 0·457 millivolt for the lead-copper couple at $-192°$; 0·553 at $-253°$; and 0·559 at 270·74°. P. G. Tait, and H. Pécheux measured the e.m.f. of the lead-copper couple. F. G. Wick gave for the *lead-silicon* couple at $-185°$, 63 millivolts; at 0°, zero; at 100°, -42; at 200°, -77; and at $-300°$, -112 millivolts. For the *lead-constantin* couple P. Cermak gave 0·4 millivolt at 17·4°; 90·2 millivolts at 254°; 118·3, at 325°; 141 at 365°; 147·2 at 383°; and 173·3 at 445°—there is no abrupt change when the lead fuses. K. Siebel measured the values for liquid and solid lead at the m.p. According to G. Wietzel, the thermoelectric force approximates to zero at the absolute zero of temp. Table III was compiled by F. E. Fowle from the results of E. Becquerel, A. Matthiessen, P. G. Tait, and W. Haken. The thermoelectric power, $dE/d\theta$, in microvolts is defined as the e.m.f., E, produced by one degree difference of temp. between the junctions, so that $dE/d\theta = E_0 + a\theta$, where E is the thermoelectric power at 0°, a is a con-

stant, and θ, the mean temp. of the junctions. G. Borelius examined the effect of mechanical work on the thermoelectric power of lead ; and E. Wagner examined the effect of press. on the copper-lead couple. H. Pélabon measured the thermo-electric power of molten lead against solid metals. The **Peltier effect** was measured by E. Edlund, A. Battelli, H. Jahn, P. Cermak, and K. Bädeker. The effect of press. on a couple of compressed and uncompressed lead was measured by P. W. Bridgman, and the results are shown in Table IV. The **Thomson effect**

TABLE IV.—THE EFFECT OF PRESSURE ON THE SEEBECK, PELTIER, AND THOMSON EFFECTS.

Temp.	Seebeck effect. Volts $\times 10^6$			Peltier effect. Joules per coulomb $\times 10^6$			Thomson effect. Joules per coulomb $\times 10^6$		
	Press. kgrms. per sq. cm.			Press. kgrms. per sq. cm.			Press. kgrms. per sq. cm.		
	2000	6000	12000	2000	6000	12000	2000	6000	12000
10°	+0·08	+0·25	+0·52	+2·4	+6·6	+13·8	+1·4	+2·2	+6·0

was examined by P. Cermak, O. Berg, and A. Battelli. G. Borelius and F. Gunneson found that at $-153°$ the Thomson effect is $-0·19$; at $-120°$, $-0·30$; at $-73°$, $-0·45$; at 27°, $-0·68$; and at 127°, 0·85. P. W. Bridgman's observations on the effect of press. with compressed and uncompressed lead are shown in Table IV. The **Corbino effect** was studied by O. M. Corbino, and E. P. Adams and A. K. Chapman. The **Hall effect** was studied by A. von Ettinghausen and W. Nernst, H. Zahn, and P. Drude. H. K. Onnes and co-workers examined the influence of a very low temp. on the Hall effect.

According to W. M. Jones,[32] when lead is rubbed with silk it becomes positively electrified. H. F. Vieweg studied the frictional electricity of lead. S. Procopiu showed that if two lead wire electrodes be in circuit and in water, and one be stirred, it becomes positively electrified ; and R. D. Kleeman and W. Fredrickson, that lead acquires a positive charge when immersed in distilled water, and A. Coehn and A. Lötz said that when shaken in an evacuated glass tube, it acquires a positive charge. A. Coehn and A. Curs studied the contact electricity of lead for quartz, and glass. J. Erskine-Murray measured the contact potential of lead and gold alone or in the presence of water or alcohol. The **Volta difference of potential** of two metals in contact in air varies with the condition of the metal surface and the nature of the surrounding atm. W. E. Ayrton and J. Perry gave for ordinary commercial metals at 18° in volts,

	C	Pt	Cu	Brass	Fe	Sn	Zn	Zn-Hg
Pb .	−0·858	−0·771	−0·542	−0·472	−0·401	−0·099	0·210	0·357

Observations were also made by W. Hankel, H. Pellat, and F. Exner and J. Tuma, A. Volta, J. W. Ritter, T. Seebeck, J. C. E. Péclet, P. S. Munk af Rosenschöld, J. M. Gaugain, J. C. Poggendorff, and C. H. Pfaff placed lead near the middle of the **electrochemical series:**

K, Ba, Mg, Al, Mn, Zd, Cd, Fe, Co, Ni, Sn, **Pb,** H, Cu, Bi, Sb, Hg, Ag, Pd, Pt, Au.

A. Coehn and A. Lotz found lead to be electropositive towards glass. G. T. Fechner measured the series obtained, using water and a soln. of sodium chloride as electrolytes ; H. Davy, M. Faraday, and J. C. Poggendorff, dil. sulphuric acid ; A. de la Rive, M. Faraday, and A. Avogadro and V. Michelotti, dil. and conc. nitric acid ; M. Faraday, hydrochloric acid ; P. Marianini, sea-water ; J. C. Poggendorff, soln. of ammonium chloride, potassium cyanide, and potassium ferrocyanide ; and H. Davy, and M. Faraday, soln. of potassium hydroxide and sulphide.

F. W. Bergström found the electrochemical series in liquid ammonia : Pb, Bi, Sn, Sb, As, P, Te, Se, S, I.

A. Naccari and M. Bellat found for carbon and lead in an aq. soln. of chromic acid, 83·7 when the e.m.f. of a normal Daniell's cell is taken as 100. C. Hocken and H. A. Taylor observed 0·559–0·627 volt with the zinc-lead couple in dil. sulphuric acid ; and 0·509–0·510 volt, with a conc. soln. of zinc sulphate. S. P. Thompson found respectively 0·64, 0·609, and 0·44 volt for the lead-carbon couple in aq. soln. containing 99·4, 19·4, and 1·18 grms. of potassium cyanide per litre. A. Overbeck and J. Edler observed the effect with the mercury-lead couple with soln. of the hydroxides, carbonates, nitrates, chlorides, bromides, iodides, and sulphates of potassium, sodium, zinc, and cadmium, and with sulphuric, nitric, and hydrochloric acids, and with aq. ammonia. R. H. Gerke studied the e.m.f. of cells with lead, lead acetate soln., and lead amalgam ; lead, lead chloride soln., and silver or mercury ; lead, lead iodide soln., and silver. W. E. Henderson and co-workers studied the possibility of making standard cells of the type PbHg | PbSO$_4$ | Na$_2$SO$_4$.10H$_2$O (sat. soln.) Hg$_2$SO$_4$ | Hg with soln. of the sulphates of potassium lithium, copper, magnesium, zinc, cadmium, manganese, nickel, or cobalt in place of the sodium salt. G. Tammann discussed the potential difference of lead and cadmium in their fused chlorides ; and C. Krahmer, of cells with lead and a lead halide in sat. soln. against another electrode. According to J. N. Frers, an examination of the system lead anode | lead chloride-silver chloride | lead chloride-platinum cathode at 210° shows that only the silver ion of silver chloride wanders. Similarly, in the system lead anode | lead chloride-platinum cathode, migration is confined to the chlorine ion of the lead chloride. This shows that certain ions are retained with extraordinary firmness in the lattice, whereas others are much more readily removed from the positions which they occupy in the lattice system. H. von Steinwehr gave $6·3 \times 10^{-5}$ atm. for the **electrolytic solution pressure :** Pb→Pb".

The **electrode potential** of lead can be obtained by using lead electrodes, or, according to P. Günther,[33] a film of lead deposited on platinum. G. N. Lewis and T. B. Brighton found the electrode did not alter with the ageing of the lead, cast lead six years old gave the same value as a freshly deposited lead-tree. J. Brown found the potential of lead in molten lead chloride, or potassium chloroplumbite is nearly the theoretical value. B. Neumann obtained —0·079 volt in soln. of lead acetate ; —0·095 volt in soln. of lead chloride ; and —0·115 volt in soln. of lead nitrate. G. Grube, in potassium plumbite ; A. von Oettingen, in lead acetate ; W. Ostwald found with soln. of lead sulphate in sulphuric acid, 0·001 volt with the eq. conc. of the acid 1·04, and 0·041 volt with the acid conc. 6·4. B. Neumann found 0·182 volt against a normal hydrogen electrode in soln. of the chloride ; and 0·162 volt in soln. of the nitrate. Measurements were also made by A. C. Cumming, S. Procopiu, W. K. Lewis, O. Sackur, and N. T. M. Wilsmore, with soln. of lead nitrate. O. P. Watts and N. D. Whipple used N-NaOH ; P. P. Lebedeff, and C. Immerwahr, N-NaHS ; S. B. Christy, soln. of potassium cyanide ; W. D. Bancroft, soln. of alkali halides, and of sodium sulphide ; and G. Trümpler, and L. Rolla, soln. of sodium sulphides ; C. Zenghelis, soln. of potassium chloride, bromide, hydrotartrate, iodide, ferrocyanide, cyanide, chromate, sulphide, and hydroxide ; sodium thiosulphate, phosphate, and carbonate ; ammonia ; and ammonium carbonate. S. Labendzinsky used mixed soln. of alkali nitrate, chloride, and acetate ; M. G. Mellon and W. E. Henderson, soln. of sodium sulphate and sulphates of nickel, cobalt, manganese, or zinc. F. H. Getman gave 0·1293 volt, and H. Gordon, 0·108 volt, for the potential of lead against a normal hydrogen electrode ; and 0·4121 volt against the normal calomel electrode ; G. N. Lewis and T. B. Brighton gave 0·4125 volt ; W. E. Henderson and G. Stegeman, 0·4696 at 25° ; and P. Günther 0·4916–0·000132θ in a sat. soln. of lead chloride. W. Ostwald measured the electrode potential of lead in hydrochloric, hydrobromic, hydriodic, nitric, sulphuric, orthophosphoric, formic, acetic, propionic, oxalic,

and benzene-sulphonic acids. A. L. Clark examined the polarization capacity of the acid : lead surfaces. A. A. Noyes and K. Toabe found that dil. perchloric acid referred to the hydrogen electrode 0·132 volt at 25°. G. N. Lewis and T. B. Brighton measured the potential of the lead electrode in sat. soln. of lead chloride, bromide, and iodide. From the results obtained with the iodide soln., the normal potential is found to be 0·4125 against the normal calomel electrode and 0·1295 against the normal hydrogen electrode. H. Hock and F. Klawitter studied the behaviour of lead anodes in the electrolysis of zinc sulphate soln. S. Procopiu noted that agitation, and illumination raise the electrode potential ; and W. Spring, that hard lead (rolled) is more negative than soft lead by 0·12 millivolt at 20°. G. Athanasiu ascribed the e.m.f. generated when lead plates are immersed in a soln. of a salt of the metal, and one plate is illuminated, to the heating effect of the radiation. W. Löb and R. W. Moore measured the electrode potential of lead in a soln. of· sodium hydroxide and nitrobenzene ; L. Kahlenberg, in a soln. of lithium chloride in pyridine ; and F. M. G. Johnson and N. T. M. Wilsmore, in a soln. of lead nitrate in liquid ammonia. J. Neustadt and R. Abegg said ·that the position of lead in the electrochemical series is not materially affected in the presence of non-aqueous solvents. G. Tammann measured the potential of lead against fused silver and cuprous chlorides.

C. R. A. Wright and C. Thompson, and N. T. M. Wilsmore measured the **potential difference** between *zinc* and lead in a soln. of zinc sulphate ; C. R. A. Wright and C. Thompson, N. T. M. Wilsmore, and J. B. Baille and C. Féry, in soln. of zinc chloride ; C. R. A. Wright and C. Thompson, in soln. of zinc iodide ; W. D. Bancroft, in soln. of potassium chloride, bromide, and iodide, and sodium chloride, bromide, and iodide ; and C. R. A. Wright and C. Thompson, in soln. of zinc acetate.

G. Magnanini found for the potential difference in centivolts between zinc in N-H_2SO_4 and lead in different soln. : 0·5H_2SO_4, 51·3 ; N-NaOH, 31·8 ; N-KOH, 32·0 ; 0·5N-Na_2SO_4, 50·8 ; N-$Na_2S_2O_3$, 45·3 ; N-KNO_3, 42·6 ; N-$NaNO_3$, 51·0 ; 0·5N-K_2CrO_4, 41·2 ; 0·5N-$K_2Cr_2O_7$, 78·4 ; 0·5N-K_2SO_4, 51·0 ; 0·5N-$(NH_4)_2SO_4$, 53·2 ; 0·25N-K_4FeCy_6, 50·7 ; 0·167N-K_3FeCy_6, 81·2 ; N-KCyS, 52·8 ; 0·5N-$Sr(NO_3)_2$, 50·6 ; 0·125N-$Ba(NO_3)_2$, 51·7 ; 0·2N-$KClO_3$, 53·8 ; 0·167N-$KBrO_3$, 51·3 ; N-NH_4Cl, 51·3 ; N-KF, 41·1 ; N-NaCl, 51·2 ; N-KBr, 47·2 ; N-KCl, 51·6 ; 0·5N-Na_2SO_3, 41·0 ; NaOBr (using bromine eq. to· NaOH unity), 73·1 ; N-tartaric acid, 61·3 ; 0·5N-tartaric acid, 61·6 ; and 0·5N-potassium tartrate, 51·5.

C. R. A. Wright and C. Thompson, N. T. M. Wilsmore, H. Jahn, and F. Braun measured the potential difference of lead against *cadmium* in soln. of the nitrate ; C. R. A. Wright and C. Thompson, N. T. M. Wilsmore in soln. of the chloride, and bromide ; and W. D. Bancroft, in soln. of potassium chloride, bromide, sulphate, and nitrate. F. M. G. Johnson and N. T. M. Wilsmore measured the e.m.f. of the cell Pb | 0·1N-$Pb(NO_3)_2$, sat. soln. $Cd(NO_3)_2$ | Cd, and found −0·515 volt, and with 0·01N-$Pb(NO_3)_2$, −0·495 volt. J. Oblata measured the e.m.f. of cells with $Cd_{amalgam}$ | $CdCl_{2aq.}$ | $PbCl_{2aq.}$ | $Pb_{amalgam}$=0·14186 volt ; and with soln. of the iodides in place of the chloride, 0·09825 volt. G. Tammann measured the e.m.f. of a kind of Daniell's cell with fused chlorides and lead in contact with cuprous or silver chloride. C. Christiansen measured the potential difference of lead against *mercury* in moist and dry oxygen ; and C. R. A. Wright and C. Thompson, and N. T. M. Wilsmore in soln. of the nitrate. W. E. Henderson and G. Stegeman found the e.m.f. of the cell lead amalgam | $PbSO_4$,$NaSO_4$·10H_2O,Hg_2SO_4 | Hg to be 0·96343 volt at 18° ; and at $\theta°$, E=0·96463+0·0$_3$174(θ−25)+0·0$_6$38(θ−25)^2. C. R. A. Wright and C. Thompson, and N. T. M. Wilsmore measured the potential difference of lead against *copper* in soln. of the nitrate, and acetate. H. Jahn also worked with the acetate. C. R. A. Wright and C. Thompson, N. T. M. Wilsmore, J. N. Brönsted, and P. Günther measured the potential difference between lead and *silver* in soln. of the chloride. W. D. Bancroft measured the difference of potential between lead and *bismuth* in soln. of potassium or sodium chloride, bromide, or iodide. C. R. A. Wright and C. Thompson, and N. T. M. Wilsmore

measured the difference of potential between lead and *iron* in soln. of the sulphate. H. Götz and A. Kurz gave 0·93 volt for the difference of potential of lead against *graphite* in water. O. Sackur's measurements of the e.m.f. of the cell Pb | Pb(NO₃)₂,Sn(NO₃)₂ | Sn show that the electrolytic **solution pressure** of lead is about 17·2 times that of tin.

According to C. M. van Deventer, if the lead in sulphuric acid becomes covered with a film of lead sulphate, it may appear to become more electronegative than hydrogen. J. Tafel showed that polished and prepared lead electrodes have nearly the same polarization values. The cathode process may produce mechanical and chemical changes at the surface of the cathode, and these changes influence the potential values, so that the latter are more or less dependent on the previous history of the cathode. Lead exhibits two distinct polarization states when the anode liquid has access to the cathode, a state of " elevation " and a state of " depression." The change from the one to the other takes place during electrolysis, and often occurs suddenly. Cathode process and anode process are opposed to each other, and what leads to the state of depression is some change in the cathode surface induced by an unknown product of the anode process. When the cathode is protected from the anode liquid, the maximum **polarization** value is attained in a short time—say half an hour. He does not consider that the varying polarization is due to varying thicknesses of the gaseous layer on the cathode, but rather to the cathode surfaces having different effects on the process of forming hydrogen gas. The polarization of lead electrodes in soln. of lead nitrate was studied by H. Jahn ; in soln. of lead iodide, or bromide, by A. Gockel, and V. Czepinsky. A. L. Clark, J. T. Burt-Gerrans and H. R. Hugill, H. D. Holler, and M. Dresbach and H. R. Hosmer also investigated the subject. A. Günther-Schulze [34] discussed the **electrolytic valve action** of lead in conc. sulphuric acid ; and W. Winter, the anodic valve action in potash-lye.

According to W. Hittorf,[35] lead does not assume a **passive state** in the same sense that iron becomes passive, but it behaves as if it were passive in soln. of some oxy-salts. For instance, the e.m.f. of the cell Pb | Na₂SO₄,H₂CrO₄ | Pt is at first 1·78 volts, but quickly falls below one volt. F. Förster, W. R. Dunstan and J. R. Hill, W. J. Müller, O. Sackur, G. C. Schmidt, G. Grube, P. P. Lebedeff, and M. le Blanc agree that the passivity of lead is produced by a film on the surface of the metal. C. W. Bennett and W. S. Burnham showed that a lead anode in dil. sulphuric acid becomes covered with lead dioxide, in quantities such that there is no question about the film. The combination is noble, but the film is destroyed by hydrochloric acid. When thus protected by oxide, the lead dissolves only slowly in sulphuric or nitric acid. They were unable to induce the passivity of lead without a visible film. K. Elbs and F. Fischer showed that with conc. sulphuric acid, at a high current density, and low temp., lead as anode dissolves as quadrivalent lead, and thus is regarded as a case of retarded dissolution analogous to the case of chromium. According to E. Newbery, both in acid and in alkali, a lead anode rapidly becomes coated with dioxide at moderate current densities, but at all current densities it shows a strong positive potential to an oxygen electrode after the dioxide coating has formed. While the coating is forming, the overvoltage rises steadily and remains very constant at a high value when the coating attains a thickness·approaching 0·1 mm. Lead is therefore a very suitable electrode for very powerful oxidation in dil. sulphuric acid electrolytes. In alkali its use is attended with certain disadvantages owing to the formation of plumbates which may interfere with the course of a reaction. The solubility of the dioxide in alkali prevents the formation of the protective coating at low current densities, and hence under these conditions lead behaves as an active metal. With a current density of 100 milliampères per sq. cm. the metal becomes passive in about forty seconds, whilst it requires about fifteen minutes with a current density of 10 milli-ampères per sq. cm. Lead is the only electrode so far examined which is passivated more easily in acid than in alkali. U. Sborgi and P. Marchetti

found that anodes of lead show a partial mechanical passivity in acetone soln. of silver nitrate.

The **overvoltage** of hydrogen on polished lead electrodes was found by W. A. Caspari to be 0·631 volt; on etched electrodes, 0·631 volt; on electrolytic spongy lead, 0·628 volt; and on amalgamated lead, 0·540 volt. C. Hambuechen gave 0·50 volt for the overvoltage of hydrogen on lead. The subject was investigated by E. Newbery, W. Löb and R. W. Moore, T. Ericson-Aurén and W. Palmaer, P. Fischer, J. Tafel and co-workers, A. Coehn and K. Dannenberg, S. Dunnill, F. Meunier, A. Sieverts and P. Lueg, M. Knobel, A. Thiel and W. Hammerschmidt, S. Glasstone, etc.

W. Ostwald [36] gave −10 Cals. for the **heat of ionization** of lead, Pb··, from metallic lead. L. Boltzmann measured the thermal value of the electrolysis of soln. of lead salts when gas is developed. A. A. Noyes, and K. G. Falk gave 0·487 for the **transport number** at 25°; while A. A. Noyes and E. H. Woodworth gave 68·3 for the **speed of migration**; H. F. Fernau, 66·1; and F. Kohlrausch, 61·10– 61·15 at 18°. He also gave 0·0244 for the temp. coeff. C. L. von Ende found that disturbances were produced when mercury amalgam is used as an electrode owing to the formation of lead dioxide. M. le Blanc [37] found the **decomposition voltage** of N-Pb(NO$_3$)$_2$ to be 1·52; H. Jahn gave 1·96. Observations were also made by K. Elbs and J. Forssell, J. E. Root, H. W. Gillett, and W. D. Bancroft. G. Bödländer found for

PbSO$_4$	Pb(OH)$_2$	PbS	PbF$_2$	PbCl$_2$	PbBr$_2$	PbI$_2$
4·70	1·10	0·40	2·27	1·80	1·40	0·86

The electrodeposition of lead.—Metallic lead can be readily and quantitatively obtained by cathodic deposition from alkaline electrolytes containing phosphates, oxalates, cyanides, plumbates, etc., and this process is used in electro-analysis [38]; but the drying of the lead without oxidation is considered so difficult that it is usual to take advantage of the fact that lead is deposited as lead dioxide on the anode during the electrolysis of acidulated soln. V. Kohlschütter and F. Ubersax studied the electrodeposition of lead crystals from soln. of lead nitrate. H. Freundlich and J. Fischer examined the influence of a number of colloids on the quality of the lead deposited from soln. by electrolysis, as well as when precipitated by zinc. C. Marie and G. Lejeune found the energy required to liberate lead is increased when a colloid, like gelatin, is added to the soln. The colloid reduces the amount of metal deposited by a given current. The **electrolysis** of neutral soln. of *lead nitrate* was investigated by E. Becquerel [39]; soln. of *lead nitrate* in acid or neutral soln., by F. Wöhler,[40] C. Luckow, etc.; *lead chloride*, by L. Glaser; *lead cyanide*, by J. Haas,[41] *lead acetate*, by F. C. Mathers,[42] E. P. Clark, etc.; by A. G. Betts [43]; in *sulphuric acid* soln., by F. Haber,[44] L. Glaser, etc.; in *hydrochloric acid* soln. by K. Elbs,[45] E. P. Schoch and D. J. Brown, etc.; in *hydrobromic acid* and *hydriodic acid* soln., by K. Elbs and R. Nübling; in *fluorides*, by F. Fischer and K. Thiele [46]; in *perchloric acid* soln., by F. C. Mathers,[47] H. Freundlich and J. Fischer, etc.; in *hypophosphorous acid*, and *phosphorous acid* soln., by K. Elbs and F. W. Rixon [48]; in *phosphoric acid* soln., by A. F. Linn,[49] F. Fischer, etc.; in *pyrophosphoric acid*, by A. Brand [50]; in *fluoborates*, by G. Mardus,[51] W. Blum and co-workers, etc.; in *fluosilicates*, by A. G. Betts,[52] H. Senn, etc.; in *fluotitanates*, by G. Titschack; in *chromic acid* soln., by C. Luckow,[53] and M. le Blanc and E. Bindschedler; in *formic acid* soln., by R. Marc,[54] H. S. Warwick, etc.; in *acetic acid* soln., by W. Hartmann,[55] R. C. Snowdon, etc.; in *lactic acid* soln., by F. C. Mathers and B. W. Cockrum,[56] and E. Jordis; in *benzoic acid* soln., and *salicylic acid* soln., by R. Marc [57]; in soln. of organic *sulphonates*, by A. G. Betts,[58] G. Titschack, and F. Fischer and co-workers; in *oxalic acid* soln., by A. Riche,[59] A. Classen, etc.; and in soln. of *sodium hydroxide*, by P. Schützenberger,[60] A. G. Betts, etc.

The electrolysis of the *fused lead halides* furnishes a conductivity curve with

two breaks which, on the ionic theory, are interpreted to mean that the dissociation occurs in two stages, $PbX_2 \rightleftharpoons PbX^{\cdot} + X'$, and $PbX^{\cdot} \rightleftharpoons Pb'' + X'$. The subject has been investigated by R. Lorenz,[61] C. C. Garrard, etc. The electrolysis of *non-aqueous soln.* has not been extensively studied; L. Kahlenberg,[62] and A. W. Speransky and E. G. Goldberg worked with soln. of lead nitrate in *pyridine;* and H. Röhler, with soln. of lead chloride, or nitrate in *formamide.* Electrolysis using a *rotating anode* was examined by A. Fischer and R. J. Boddaert,[63] F. M. Perkin, etc.; and using an *alternating current,* by P. Vaillant,[64] E. Wilson, etc. The *anodic behaviour of lead* has been investigated by W. Lust,[65] E. Newbery, etc.; the *cathodic behaviour of lead,* by J. Tafel and co-workers,[66] etc.; the *anodic behaviour of lead sulphide,* by I. Bernfeld,[67] and P. P. Lebedeff; the *cathodic behaviour of lead sulphide,* by I. Bernfeld,[68] H. Danneel, etc.; and the *anodic behaviour of lead dioxide,* by A. Hollard,[69] H. J. S. Sand, S. Glasstone, etc.

Accumulators.—In 1801, N. Gautherot[70] showed that the recently invented voltaic pile when at work seemed to develop a resisting or opposing force which tended to choke the flow of the electric current; and that if the current be sent through a pair of plates dipping in a saline liquid, the latter give a transient current immediately after disconnection with the pile. J. W. Ritter also used this result to make what he called a *secondary pile* which when charged by a primary battery could give transitory currents of considerable intensity. In 1842, W. R. Grove made his gas cell (**1.** 16, 7) in which the hydrogen and oxygen liberated in separate tubes fitted with platinized electrodes by the action of the primary current can on a closed circuit re-form water and generate a small current reproducing the original conditions. The reactions in this cell have been closely investigated by K. Siegl. E. J. Wade said: " No storage cell presents the principle of reversibility in a more simple or striking form than does the gas-cell of W. R. Grove." W. J. Sinsteden investigated the subject in 1854. G. Planté placed rods of various metals in an acid and passed a current through the soln.; on cutting the battery out of the circuit, he found momentary secondary currents were given by all the metals he tried, but that obtained with lead electrodes in dil. sulphuric acid, exceeded all others in duration and intensity. G. Planté developed this observation and showed how cells could be constructed for " storing electricity." Two coils of lead wire were dipped in dil. sulphuric acid; and a current was sent through the liquid from one plate to the other. The metal at one pole became covered with lead dioxide, and hydrogen was given off at the other pole. The lead cell came to be variously called an accumulator, secondary cell, or storage cell. G. Planté's cell was a little in advance of its time, but as soon as the evolution of the dynamo had advanced far enough to enable currents of high potential to be produced cheaply, the possibilities of the mysterious storage cells began to be recognized. The peroxide of G. Planté's cell was prepared from the electrode itself. C. A. Faure patented a method of preparing the peroxide from lead oxides as salts mechanically applied at the surface of the electrode. The results were so good that numerous inventors were attracted, and many modifications of G. Planté's and C. A. Faure's cells were worked out and patented. Cells based on that of G. Planté are called *formed cells;* those on that of C. A. Faure, *pasted cells.* Various forms of " paste " were described, and numerous forms of grids, lattices, etc., were devised for supporting the active material. Descriptions of the different types of cell, the design of cells, and working details will be found in books specially devoted to this subject.

Lyndon, *Storage Battery Engineering,* New York, 1903; F. Dolezalek, *Die Theorie des Bleiaccumulators,* Halle, 1901; L. Jumau, *Accumulateurs électriques,* Paris, 1907.

G. Planté recognized that the high e.m.f. of the cell is a result of the deoxidation of the lead dioxide at the anode, and the oxidation of lead at the cathode, but he wrongly assumed that the dioxide was reduced to metallic lead, and that the lead at the other electrode was oxidized nearly up to the dioxide state. He did not consider the chemical function of the sulphuric acid, although he knew that lead sulphate could be produced during the working of the cell. Later, it was assumed that the function of the acid was merely to make the electrolyte conducting, and that in charging the cell the hydrogen and oxygen were occluded at the respective electrodes, part of the oxygen forming lead dioxide. The working of the cell was considered to be analogous to the working of the ordinary gas-cell; and the large capacity of the accumulator was attributed to the enormous surface of the absorption of gases produced by the porous mass of reduced oxides. O. J. Lodge ascribed the activity of the negative electrode to occluded hydrogen, but at the positive pole the reduction of the dioxide to monoxide was noted. The union of the monoxide with the acid to form lead sulphate was considered as a secondary reaction which was considered to be an unmitigated evil. J. H. Gladstone and A. Tribe showed that at the negative electrode only a mere trace of hydrogen is absorbed. This was confirmed by J. Shields. J. H. Gladstone and A. Tribe showed that in the regular discharge of the cell lead sulphate is the normal product; similarly at the peroxide plate, lead sulphate is normally formed at the expense of the sulphuric acid electrolyte. As a result lead sulphate is formed on both electrodes during the discharge. This, the so-called *double sulphate theory*, gave rise to some controversy since it seemed highly improbable that large quantities of non-conducting insoluble lead sulphate could be produced under normal conditions, especially when it is remembered that attempts to reduce lead sulphate by electrolysis in dil. sulphuric acid failed, and that it could be peroxidized only with some difficulty. E. Frankland obtained a number of basic sulphates, $3PbSO_4.2PbO$, and $PbSO_4.PbO_2$, by the action of dil. sulphuric acid on litharge and red-lead respectively, and suggested that these may be formed during the discharge of the cell; but G. H. Robertson, and J. H. Gladstone and W. Hibbert showed that these sulphates are probably only mixtures. Hence, E. Frankland's results mean that lead sulphate is truly produced at both electrodes during the discharge of the cell, and that appreciable quantities neither of oxygen nor hydrogen are occluded by the electrodes during the charging of the cell. S. Schenck and S. Farbaky found that the change in the conc. of the sulphuric acid in a cell during the discharge was 3·6 grms. when the double sulphate theory required 2·24 grms. A. Pfaff also discussed the changes in the conc. of the acid during the discharge of the cell.

G. Planté noted that an unstable oxygenated compound—possibly hydrogen dioxide—is formed during the charging of the cell, and he knew that persulphuric acid is a direct product of the electrolysis of dil. sulphuric acid. J. H. Gladstone and A. Tribe detected persulphuric acid in the charged cell, and H. E. Armstrong and G. H. Robertson said that this acid probably plays an important rôle in the cell. The presence of persulphuric acid was also discussed by G. Darrieus, and P. Schoop. M. Mugdan showed that the addition of persulphuric acid to the cell reduces its e.m.f. K. Elbs and co-workers suggested that during the charging, lead persulphate is first formed, and that this breaks down into lead dioxide and sulphuric acid. W. Nernst showed that the decomposition of lead persulphate is an irreversible process, and since the reactions in the accumulator are reversible, F. Dolezalek maintained that this interpretation of the function of the persulphate cannot be correct. W. Esch regarded the hydrotrisulphatometaplumbic acid, $H_2Pb(SO_4)_3$, as the intermediate compound. The double sulphate theory was accepted by E. N. Reynier, A. Crova and P. Garbe, H. Aron, A. Gérard, W. Kohlrausch and C. Heim, F. Streintz, M. Mugdan, A. Jouve, etc. The double sulphate hypothesis thus takes on the following form:

If two corrugated lead plates be covered with a paste of litharge, PbO, and

dipped in a 20 per cent. soln. of sulphuric acid, the litharge on the plates is converted into lead sulphate, $PbSO_4$. If an electric current be passed through the cell, hydrogen is evolved at the cathode, and oxygen at the anode during the electrolysis of the sulphuric acid. The hydrogen at the cathode reduces the lead sulphate producing a grey film of " spongy " metallic lead : $PbSO_4 + H_2 = H_2SO_4 + Pb$; and at the anode, the oxygen transforms the lead sulphate directly into lead dioxide or maybe into lead persulphate : $2PbSO_4 + 2H_2SO_4 + O_2 = 2Pb(SO_4)_2$ $+2H_2O$; the persulphate is at once hydrolyzed into lead peroxide and sulphuric acid : $Pb(SO_4)_2 + 2H_2O = PbO_2 + 2H_2SO_4$. In either case, a dark brown film of lead peroxide is formed on the lead plate. The current may then be stopped. If the terminals of the cell be then connected with a suitable resistance, a current at nearly two volts press. can be obtained, and this continues for about twelve hours. The cell is then said to be " discharged." The brown film of lead dioxide on the anode gradually disappears during the discharge of the cell, and a white film of lead sulphate takes its place. The reaction on the anode during the discharge of the cell is $PbO_2 + Pb + 2H_2SO_4 = 2PbSO_4 + 2H_2O$. When the cell is being charged, the reaction can be represented by the same equation taken from right to left :

$$2PbSO_4 + 2H_2O \rightleftharpoons Pb + PbO_2 + 2H_2SO_4$$
Charge→   ←Discharge.
As soon as the dioxide has disappeared, the electromotive force of the cell drops rapidly, although the voltage keeps remarkably constant as long as any dioxide remains on the plate. This is illustrated by the curve, Fig. 14. The curve from B to C shows that the voltage remains nearly constant for ten to twelve hours while the cell is discharging ; the curve from C to D represents the drop in voltage when the dioxide is almost all gone. The cell should be recharged before it has reached this condition, otherwise the efficiency of the plates may be reduced. An accumulator may thus be regarded as a cell with metallic lead plates, or with lead plates specially designed to hold as large an amount of litharge or lead oxide as possible. The plates dip in dil. sulphuric acid. When

FIG. 14.—Voltage Drop of Accumulator.

charged, the accumulator acts as if it were a primary cell $PbO_2 \mid H_2SO_4 aq. \mid Pb$. To summarize, the changes at the electrodes during charge and discharge are :

				CHARGING.	DISCHARGING.
Cathode	.	.	.	$PbSO_4 \rightarrow Pb$	$Pb \rightarrow PbSO_4$
Anode	.	.	.	$PbSO_4 \rightarrow PbO_2$	$PbO_2 \rightarrow PbO \rightarrow PbSO_4$

During the discharge, the surface of both plates becomes covered with a film of white lead sulphate, and hydrogen is evolved at the cathode : $Pb + H_2SO_4$ $= PbSO_4 + H_2$. The hydrogen is partly absorbed by the lead which has not been converted into sulphate. The presence of the absorbed gas raises the electromotive force of the cell during discharge until it is all consumed. This occupies but a few minutes ; during this time, the voltage is represented by the curve AB.

The hypothesis just indicated can be translated into the language of the ionic hypothesis. In the charged cell, we have a liquid containing $H^.$ and SO''_4 ions, with lead and lead dioxide electrodes. When the cell is discharging, the $H^.$ ions travel towards the PbO_2 plate and reduce the lead dioxide to lead monoxide : $2H^. + PbO_2 = H_2O + PbO$; and this plate accordingly receives a positive charge, owing to the de-electrification of the $H^.$ ions. The SO''_4 ions simultaneously travel to the lead plates converting the lead at the surface of the plate into lead sulphate : $SO''_4 + Pb \rightarrow PbSO_4$, and the plates are at the same time charged negatively. In consequence, a positive current of electricity travels from the " peroxide " plate to the " lead " plate outside the cell, and from the " lead " to the " peroxide "

plate in the liquid. A secondary reaction between the sulphuric acid and the lead monoxide of the "peroxide" plate leads to the formation of lead sulphate, and consequently the consumption of the sulphuric acid in the liquid in the cell is relatively large during discharge. When the cell is to be re-charged, the "peroxide" plate is connected with the positive pole of the dynamo, and the "lead" plate with the negative pole of the dynamo. The H· ions of the cell travel to the negatively charged plate, an *equivalent* number of SO''_4 ions pass into the soln. and metallic lead remains on the plate. The effect is to reduce the lead sulphate back to metallic lead. The SO''_4 ions travel to the positively charged "peroxide" plate and form lead persulphate : $2SO''_4 + 2PbSO_4 = 2Pb(SO_4)_2$. The lead persulphate is immediately hydrolyzed to lead peroxide as indicated above. Sulphuric acid is thus regenerated, and the cell is brought back to its original condition. According to M. le Blanc, the active ion in the charged cell is quadrivalent Pb····, which during discharge changes to Pb·· ; C. Liebenoff's theory assumes that the active ion in the charged cell is PbO''_2. These two modifications of the ion theory have been discussed by E. Abel, F. Förster, W. Löb, etc.

There is no fundamental difference in the principles of action between the lead accumulator and other combinations, only the chemical characters of lead and its compounds are peculiarly suited for the purpose to be achieved. Primary and secondary cells can both be regarded as machines for converting chemical into electrical energy. It will be observed that if electrolytically prepared lead dioxide be packed about a core of lead, and put in dil. sulphuric acid along with a similar electrode about which is packed electrolytic spongy lead, the cell would be called a primary one although it possesses all the chief characteristics of a lead accumulator. Every secondary cell can thus be regarded as a primary cell, and every primary cell a potential secondary cell. In charging the lead accumulator, electrical energy is converted into chemical energy, and in discharging, as with primary cells generally, chemical energy is converted into electrical energy. The energy changes in the cell have been discussed by A. Lottermoser and M. Grützner, and I. M. Tscheltzoff, and F. Dolezalek. The result of the calculation has been cited in support of the assumed theory of the reactions in the lead accumulator.

The thermal values of the reactions, so far as are known, are $2(Pb,SO_4) = 225,940$ cals. ; $2(H_2,O) = 136,720$ cals. ; $2(H_2,SO_4) = 179,360$ cals. ; $2(H_2,SO_4,Aq.) = 215,060$ cals. ; and $(Pb,O_2) = 62,300$ cals. This gives 121,000 cals. for the thermal value of the reaction with undiluted sulphuric acid ; and 85,300 cals. with very dil. acid. If the acid has a sp. gr. 1·160, corresponding with $2(H_2,SO_4,19H_2O) = 211,870$ cals., the heat of the reaction is 88,490 cals. From Gibbs-Helmholtz's equation (1. 16, 8), the e.m.f., E, is given by $E = Q/C + T(dE/dT)$, where dE/dT represents the observed temp. coeff. of the reaction, namely $0·4 \times 10^{-3}$; at 17°, $T = 290°$ K. The heat of the reaction $Q = 88,490$ cals. $= 88,490 \div 0·24$ joules ; and $C = 2 \times 96,540$; hence $E = 2·03$ volts. This agrees closely with the observed values 1·99–2·01 volts.

While J. H. Gladstone and A. Tribe's double sulphate theory assumes that the positive active material combines with as much sulphuric acid as the negative material : $PbO_2 + H_2 + H_2SO_4 = PbSO_4 + 2H_2O$, G. Darrieus maintained that it is merely reduced to the monoxide : $PbO_2 + H_2 = PbO + H_2O$; D. G. Fitzgerald, that it is reduced to the sesquioxide : $2PbO_2 + H_2 = Pb_2O_3 + H_2O$; and S. Drzewiecky, and C. Féry assumed Pb_2O_5 was formed :

$$2PbO_2 + Pb_2SO_4 + H_2O \rightleftharpoons Pb_2O_5 + H_2SO_4 + 2Pb$$
Charge→   ←Discharge.
C. Féry's argument that the oxide on the plate is Pb_2O_5 and that during the discharge this changes to PbO_2, and on the negative plate the active lead becomes Pb_2SO_4 not $PbSO_4$, is based on (i) the colour of the oxide on the one plate is darker than PbO_2, and on the other plate is darker than $PbSO_4$; (ii) the active oxide in a stream of hydrogen becomes warm, gives off water, and forms ordinary lead dioxide; (iii) if the active polyoxide is used as one plate in all with dil. sulphuric acid and zinc, the e.m.f. is 2·4 volts, whereas with ordinary lead dioxide

0·7 volt is obtained—this statement does not agree with the observations of F. Streintz—and (iv) the analyses correspond with Pb_2O_5 rather than with PbO_2. The analyses of the active materials are open to many sources of error, and are not conclusive. G. Crut supported C. Féry's hypothesis. The work of D. A. MacInnes and co-workers, A. Pfaff, H. Cassel and F. Todt, W. Kohlrausch and C. Heim, shows that C. Féry's claims are not well-founded; and M. Knobel found that the acid consumption in the cell is in harmony with the double sulphate theory of J. H. Gladstone and A. Tribe. The bulk of the evidence from the chemical characteristics of the compounds involved, and the electrical properties of the cell also favours the double sulphate theory. M. Hartenheim found that the effect of radium is to decrease the internal resistance of the cell.

A number of combinations other than the $Pb–PbO_2$ cell have been proposed—*e.g.* E. Thomson and E. J. Houston [71] (1879) proposed a reversible Daniell's cell; H. Sutton (1881) proposed a $Cu–H_2SO_4–PbO_2$ cell; E. Reynier (1883) proposed a somewhat similar arrangement; A. d'Arsonval (1879), J. Carpentier (1879), K. E. Böttcher (1882), and C. H. Cathcart (1882), $Zn–H_2SO_4–PbO_2$; W. Main (1887–92), A. V. Meserole (1887), L. Epstein (1894), H. Leitner (1895), and E. Julien (1885) proposed forms of the $Zn–PbO_2$ cells; A. E. Peyrusson (1887), C. E. Lee (1897), and E. Commetin and R. Viau (1904), $Cd–PbO_2$ cells; F. de Lalande and G. Chaperon (1881–4) used the $Zn–KOH–CuO$ cell reversibly as an accumulator; E. Commetin, G. Bailhache, A. de Virloy and L. de Bousignac (1884), J. B. Entz and W. A. Phillips (1889–91), and C. Desmazures (1886–7) proposed modifications of this cell; A. Dun and F. Hasslacher, and T. de Michalowsky (1899), $Zn–NiO$ cell; H. Aron (1886), the $Zn–KOH–HgO$ cell; T. A. Edison (1900), $Cd–CuO$ cell with an alkaline electrolyte; and a $Fe–NiO$ cell with an alkaline liquid.

G. von Hevesy and R. Lorenz [72] found the **electrocapillary phenomenon** with fused salts in the systems $Pb:KCl$; $Pb:KI,KCl$; and $Pb:NaI,NaCl$ closely resembled that with mercury-sulphuric acid electrometer. W. Crookes noted the spluttering of lead cathodes in the **discharge tube** in attenuated air. W. B. Nottingham studied the characteristic curves of the normal lead arc. F. Fischer and co-workers noted the disintegration of lead in liquid argon; and studied the volatilization of lead from cathodes in various attenuated gases; V. Kohlschütter and co-workers also made observations on this subject. For the spluttering of lead in the arc discharge under liquids, *vide* colloidal metals. G. A. Helmsalech investigated the electric discharge from lead electrodes; F. W. Aston, the effect of the lead cathode on the width of Crookes' dark space (**4**. 25, 4); and E. Rumpf, the polarization which occurs with lead cathodes in vacuum tubes with air and hydrogen. J. Lavaux, and J. Lifschitz observed no luminous phenomena—**volta-luminescence**—with lead anodes such as are shown by bismuth, and some other metals. G. Hoffmann found that two lead plates separated a distance of the order $400\mu\mu$ produce a current with a critical field strength of $2·2\times10^6$ volts per cm.

According to M. Faraday,[73] lead is diamagnetic. K. Honda found that lead which has crystallized from the metallic state has a **magnetic susceptibility** ten times greater than hammered or drawn lead. M. Loutschinsky gave for the magnetic susceptibility of crystalline lead $-2·4\times10^{-6}$ mass units, and of hammered lead, $-0·2\times10^{-6}$ mass units. Hence, the magnetic susceptibility of the normal crystalline metal is ten times higher than when it has been hammered, rolled, or drawn. K. Honda gave $-0·12\times10^{-6}$ mass units between 18° and 330°, and $-0·08\times10^{-6}$ mass units between 330° and 600°. There is therefore not much change, and M. Owen observed very little change between $-170°$ and 327°. J. Königsberger found $-1·4\times10^{-6}$ vol. units for the magnetic susceptibility; and L. Lombardi, $-0·84\times10^{-6}$. G. Borelius applied the electron theory to explain the magnetic properties of lead. W. Voigt and S. Kinoshita, and S. Meyer examined the magnetic properties of a number of lead compounds; and S. Meyer gave $-0·025\times10^{-6}$ for the **atomic magnetism**; and P. Pascal gave $-295·0\times10^{-7}$ for lead in aliphatic organometallic compounds, and $+66·0\times10^{-7}$ in aromatic organometallic compounds; and $-45·8\times10^{-6}$ for ordinary lead. The **magnetic moment**

of lead was studied by W. Gerlach and A. C. Cilliers. E. H. Williams observed that compounds with an odd mol. number are paramagnetic, and those with an even mol. number, diamagnetic.

§ 5. The Chemical Properties of Lead

The chemical properties of lead present some strange and peculiar contrasts which at first sight seem inconsistent. For example, the metal resists the action of sulphuric and hydrochloric acids much better than iron, zinc, or tin, and yet it is readily attacked by weak organic acids ; it is slowly dissolved even by water, and is very susceptible to corrosion by the action of moist air. O. Sackur [1] has compared the chemical properties of lead and tin. The position of lead in the electrochemical series is close to that of tin, and not far from that of hydrogen, both metals being slightly more electropositive than hydrogen. Consequently, lead will have little tendency to displace hydrogen from aq. soln. of the acids, even when this tendency is not interfered with by the insolubility of the products of the reaction. Thus, lead has a greater soln. press. than tin, but it dissolves in hydrochloric acid less readily than tin. The greater soln. press. of lead in comparison with that of tin is partly explained by the feeble ionization of the stannous salts, and the stronger basic properties of lead oxide as exemplified by the stability of its oxysalts. Owing to the low tendency exerted by lead to displace hydrogen from the acids, its ready dissolution by the feebler acids, say acetic acid, is attributed to the accelerating influence of atm. oxygen. Tin is not so readily oxidized as lead, and hence it is not attacked by, say, acetic acid. The difference in the action of aerated water on the two metals is attributed to the same cause—the strong basic properties of lead.

B. Hodgson [2] referred to the absorption of gas by lead electrodes in vacuum tubes ; and M. Guichard found that after lead had been heated for 11 hrs. at 750° and 8 hrs. at 550° under reduced press., it still evolved gas at the rate of 0·1 c.c. per 100 grms. per hour. G. Neumann and F. Streintz said that fused lead absorbed 0·11–0·15 vol. of **hydrogen,** and P. Schoop, E. Rumpf, and S. Drzewiecky also said that lead absorbs hydrogen. On the other hand, E. Frankland, M. Cantor,

G. Meyer, A. M. Scott, W. Stahl, and J. H. Gladstone and A. Tribe were quite unable to detect any absorption of hydrogen either by molten lead, or by lead made the negative electrode in the electrolysis of dil. sulphuric acid. J. Shields confirmed these results, and showed that G. Neumann and F. Streintz's report was due to a mal-observation; if any gas is absorbed it is purely a surface effect and plays no essential part in the working of the lead accumulator. M. Guichard said that the hydrogen absorbed by lead is only slowly expelled by heat. F. H. Newman, and A. Sieverts also included lead among the metals which do not dissolve hydrogen—the former worked with lead electrodes in a discharge tube. H. G. Deming and B. C. Hendrichs found hydrogen diffuses through lead at 265° at the rate of 0·001 mgrm. per hour per sq. cm. per mm. thickness. N. S. Kurnakoff and N. J. Stepanoff inferred that lead may form a hydride of the type: PbH_2, *viz.* PbH_4; S. Drzewiecky assumed that Pb_2H_2 exists. D. P. Smith, and F. Paneth considered that the position of lead in the periodic table is not incompatible with the existence of a hydride. E. Newbery found that an unstable **lead hydride**—or overvoltage compound—is formed when hydrogen is liberated at a lead electrode. F. Paneth and O. Nörring activated magnesium powder with thorium-B and thorium-C in a desiccator for half an hour, and dissolved the product in 0·1–0·2N-HCl. The resulting gases were carried in a stream of hydrogen through a cotton-wool filter to a heated Marsh tube. The radioactivity of the metallic deposit, consisting chiefly of thorium-C (bismuth), was then examined. For the first few hours its behaviour was indistinguishable from that of thorium-C, but after 24 hrs., by which time the thorium-C should have disappeared, a notable activity remained, the rate of disappearance of which corresponded with that of thorium-B (lead). The " yield " of lead obtained, however, was only about onehundredth that of the bismuth. The lead hydride appeared to be stopped or decomposed more readily by a thick cotton-wool filter than bismuth hydride. Attempts to prepare the hydride by the action of acids on ordinary lead-magnesium alloys were unsuccessful, and so were numerous attempts by electric methods— for example, induction sparks or an arc in an atmosphere of hydrogen. Success was eventually attained by a combined electrolysis-spark process. Using dil. sulphuric acid as electrolyte and a lead-glycerol cement cathode, with an e.m.f. of 220 volts, the apparatus was so arranged that intermittent sparking at high frequency occurred between the cathode and the electrolyte. The cathode gases were passed to a condensing tube immersed in liquid air where any lead dust was deposited, whilst the hydride was liquefied. On allowing the temp. to rise, the hydride was again vaporized and passed through a cotton-wool filter to a heated Marsh tube, where it was decomposed and lead deposited. The deposit had a dull grey colour, and was close to the flame, but not so close as a tin deposit. The lead was identified by a number of chemical tests which distinguished it from arsenic, antimony, tin, tellurium, or bismuth. A number of modifications of the experiment indicated that the hydrogen required for the formation of the hydride is not derived from the electrolysis of the electrolyte, but probably through the action of the spark, positive hydrogen ions combining directly with negative lead ions. F. Paneth and E. Rabinovitsch calculate the b.p. of lead hydride to be −13°; the composition corresponds with **lead tetrahydride**, PbH_4. E. J. Weeks prepared **lead dihydride**, Pb_2H_2, as a grey powder, by the action of aluminium foil on a soln. of an alkali plumbite. It does not form the tetrahydride when heated in the absence of air, but if heated in hydrogen, it is probably reduced to the tetrahydride : $Pb_2H_2+3H_2=2PbH_4$. The dihydride oxidizes rapidly in air ; it is vigorously attacked by fused potassium nitrate under conditions where finely divided lead is only slowly attacked.

A. Sieverts and W. Krumbhaar observed no sign of the dissolution of **nitrogen** in lead at 600°. F. H. Newman found that nitrogen is not absorbed by lead electrodes in the electric discharge. F. Fischer and G. Iliovici observed no sign of the combination of lead with argon when the arc or spark discharge between

lead electrodes is passed beneath liquid **argon.** G. Lunge and E. Schmid[3] found that lead usually contains but a minute trace of **oxygen**—about 0·0025 per cent.—but when the lead is contaminated with from 0·01 to 1 per cent. of copper, the quantity of oxygen is much increased. W. Stahl showed that the dissociation of lead oxide occurs over 2075°, and the oxygen absorbed by lead is probably chemically combined. Lead reduced from the tartrate at as low a temp. as possible was found by W. van Rijn to be *pyrophoric;* and G. C. Winkelblech found that lead reduced by hydrogen from gently heated lead oxide remains unaltered in **air** at ordinary temp., but takes fire when heated, burning with a feeble glow and forming lead oxide. P. A. von Bonsdorff showed that dried lead and oxygen or air suffer no change at ordinary temp., but if moisture be present, the metal becomes tarnished owing to the formation of a surface film of oxide ; in an atm. sat. with moisture, this oxidation takes place in a few days, and the bright surface of the metal acquires in succession all the colours of the rainbow before it becomes dull grey. The action is hastened by a gentle heat. G. Tammann and co-workers estimated that it would take 90 years to produce a visible film on polished lead in an atm. of dry air at 15°. W. Müller considered that pure oxygen has a smaller affinity for lead than atm. air. B. Lambert and H. E. Cullis showed that lead distilled in vacuo, and kept for some months, can be exposed to ordinary air for many days without any appreciable diminution of its brilliant metallic lustre, but more prolonged exposure causes the gradual formation of a surface-film of a dark-coloured oxide. When lead near its m.p. is kept exposed to air, its surface becomes covered with a grey powder which J. J. Berzelius supposed to be a suboxide, Pb_2O ; at its m.p., the lead forms the yellow oxide, PbO, and afterwards gradually passes into the red oxide, Pb_3O_4. J. Percy added that " the surface of the metal after fusion becomes beautifully iridescent, and the superficial film thus coloured may be removed and permanently preserved." The atm. corrosion is facilitated by the presence of carbon dioxide. G. Jung studied the optical properties of tarnish films. C. L. Bloxam has said that " in breach-loading cartridges where grease is employed as a lubricator, the bullets have sometimes become partly converted into white-lead, and thus increased so much in bulk as to burst open the copper case of the cartridges and render them useless." If the grey film be skimmed from molten lead so that the clean surface is continually renewed, the metal is ultimately all converted into *lead-ash,* a yellowish-grey mixture of lead and its oxide. At a bright red heat, the oxidation of the metal is rapid, and, at that temp., the resulting oxide is molten. At a still higher temp. the lead volatilizes and burns with a white light, forming flocculent lead oxide called *flores plumbi,* or *flowers of lead.* Oxygen, according to W. Manchot, shows a slight action on lead at 132° in 5 mins. ; the action is more pronounced at 180°–197° ; and at 227°, the action is very marked. N. B. Pilling and R. E. Bedworth found that at 300°, the oxidation of lead proceeds with comparative rapidity in air, forming a reddish-brown oxide, smooth and adherent to the metal. The quantity of oxygen, W, forming the oxide in the time, t, is given by $W^2=kt$, where k is the constant of proportion.

C. Engler and W. Wild found that the mist which is produced when **ozone** acts on clear filings of moist lead is lead oxide. W. Manchot found that in an atm. containing one per cent. ozone there is the faintest sign of reaction at 100°, one minute's exposure at 132° produces a golden yellow film, and in 5 mins. a steel-blue film ; as the temp. rises further the action becomes faster ; at 180°, the steel-blue film appears in $\frac{1}{4}$ min. ; at 197°, in 5 secs. ; and at 227°, immediately. Lead which has been rendered passive by immersion in nitric acid, and well washed, reacts with ozone, producing in 10 secs. a golden-yellow colour.

The atmospheric oxidation is complicated by the presence of **water ;** as just indicated, if moisture be absent, neither oxygen nor air attack lead. W. G. Whitman and R. P. Russell studied the effect of dissolved oxygen on the rate of attack of lead by acids. F. Clowes said that in an atm. of hydrogen or in vacuo, air-free

water dissolved 0·3 part of lead per million; F. C. Calvert and R. Johnson said that 200 litres of air-free distilled water dissolved 1·529 grms. of lead per sq. metre in 8 weeks; H. Heap, J. I. Pierre, and W. C. Parsons observed very little action. A. Traube-Mengarini and A. Scala said that lead yields a colloidal soln. of the metal when treated with distilled water free from oxygen and in vacuo; the particles show the Brownian movement. According to C. D. Bengough and J. M. Stuart, the surface attack of lead by water produces a film of the colloidal gel lead hydroxide, but this film soon crystallizes, and no longer protects the metal from further attack. In contact with oxygen from the air the colloidally dissolved metal is rapidly transformed into the colloidal hydrated oxide, the particles of which slowly aggregate to form crystals of various forms. Electrolytes, above a conc. characteristic for each, prevent the corrosion of lead; below this conc. corrosion continues, but the colloid is coagulated and deposited on the surface of the metal. It is considered that the colloidal state is an ionized combination of a colloid with water. On the other hand, if the water be thoroughly purified and free from dissolved gases, and the lead be thoroughly purified, and confined in quartz vessels, it is probable that there will be no reaction with the metal, for B. Lambert and H. E. Cullis, W. R. Nichols, W. van Rijn, R. Phillips, E. N. Horsford, C. Stalmann, P. Yorke, U. Antony and T. Benelli, G. Wolffhügel, and M. Müller were unable to detect any reaction between lead and air-free water at ordinary temp. J. C. Thresh also found that water alone has no action on lead.

L. B. G. de Morveau, A. Baumé, N. C. de Milly, M. Luzuriaga, and M. Delaville observed that when in contact with lead, water acquires *un aspect laiteux;* and P. A. von Bonsdorff, and G. Wetzlar showed that in the presence of air freed from carbon dioxide lead is attacked by water, forming white flakes of lead hydroxide, and the water becomes sat. with that compound.· Confirmatory observations have been reported by A. Scala, J. C. Thresh, W. R. Nichols, and H. Heap. O. Bauer and E. Wetzel showed that the attack on lead by distilled-water in air is less than by rain-water; and, according to R. Christison, the attack by distilled-water alone is greater than when salts are present in soln.; and L. B. G. de Morveau, and M. E. Chevreul, greater than hard-water. J. F. Liverseege and A. W. Knapp found that exposure to light increases the action of water on lead; and that the nearer the lead is to the surface of the water, the greater the corrosion; that the differences in the corrosive action of different waters are not due to the difference in the contained oxygen, but in opposition to E. Reichardt, the volume of oxygen in soln. limits the amount of lead eroded, if no more oxygen be admitted: and that in closed tubes the amount of lead eroded only corresponds to the maximum amount of plumbous oxide or salt that could be produced by the oxygen present (thus 7·8 c.c. per litre of oxygen give 14 parts of plumbous lead per 100,000). N. W. Fischer found that if a platinum wire be wound about the lead, the oxidation by air and water is accelerated. P. Yorke found that a clean iron nail driven through the lead plate produces a quicker attack, and the nail does not rust in the vicinity of the lead. M. Pettenkofer said that lead soldered with tin is less rapidly attacked than before, while F. J. Otto, and A. Smith said it is more quickly attacked. L. Besnou, G. Wolffhügel, and F. E. Wynne noted the rapid attack on tinned lead tubes. F. Malméjac showed that lead strips in the mineral water of Sétif lost 0·20 grm. in 20 days under conditions where a similar strip wrapped with iron wire lost 0·04 grm., and with copper wire 0·10 grm. A. Scala found that the solubility of lead in water is not hastened by alloying the metal with tin, or using Pb-Zn, Pb-Sn, Pb-C, or Pb-Cu couples. P. Carles observed that the presence of foreign metals may hasten the corrosion by forming sacrificial couples (1. 16, 3).

B. Lambert and H. E. Cullis showed that the corrosion of lead proceeds very quickly even when the metal, the oxygen, and water are of the highest attainable degree of purity; if the lead be kept a long time in vacuo before it is exposed to the oxygen, the rate of corrosion is enormously decreased. M. Berthelot found the corrosion is accelerated in the presence of acids. C. F. Schönbein raised the

question : Does all the oxygen concerned in the corrosion of the metal actually unite with the metal ? and returned the answer : No ! He called that part of the oxygen which unites with the metal the *bound oxygen,* and the other part which he found to produce hydrogen dioxide, he called active oxygen. The oxygen is said to be *activated* during the oxidation. C. Engler called the substance undergoing oxidation the *auto-oxidizer,* and the substance which simultaneously unites with the active oxygen, the *acceptor.* C. F. Schönbein showed that just so much oxygen is ·rendered active or consumed in the formation of hydrogen dioxide as is consumed by the oxidizing metal. An exact proof is not always possible because some hydrogen dioxide may be due to a secondary reaction.

A gram of lead was mixed with 200 grms. of mercury, and shaken with 300 c.c. of standardized sulphuric acid (1 : 55) in the presence of oxygen. The lead sulphate which formed was filtered off, and the amount of sulphate still remaining was determined by the titration of an aliquot part of the filtrate. The reactions were presumably $Pb(auto-oxidizer) + H_2O(acceptor) + O_2 = PbO + H_2O_2$; and then $PbO + H_2SO_4 = H_2O + PbSO_4$. The amount of bound oxygen consumed in the primary formation of lead monoxide was then computed. The amount of active oxygen was obtained by titrating an aliquot portion of the soln. with standard potassium permanganate soln. It was found that the ratio bound oxygen : active oxygen $= 1\cdot46 : 1\cdot39$. This is in agreement with C. F. Schönbein's hypothesis.

M. Traube confirmed these results. W. Merckens said that the tendency of metals to form hydrogen dioxide in moist air is smaller the higher the metal stands in Volta's electrochemical series—Mg, Al, Zn, Cd, Ni, and Co. C. F. Schönbein considered that the mercury acted by amalgamating with the lead, and by keeping it in a clean finely divided condition for the attack by water and oxygen. Lead alone gives less hydrogen dioxide than lead amalgam. M. Traube represented the reaction :

$$Pb + O < \begin{matrix} H \\ H \end{matrix} + \begin{matrix} O \\ O \end{matrix} = PbO + \begin{matrix} H - O \\ H - O \end{matrix}$$
followed by $PbO + H_2O = Pb(OH)_2$. C. F. Schönbein assumed that the oxygen itself is compounded of a negatively and a positively charged atom. The former united with water producing hydrogen dioxide, and the latter united with lead to produce lead monoxide. Various modifications of these hypotheses have been discussed by J. W. Mellor.

In the *hydrogen dioxide theory of corrosion* advocated by W. R. Dunstan and co-workers it is assumed that the formation of hydrogen dioxide is directly concerned in the wet oxidation of the metals : $Pb + H_2O + O_2 = PbO + H_2O_2$; and $PbO + H_2O = Pb(OH)_2$, and $Pb + H_2O_2 = Pb(HO)_2$. An opposing hypothesis assumes that the hydrogen dioxide is a secondary product of the reaction formed by the action of ordinary molecular oxygen on nascent hydrogen, after, and not during, the actual corrosion. The **hydrogen dioxide** can convert the lead hydroxide produced by the reaction into a higher stage of oxidation ; and B. Lambert and H. E. Cullis found that if the oxidation is allowed to proceed for many months, lead dioxide, and possibly the sesquioxide and tritatetraoxide are formed. J. W. Shipley also attributed the formation of the higher oxides of lead to the hydrogen dioxide produced as just indicated.

In the *electrolytic theory of corrosion,* advocated by W. R. Whitney, J. W. Shipley, and B. Lambert and H. E. Cullis, it is assumed that the pure metal is not homogeneous, for it contains at least two allotropic forms. The resulting differences in the physical character produce electrolytic action between the different parts of the metal. The resulting film of hydrogen protects the metal from further attack by offering an enormous resistance to the passage of the current. If oxygen is present, the film of hydrogen is oxidized, the polarization is destroyed, and water and hydrogen dioxide are produced. The theory can also be expressed in the language of the ionic hypothesis. L. A. Stenger believed that the varying conc.

of the salt soln. in contact with the lead produced concentration-cells which caused electrolytic action. H. S. Rawdon referred the "perishing" of the metal to the electrolytic dissolution of its intergranular impurities with the resulting isolation of the crystallites. A. Scala found that the solubility of lead in distilled water is not appreciably affected by connecting the lead with zinc, tin, or copper.

According to H. V. Regnault,[4] lead at a white heat is decomposed by water-vapour forming lead oxide : $Pb+H_2O \rightleftharpoons PbO+H_2$, but, according to P. A. von Bonsdorff, the decomposition does not occur at a red heat. Lead monoxide is reduced by hydrogen, so that the reaction, as symbolized, is reversible. A. S. Taylor, G. Wolffhügel, and J. C. Lermer observed that steam attacks lead, and particularly so in the presence of air and carbon dioxide. The last-named found that by alloying the lead with increasing proportions of tin, the corrosion becomes less and less. According to F. Stolba, boiling water decomposes lead with the evolution of hydrogen, and the formation of soln. of lead hydroxide with an alkaline reaction. J. Percy reported that if the boiling water be quite free from atm. air, it has no action on lead ; but if air has access to the boiling water, or if the water has not been de-aerated, the lead is attacked and the metal can be detected in the water. An alloy of lead with 2 per cent. of antimony was not attacked by boiling water deprived of air, and even if air had access the action was very slow. Neither an alloy of lead with 5 per cent. of zinc nor one with 5 per cent. of zinc and 5 per cent. of antimony was attacked by boiling water freed from air. S. Zinberg found that the addition of a trace of copper to lead causes a turbidity in water in contact with the lead, while adding less than 0·25 per cent. of lead to brass or bronze makes it corrodible by water. Adding tin to lead makes it less corrodible by water. The opposite effect is explained by the potential of tin in the lead-tin alloys, which being higher than that of lead, prevents the formation of hydrated lead oxide, whilst the potential of copper being lower than that of lead cannot protect the lead from the action of water.

At the beginning of our era, Pliny, in his *Historia naturalis* (31, 19), mentioned the corrosive action of natural waters on metals ; and he also referred to the use of lead in making pipes. Near the beginning of our era, T. Varro, in his *Rerum rusticarum*, stated that lead conduits were used in Rome to distribute the water from the Appian Way ; and although Vitruvius in his *De architectura* mentioned the danger attending the use of lead pipes for the water supply of Rome, it was only during the Middle Ages that the corrosive action of water on lead began to attract serious attention, and systematic observations were inaugurated near the beginning of the nineteenth century. Since that time, the action of atmospheric agents— water, carbon dioxide, and oxygen—and of natural waters containing the two gases in soln. has attracted numerous investigators chiefly on account of the extensive use of lead-piping for leading water-supplies into houses ; and of sheet-lead for lining cisterns for storing water. The subject is of particular importance in view of the toxic properties of water contaminated with lead compounds in soln. As indicated above, the dissolution of lead by water is largely conditioned by the presence of oxygen or air. This has been demonstrated by the observations [5] of A. J. Balard, L. Besnou, A. Bobierre, P. A. von Bonsdorff, F. C. Calvert and R. Johnson, R. Christison, A. Faiszt, M. J. Fordos, P. Fortner, E. N. Horsford, R. Kersting, H. Klut, B. Lambert and H. E. Cullis, M. Müller, M. Pettenkofer, R. Phillips, M. Pleissner, J. Rodenburg, S. Ruzicka, J. Smith, G. Wetzlar, G. Wolffhügel, and P. Yorke. Owing to the action of potable water on lead, it is often recommended that the water which has been standing in the pipes overnight should be run off in the morning.

Increasing the proportion of oxygen dissolved in the water was found by T. Paul and co-workers to hasten the corrosion of lead. The soln. is sat. with lead oxide or hydroxide which is formed when it contains 110 mgrms. PbO per litre. F. Clowes found that by passing oxygen into 100 grms. of distilled water, 0·013 grm. of lead dissolved in 24 hrs., 0·023 in 48 hrs., and 0·029 in 72 hrs. The speed of corrosion

was diminished in the presence of carbon dioxide, sulphuric acid, carbonates, sulphates, or lime-water. P. F. Frankland found that water containing oxygen is less active when the water is compressed, while the activity of water containing carbon dioxide is not materially affected by increasing the press. J. H. Marais said that water saturated with carbon dioxide will dissolve 0·012 grm. of lead per litre.

F. Clowes found that water containing **carbonic acid** alone corrodes lead far more slowly than water with oxygen in soln.; thus, under similar conditions, as in the experiments with oxygen alone, he found 0·005 grm. of lead was dissolved in 24 hrs., 0·008 grm. in 48 hrs., and 0·017 grm. in 72 hrs. Observations were also made by M. M. P. Muir, J. Milne, S. Ruzicka, J. Rodenburg, and C. Umney. L. Bourgeois found the crystalline deposit sometimes formed has the composition $3PbO.2CO_2.H_2O$. According to J. F. Liverseege and A. W. Knapp (expressing the alkalinity of water as parts of $CaCO_3$ per 100,000 parts of water, and the erosion in terms of parts of lead per 100,000 parts of water dissolved when $\frac{1}{4}$ sq. in. of lead is immersed in 10 c.c. of the liquid per day), for waters of low alkalinity (0·4) the increase of carbon dioxide produces little effect until as much as 1 per cent. is present (Fig. 15), so that in all probability with our ordinary treated and untreated waters carbon dioxide is not an important factor in erosion. From 1 to 2 per cent. of carbon dioxide causes a sudden change, for this quantity is sufficient to prevent " erosion " and to cause " plumbo-solvency," i.e., the lead precipitate ceases to appear, lead hydrocarbonate being soluble. Carbon dioxide is not necessary

FIG. 15.—The Effect of Carbon Dioxide on the Corrosion of Lead.

for the corrosion, for lead is attacked in the absence of free carbon dioxide. E. Gudeman showed how carbonated water will attack the solder used in sealing fruits, etc., in tins.

The effect of the dissociation or ionization of the carbonic acid in soln. was worked out by T. Paul and co-workers, on the basis of J. Walker and W. Cormack's and G. Bodländer's results : $[H\cdot][HCO_3{'}]=k_1[H_2CO_3]$, and $[H\cdot][CO''_3]=k_2[HCO']$, where $k=3\cdot04\times10^{-7}$, and $k_2=1\cdot3\times10^{-11}$. Assuming the lead carbonate is present as a solid phase, and that the lead carbonate in soln. ionizes $PbCO_3\rightleftharpoons Pb\cdot\cdot+CO_3{''}$, it follows that $[Pb\cdot\cdot][CO''_3]=k$; and from these equations, $[Pb\cdot\cdot]=(kk_1[H_2CO_3])/(K_2[HCO'_3])$; meaning that the concentration of the lead ions in soln. is directly proportional to the conc. of the free carbonic acid, and inversely proportional to the square of the conc. of the hydrocarbonate ions. M. M. P. Muir found that by increasing the press. of the dissolved carbon dioxide up to 6 atm. the solvent action of water on lead was increased. The joint action of air and carbon dioxide has been investigated by R. Christison, T. Graham and co-workers, L. B. G. de Morveau, M. Müller, M. M. P. Muir, T. Paul and co-workers, E. Reichardt, M. Traube-Mengarini and A. Scala, R. Wagner, G. Wölffhügel, P. Yorke, etc. F. Clowes noted that the rate of corrosion is retarded by the presence of carbonic acid, thus, under the same conditions as in the previously described experiments but in the presence of 8 vols. of oxygen to one vol. of carbon dioxide, 0·015 grm. of lead was dissolved in 24 hrs., and 0·018 grm. in 48 hrs. T. Graham and co-workers showed that while small proportions of carbon dioxide in water decreased its corrosive action, larger proportions increased the effect. P. F. Frankland, and A. Wagner thus found that carbon dioxide is more active than oxygen in accelerating the corrosion of lead by water. H. Heap, and F. Clowes showed that the oxygen first attacks the lead, $2Pb+O_2=2PbO$; the oxide is hydrated $PbO+H_2O=Pb(OH)_2$; and the hydroxide is attacked by the carbonic acid, $2Pb(OH)_2+CO_2=H_2O+CO_3(Pb.OH)_2$, and $Pb(OH)_2+CO_2=PbCO_3+H_2O$; and the lead carbonate passes into the hydrocarbonate, $PbCO_3+CO_2+H_2O\rightleftharpoons Pb(HCO_3)_2$. H. Heap
found that the corrosive action of natural water increased with rise of temp. up to 100°, while with distilled water, the activity increased from 5° to 50°, and thereafter decreased as the temp. rose from 50° to 100°.

A. Barillé found that the action of Seltzer water on the syphon of the metal container—an alloy of lead and tin or antimony—for 6 months dissolved the eq. of 0·0905 grm. of lead sulphate, and 0·0381 grm. of stannic acid per litre ; and that the alloys were more readily attacked than the individual metals.   J. Attfield, G. Brownen, A. Chevallier, J. M. Cyrnos, A. Gautier, J. Steiner, W. Thomson, and A. F. Wilson have discussed the solvent action of soda-water, and other mineral-waters on lead, and plumbiferous alloys.   C. H. Crowe, and H. F. Whittaker discussed the general subject of the corrosion of lead.

If clean strips of lead are immersed in distilled-water and ordinary tap-water contained in stoppered bottles, and allowed to stand for some months, the distilled-water will contain basic lead carbonate in suspension while the tap-water will be clear.   In the latter case, the action has been stopped by the formation of a coherent, protective crust of salt on the metal.   The phosphates, carbonates, and hydrocarbonates in water are the most efficacious, and the sulphates and chlorides are also good.   One part of calcium hydrocarbonate in 50,000 parts of water affords a protective coating ; so does lime when present in amounts below 1 : 10,000 ; if more than this amount of lime is present, the lead is attacked.   Owing to the solvent action of the water supply on lead pipes in some towns in Lancashire and Yorkshire lead poisoning was prevalent for a considerable period before its real nature was recognized, and the cause discovered.   Lead, being a cumulative poison, may produce serious results if regularly taken in very minute quantities over long periods of time.   The softest and purest water and peaty waters often act most. readily on lead, so that lead has always been considered a more or less dangerous metal in connection with the supply of potable water.   These waters are treated with limestone to make them safe.   The subject has therefore attracted a great deal of attention.   The results of the various observations show that water of a moderate degree of temporary and permanent hardness, and containing but little dissolved nitrates and inappreciable quantities of ammonium salts, may be safely conveyed in lead pipes.   L. Greenburg traced the lead in some cistern-water to the flashing on the roofs of buildings which collected the rain-water.

Observations on the solvent action of rain and other natural waters on lead have been made by A. H. Allen, U. Antony and T. Benelli, A. J. Balard, H. Bamberger, O. Bauer and E. Wetzel, E. de Beaumont, E. Belgrand, A. Bellocq, M. Berthelot, L. Besnou, C. H. Bisserié, A. Bobierre, C. Bouillaud, A. C. Brown, F. C. Calvert and R. Johnson, P. Carles, M. Champouillon, M. E. Chevreul, H. W. Clark, F. Clowes, J. B. A. Dumas, G. Flögel, M. J. Fordos, F. Fischer, P. F. Frankland, R. H. Gaines, J. H. Garrett, H. Heap, E. N. Horsford, A. C. Houston, W. P. Jorissen, W. Kaiser, H. Klut, G. Kühnemann, C. G. de Laval, J. H. Marais, M. Mayençon and M. Bergeret, H. Medlock, M. Müller, W. R. Nichols, J. Rodenburg, P. Schmidt, C. Schneider, P. Schweitzer, J. C. Thresh, E. Vandevyverre, A. Wagner, W. C. Williams, G. Wolffhügel, and H. W. Woudstra and C. J. Snuif.

C. H. Crowe, M. M. P. Muir, and S. Ruzicka said that the presence of soluble *chlorides* diminished the magnitude of the attack, and M. Traube-Mengarini and A. Scala said that the chlorides decrease the formation of hydroxide in a marked manner.   On the other hand, J. C. Thresh, A. J. Balard, M. J. Fordos, T. Graham and co-workers, C. H. Bisserié, E. N. Horsford, H. Letheby, A. Mailhe, J. B. Nevins, R. Phillips, and C. Reichel found the presence of chlorides raised the solvent action of water on lead.   Table V contains some results selected from S. Ruzicka's observations.   Pieces of lead, obtained by cutting longitudinally pieces of tubing 11·5 cms. long, and 2 cms. external diameter and 1·3 cms. internal diameter, were exposed for 24 hrs. to water of different degrees of hardness, and the results are expressed in mgrms. of lead dissolved at ordinary temp.   Numbers in brackets are doubtful.   The salts marked with an asterisk were employed with

air-free water. J. A. N. Friend and J. S. Tidmus found after 200 days' exposure to 99·9 per cent. lead at a mean temp. of 8·5°, with sodium chloride soln. :

NaCl	.	0	2·5	5·0	7·5	10·0	15	30	60 grms. per litre
Loss	.	0·0334	0·2331	0·2626	0·4003	0·6982	0·5670	0·2425	0·1267 grm.

and with potassium chloride soln. under the same conditions for 201 days :

KCl	.	.	0	2·5	5·0	8·0	15·0	40	80 grms. per litre
Loss	.	.	0·0315	0·5006	0·3747	0·5056	0·2453	0·0574	0·0496

J. A. N. Friend and R. H. Vallance found that the presence of colloids retards the corrosive action. The effect of chlorides in the presence of sulphates, nitrates, and carbonates was examined by C. H. Bisserié, C. H. Crowe, R. Christison, S. Ruzicka, A. Mailhe, and P. Yorke. C. Reichel found that when soln. of *sodium chloride* are in contact with lead, in air, a crust of lead chloride, oxide, and carbonate is formed, and some lead passes into soln. Common salt is more active than purified sodium chloride. Moist sodium chloride in contact with lead, or plumb-iferous tin, soon takes up appreciable amounts of lead. A. J. Hale and H. S. Foster found 0·02N-NaCl dissolved 0·02 grm. per sq. dm. per day in 7 days, and 0·08 grm. per day in 28 days at 17°–20°. A. Wagner, and G. Lunge and L. Weibel measured the corrosive action of these soln. on lead—a sat. soln. of sodium chloride in 8 days at 20° dissolved 0·010 grm. per sq. dm., and 0·015 in 2 hrs. at 100°. M. M. P. Muir found a soln. of 0·250 grm. of *calcium chloride* in a litre of water dissolved 0·5 mgrm. of lead from 5600 sq. mm. of lead in 72 hrs. A. J. Hale and H. S. Foster found 0·2N-CaCl$_2$ dissolved 0·40 grm. per sq. dm. per day in 7 days at 17°–20° and 0·15 grm. per day in 28 days ; while a 0·2N-soln. of *magnesium chloride* dissolved 0·55 grm. per sq. dm. per day in 7 days and 0·12 grm. per day in 28 days. The action of *sea-water* on lead was investigated by O. Bauer and E. Wetzel, and R. Kaiser. The lead from the fire-ship, *Firebrand*, sunk in Falmouth Harbour in 1780, and raised in 1846, was examined by A. Russell. The lead from the pump was melted, and cavities in the metal contained crystals of cotunnite, PbCl$_2$; anglesite, PbSO$_4$; and leadhillite, PbSO$_4$.2PbCO$_3$.Pb(OH)$_2$. C. Matignon observed that the powder obtained by the disintegration of lead objects in museums consists of lead carbonate and chlorides. He found that a piece of lead dipped in a 30 per cent. soln. of sea-salt, and then dried so as to become coated with salt crystals, progressively disintegrated in 3 years, while a piece of similar lead, not so treated, was not destroyed. Lead oxychloride, and sodium hydrocarbonate are formed. He attributed the effect to the cyclic effect of the catalytic agent—sodium chloride : 2NaCl+Pb+O+CO$_2$=Na$_2$CO$_3$+PbCl$_2$; and Na$_2$CO$_3$+PbCl$_2$=PbCO$_3$+2NaCl.

According to S. Ruzicka, the presence of *sulphates* hinders the attack of water on lead (Table V), and M. Traube-Mengarini and A. Scala said that sodium sulphate acts by preventing the formation of lead hydroxide. J. A. N. Friend and J. S. Tidmus found after 192 days' exposure of 99·9 per cent. lead at a mean temp. of 8°, with sodium sulphate soln. :

Na$_2$SO$_4$.10H$_2$O	.	0	2·5	5	10	20	50	100	200 grms. per litre
Loss		.	0·0428	0·0215	0·0198	0·0518	0·0170	0·0028	0·0015	0·0015

and with potassium sulphate soln. under the same conditions for 192 days :

K$_2$SO$_4$	.	.	0	2·5	5·0	8·0	15	40	80 grms. per litre
Loss	.	.	0·0379	0·0183	0·0331	0·0373	0·0574	0·0110	0·0079

Water containing aluminium and calcium sulphates was found by H. Heap to dissolve much lead, but if calcium sulphate and hydrocarbonate are present, M. Müller found that very little is dissolved.

The effect of various sulphates in natural waters was studied by A. J. Balard, P. A. von Bonsdorff, C. H. Bisserié, E. Belgrand, M. J. Fordos, T. Graham and co-workers, G. Kühne-mann, A. Mailhe, and E. Solly ; and the effect in the presence of chlorides and nitrates,

TABLE V.—THE CORROSIVE ACTION OF SALT SOLUTIONS ON LEAD.

Salt.	Degrees of hardness.						
	1¼°	2½°	5°	10°	20°	40°	100˙
NH₄Cl*	5·0	4·0	3·5	2·5	1·6	1·8	—

by T. Paul and co-workers, and S. Ruzicka. A. Wagner said that a soln. of *potassium sulphate* had no action on lead, and that the lead suffered no loss of weight in a soln. containing a gram of that salt in 100 c.c. of water although traces of lead were present in the liquid, and G. Lunge and L. Weibel found 100 grms. of *sodium sulphate* in a litre of water dissolved 0·0076 grm. of lead from a sq. dm. surface in 7 days at 20°, and 0·0058 grm. in 2 hrs. at 100°. M. M. P. Muir found 0·200 grm. of sodium sulphate in a litre of water dissolved 0·8 mgrm. of lead from a 5600 sq. mm. surface in 72 hrs. Under similar conditions, a soln. of 0·252 grm. of *calcium sulphate* in a litre dissolved 0·4 mgrm. in 24 hrs. and 0·8 mgrm. in 72 hrs. The presence of carbonates was found by T. Carnelley and W. Frew, P. F. Frankland, H. Heap, H. Klut, G. Kühnemann, M. T. Lecco, A. Leonhardt, M. Müller, M. M. P. Muir, M. Neisser, W. R. Nichols, R. Proskauer, S. Ruzicka, J. C. Thresh, etc., to retard the action of water on lead (Table V). J. C. Thresh found that the precipitation of lead carbonate is hindered by citric, tartaric, or quinic acid, while formic, acetic, or benzoic acid has very little effect. The effect in the presence of chlorides, nitrates, and sulphates was studied by M. J. Fordos, and S. Ruzicka. According to P. Carles, the presence of *nitrites* favours the attack of water on lead. C. H. Crowe, and S. Ruzicka said that the presence of *nitrates* favours more or less the action of water on lead. Similar results were obtained by A. J. Balard, P. A. von Bonsdorff, C. H. Bisserié, J. B. J. D. Boussingault, T. Carnelley and W. Frew, M. J. Fordos, P. Fortner, T. Graham and co-workers, E. N. Horsford, R. Kersting, H. Letheby, C. Stahlmann, J. C. Thresh, M. Traube-Mengarini and A. Scala, etc. (Table V). A. Wagner found that a soln. containing a gram of *potassium nitrate* in 100 c.c. of water in a week removed 14 mgrms. of lead per 11·831 sq. cm. of lead when carbon dioxide was removed from the air, and 20 mgrms. when the carbon dioxide was not removed—the filtered liquid was plumbiferous. T. Carnelley and W. Frew found the attack is very much hindered if air be excluded. M. M. P. Muir observed the solvent action of soln. of potassium nitrate on lead. C. F. Schönbein, and P. Fortner showed that lead reduces the alkali nitrates to nitrites and some metal passes into solution. J. Kliatchko and C. Binggely found that with lead electrodes soln. of potassium and lithium nitrates are reduced more rapidly than with copper electrodes and more slowly than with cadmium

electrodes. J. L. Proust found that a warm aq. soln. of lead nitrate dissolves some lead. J. A. N. Friend and J. S. Tidmus found that 99·9 per cent. lead at a mean temp. of 8·0° after 189 days' exposure to soln. of potassium nitrate, lost

KNO₃			0	5	10	15	50	100 grms. per litre.
Loss			0·0393	0·8156	1·0902	1·7188	0·8692	0·5342

S. Ruzicka studied the joint effect of nitrates, chlorides, sulphates, and carbonates. A. Wagner detected no action on lead by a soln. of a gram of *sodium carbonate* in 100 c.c. of water ; M. M. P. Muir found a soln. of 0·310 grm. of *potassium carbonate* in a litre of water dissolves 0·2 mgrm. of lead from 5600 sq. mm. cross-section in 72 hrs. A. J. Hale and H. S. Foster found 0·2N-Na₂CO₃ dissolved 0·10 grm. per sq. dm. in 28 days, and 0·00 grm. in 7 days at 17°–20°. The presence of *phosphates* in the water favours the formation of a protective film on the surface of the metal as shown by R. Christison, A. Gautier, W. R. Nichols, J. C. Thresh, A. Parkes, E. Reichardt, G. Wölffhügel, and P. Yorke. According to K. Scheringa, if a plumbiferous water be kept some time in a glass vessel, some of the lead compound is deposited on the glass. The presence of *silicates* in the water retards the action of water on glass. This was shown by the work of R. Böttger, T. Carnelley and W. Frew, F. Clowes, J. C. Thresh, P. F. Frankland, and W. Crookes and co-workers. W. Crookes and co-workers showed that 0·5 grain of dissolved silica per gallon will render water " lead-proof." According to T. Carnelley and W. Frew, M. J. Fordos, R. Kersting, H. Medlock, M. M. P. Muir, C. Stahlmann, and G. Wolfihügel, the presence of even small traces of *ammonium salts* favours the corrosion of lead (Table V). H. Heap said that this action depends on the ready dissociation of the salts in soln., so that they behave rather like dil. acids than like neutral salts. According to T. Carnelley and W. Frew, *slaked lime* acts more energetically than water alone, either with or without the exclusion of air. G. A. Stutterheim found that the presence of calcium hydroxide per litre lowered the attack in 24 hrs. from 3·7 mgrms. to 0·2–0·3 mgrm. of dissolved lead per litre. Sand, calcium carbonate, old mortar, and calcium silicate exert a protective action. L. Besnou, H. Endemann, and M. Müller also observed that limewater exerts a corrosive action ; and E. J. Kohlmeyer, cement-water. G. von Knorre found that lime-water does not attack lead if air be carefully excluded, but the action is energetic in the presence of air. The retarding action of calcium carbonate on the corrosive action of lead was discussed by M. Neisser, P. F. Frankland, T. Graham and co-workers, F. le Blanc, M Champouillon, H. Letheby, U. Antony and T. Benelli, M. Müller, H. Heap, C. G. Egeling, etc. According to J. F. Liverseege and A. W. Knapp, the erosion, expressed as the amount of lead in parts per 100,000 parts of water, dissolved, removed from ½ sq. in. of lead exposed to 10 c.c. of water for one day. The results are plotted in Fig. 16. They found that as the amount of *calcium hydroxide* present in the water increases, the amount of lead eroded falls to a minimum when there is present about 7 to 10 parts of calcium hydroxide per 100,000. After this point, an increase in the proportion of calcium hydroxide causes an increase in the erosion, which gradually approaches its original value. As the amount of *calcium carbonate* and *hydrocarbonate* present in the water increases, the amount of lead eroded continually falls. *Calcium hydrocarbonate* is by far the most effective preventer of erosion. Only about half the quantity of bicarbonate is required to form a protective coating as compared with carbonate. This would receive a theoretical explanation if, as seems probable, the coating is a carbonate of lead. As little as two parts per 100,000 of calcium bicarbonate is generally sufficient to form a plumbo-protective coating on the lead. Assuming that the actual coating is lead carbonate, it would form a layer only 0·000016 cm. thick. As suggested above, the irregularities that are observed in the erosion with water about this alkalinity may be due to the fact that the deposit does not quite cover the lead surface and leaves a little bright lead open to the ordinary erosive action. The *alkalinity* of the water (the total alkalinity expressed as parts of CaCO₃ per 100,000 parts of water) is an important factor in the corrosion of lead ; J. F. Liverseege and A. W. Knapp found that with waters of alkalinity 0·2–0·6, and generally with treated waters the alkalinity of which does not exceed 1·5, *the whole of the surface of the lead is eroded.* A flocculent precipitate forms, which falls to the bottom of the tube and leaves the lead surface quite bright but mottled.

FIG. 16.—Corrosion of Lead by Calcium Hydroxide and Carbonate.

With treated water of alkalinity 1·5–2·5, the action is usually one of *corrosion* rather than of erosion ; a loosely-held, opaque, white crust forms here and there irregularly on the lead surface. This crust appears on the upper surface of the inclined lead in an ordinary erosion test, on the under surface if the lead is placed horizontally and almost touching the glass, and on both sides if the lead stands vertically. With waters of alkalinity 2·5 and over

the lead almost invariably becomes covered with a dull whitish film, which appears to act as a *protective coating*. J. C. Thresh also discussed this question. F. Varrentrapp, and G. A. Stutterheim noted the retarding influence of soluble *iron salts*, and E. N. Horsford, of iron rust on the corrosion of lead. H. Medlock patented a process for purifying plumbiferous waters by iron. The influence of *organic matters* in water was investigated by H. M. Noad, J. C. Thresh, E. N. Horsford, T. Graham and co-workers, M. Müller, H. Medlock, T. Carnelly and W. Frew, etc. The results show that when the organic matter is oxidized to ammonium salts, the action may be accelerated. J. A. N. Friend and R. H. Vallance found that the presence of colloids—dextrin, gum, or agar-agar—reduces the corrosive action of water. S. Ruzicka found that a decoction of peat increased the corrosion, but decoctions of radish-leaves, grass, or fish reduced the attack. The activity of many natural waters, said H. Heap, is to be explained by the presence of varying amounts of ammonium nitrate, and he added : " Moorland streams are generally very pure. waters and contain small amounts of saline matter, thus approaching in character very nearly to distilled water. Thus, as one would expect, the amounts of lead they dissolve are very similar ; but river waters, having transversed stretches of rocky beds and dissolved appreciable amounts of mineral matter, behave more like dil. saline soln. and exert much milder action upon lead than the purer waters."

According to A. C. Houston, " Neutral waters sometimes erode lead in the presence of oxygen. Neutral moorland waters are not erosive unless they have been previously in contact with lead. Acid moorland waters, so-called peaty waters, are apt to possess erosive properties, but the action is not so rapid as that of distilled water They may erode not only bright but also old coated lead. Rain-water after stagnating in peaty, boggy, or marshy places becomes acid ; this acidity is greater than that which rain-water may acquire before falling on the ground. During storms, and when wet succeeds dry weather, moorland water becomes very acid and acts strongly on lead. During dry weather the water draining from moorlands is generally neutral and does not attack lead. Water draining from formations rich in iron pyrites may be acid and act on lead ; the acidity of moorland waters is seldom attributable to this cause. Acid-producing bacteria are found in peat. Neutral sterile decoctions of peat inoculated with fresh peat became acid and acquired the power of attacking lead."

J. I. Crabtree and co-workers [6] studied the action of *photographic solutions* on leaden vessels. Lead is but slowly corroded in contact with some soils, while in others active deterioration occurs. Antique objects of lead always have a white appearance due to the formation of a basic lead carbonate. According to J. H. Pepper, and C. L. Bloxam, the lead of old coffins is sometimes found to have become entirely converted into an earthy-looking mass of basic carbonate of lead. T. Carnelley and W. Frew found that a peaty soil protected lead piping from corrosion ; blue clay was highly corrosive ; chalk protected the lead, likewise also magnesium oxide, calcium carbonate, old mortar, calcium silicate, sand or a mixture of sand and calcium carbonate. The action of soils was also examined by L. A. Stenger, and J. W. Shipley. In some soils considerable damage to lead pipes is produced by electrolysis, and the electrolysis may be due to the escape of current from electric railway lines, etc. The corrosion of lead by stray currents has been discussed by O. Hähnel, R. H. Gaines, E. R. Shepard, H. Michalke, F. O. Anderegg and R. V. Achatz, W. N. Smith and J. W. Shipley, E. F. Petritsch and A. H. de Vogt, H. F. Zangger, S. C. Bartholomew, J. Chapuis and H. Deprez, M. Remaugé, M. Girousse, B. McCollum and G. H. Ahlborn, etc. Although T. Carnelley and W. Frew showed that old mortar has a protective action on lead pipes, it is well known to plumbers that lead pipes laid on new mortar are liable to corrosion. G. von Knorre showed that when lead pipes come in contact with mortar or cement where air has easy access, corrosion frequently occurs. This is attributed to the action of air and moisture ; similar observations were made by O. Bauer and E. Wetzel. According to W. Vaubel, the attack is due to the formation of a calcium peroxyhydrate, but H. Ditz and co-workers do not accept this view. R. H. Gaines studied the corrosion of lead in damp concrete for two months, and found with lead a loss of about 12 grms. per sq. ft., whereas with steel, the highest loss observed was 2·48 grms. per sq. ft., with copper 1·04 grms. per sq. ft., and with manganese bronze, 0·30 grm. per sq. ft. The corrosive action of cement, or of water seeping through concrete, was also noted by E. J. Kohlmeyer, and G. C. Bunker and A. H. Khachadoorian.

In 1787, R. Watson [7] commented on the corrosion of roofing lead.   He said :

When plumbers strip the roofs of churches, or other buildings covered with lead, which has lain undisturbed for many years, they usually find that side of the lead which is contiguous to the boards, covered with a white pellicle, as thick sometimes as a half-crown ; this pellicle is corroded lead, and is as useful for painting, and other purposes, as the best white lead.   The lead on the south side of any building is found to abound-most with this white crust ; that on the north side having very little, or none at all of it.   It is believed, also, that lead which lies on deal boards is not so apt to be covered with this white incrustation, as that which lies upon oak : if there be any truth in this observation, it may, perhaps, be explained from hence, that oak contains a much stronger acid than deal, and this strong acid being distilled, as it were, by the heat of the sun in summer, attaches itself to the lead, and corrodes it : or this corrosion may be the effect of the sun and air, which, by their constant action, calcine or corrode the lead ; and this calcined lead not being washed off by the rain, may, in the course of a great many years, form the crust here spoken of.

J. S. S. Brame also observed the corrosion of lead in contact with oak, and F. Southerden said that the roofing of Axminster church laid on deal in 1833 was sound 85 years afterwards, but the portion laid on oak in 1909, was thickly encrusted with white lead after nine years.   P. Dunsheath noted the corrosion of lead pipes in contact with oak.   C. E. Cresse noted the perforation of sheet lead by a wood borer—Capricorn beetle, Goat beetle, or Sawyer worm.

H. Moissan [8] found that at ordinary temp. **fluorine** slowly transforms lead into lead fluoride ; if the lead be warm, it burns in that gas.   According to J. B. A. Dumas, **chlorine** slowly transforms lead into chloride without incandescence, and A. Classen and B. Zahorsky showed that in the absence of hydrogen chloride, liquid chlorine has no action on lead.   J. A. Wilkinson showed that there is a flash of light when chlorine comes in contact with molten lead, and a feeble luminescence occurs when lead is heated in chlorine or **bromine** vapour and lead chloride or bromide is formed ; and J. Nicklès showed that in the presence of a soln. of bromine in dry ether, lead is rapidly converted into the bromide. E. Beckmann said that **iodine** does not dissolve lead.   G. Tammann and co-workers found that with air containing 0·0003 mol. Cl_2 per litre the film of chloride at 225° is 245$\mu\mu$ thick in 20 secs., and 490$\mu\mu$ in 90 secs.   At 290°, with air carrying 0·0033 mol Br_2 per litre, the film thickens from 300$\mu\mu$ in 20 secs. to 700$\mu\mu$ in 115 secs. ; and air with 0·06 mol I_2 per litre, at 15°, produces a film 164$\mu\mu$ thick in 4 mins. ; and 409$\mu\mu$ in 25 mins. at 167°.   J. L. Gay Lussac and L. J. Thénard found that **hydrofluoric acid** does not attack lead below the b.p. of the acid ; a protective film of insoluble lead fluoride is formed.   T. E. Thorpe and W. Kirman found that **fluosulphonic acid,** $HFSO_3$, rapidly attacks lead, forming lead sulphate and fluoride.   M. Berthelot found that **hydrogen chloride** is decomposed when heated with lead, and the reaction is irreversible ; he also showed that in the cold, dry **hydrogen chloride** does not attack lead, but if a little oxygen or water, or, according to E. Salkowsky, hydrogen dioxide, be present, the metal is slowly attacked.   Lead is so very slightly soluble in **hydrochloric acid** that it is sometimes stated to be insoluble.   F. Stolba showed that lead is very slowly attacked by hydrochloric acid in the presence of air ; an acid of sp. gr. 1·12 attacks purified lead with the production of small bubbles of hydrogen.   A. J. Hale and H. S. Foster found that 0·2N-HCl dissolves 0·06 grm. of lead per day in 4 hrs., 1·20 grms. per day in 7 days, and 0·69 grm. per day in 28 days per sq. cm. at 17°–20°.   J. P. Sharples said that the cold acid slowly attacks lead vessels, and that the hot acid attacks the lead rapidly.   A. J. Hale and H. S. Foster found that hydrochloric acid attacks lead much more rapidly than does sulphuric acid—*vide* acetic acid.   W. G. Whitman and R. P. Russell observed that the presence of oxygen favoured the attack.   In a general way, H. J. Prinz found that the presence of nitrobenzene accelerated the attack of lead by acids.   Hydrochloric acid in the presence of hydrogen dioxide was found by E. Salkowsky to dissolve finely divided lead.   Molten **lead chloride** dissolves very little lead, but as the temp. rises the percentage solubility increases,

being 0·000154 at 550°, 0·000374 at 610°, 0·000410 at 615°, and 0·000746 at 640°. The solubility is reduced if alkali chlorides are present. The solubility in aq. soln. of the chlorides of the alkalies and alkaline earths has already been discussed. **Hydrogen iodide** and **hydriodic acid** were found by H. St. C. Deville to attack lead vigorously. A soln. of **sodium hypochlorite** was found by H. P. Pearson to attack lead vigorously, forming lead dioxide ; J. H. Gladstone and A. Tribe showed that a soln. of **potassium chlorate** is not reduced by spongy lead, but in the presence of dil. sulphuric acid, potassium chloride is slowly formed. Boiling soln. of potassium chlorate were found by G. Lunge and A. Deggeler to be slowly reduced in lead vessels. A. Ditte said that a hot or cold soln. of **hydriodic acid** does not attack lead.

L. Franck [9] found that if a clean surface of lead be rubbed with **sulphur,** the metal is blackened owing to the formation of lead sulphide. F. Knapp also found lead is tarnished in contact with sulphur. K. Jellinek and J. Zabowsky discussed the affinity of lead for sulphur. W. Spring said that if a mixture of lead and sulphur be greatly compressed, 6500 atm., it forms a black graphitic mass with a crystalline fracture. E. Jannettaz obtained no sign of the crystalline sulphide (**1.** 13, 18). Lead unites directly with molten sulphur ; and, according to G. C. Winkelblech, if combination be started in a mixture of finely divided lead and sulphur contained in a test tube by heating one end, the reaction does not of itself proceed through the mass unless the tube and contents have been pre-heated in boiling water ; strips of lead take fire in sulphur vapour burning with a vivid glow, and depositing half-fused globules of lead sulphide. M. Chavastelon found lead is dissolved when placed near a fragment of sulphur even though not in actual contact. G. Little found that a reaction attended by incandescence occurs when **selenium** is heated in contact with lead, and a grey, porous, silver-white mass is formed. According to G. Rose, molten lead readily dissolves **tellurium,** and H. Fay and C. B. Gillson found that the m.p. of the metal is thereby raised. According to G. Tammann and W. Köster, air containing **hydrogen sulphide** acts very slowly on lead. H. Schiff, and C. Geitner noticed that **sulphur dioxide** is decomposed when heated with lead, forming lead sulphide, etc. H. C. Jenkins and E. A. Smith found that lead reacts with sulphur dioxide at about 300° : $Pb+3SO_2=PbS+2SO_3$; and between 327° and 400°, some lead sulphate is formed, $Pb+2SO_3=PbSO_4+SO_2$; the summation equation is $2Pb+2SO_2=PbSO_4+PbS$—R. Schenck and co-workers made observations on this subject—*vide supra,* the theory of the extraction of lead. C. Geitner found that when a mixture of **sulphurous acid** and lead is heated in a sealed tube at 200°, lead sulphate, but no sulphide, is formed. W. G. Smith and A. A. Heimrod showed that gases containing **selenium dioxide,** SeO_2, and **selenium trioxide,** SeO_3, readily attack lead containing only 0·1 per cent. of antimony. G. Rose said that molten lead easily unites with **tellurium,** and H. Fay and C. B. Gillson added that the f.p. of lead is raised by a little tellurium.

Cold conc. **sulphuric acid** was found by G. Lunge and L. Weibel to attack lead—the 99·8 per cent. acid dissolved 1·790 grms. of lead per sq. dm. surface in 6 days at 20°, and 847 grms. in 2 hrs. at 100°. A. J. Hale and H. S. Foster observed that with 500 c.c. of $0·2N$-H_2SO_4, 0·00 grm. of commercial, cold hard-rolled, and polished lead per sq. dm. per day was dissolved in 4 days at 17°–20° ; 0·01 grm. per day in 7 days ; and 0·02 grm. per day in 28 days. W. G. Whitman and R. P. Russell found that the presence of oxygen favoured the attack of lead by sulphuric acid. G. Lunge and E. Schmid found that sulphuric acid of sp. gr. 1·8 dissolves 128·1 grms. per sq. metre in 8 days at ordinary temp. ; an acid of sp. gr. 1·84 in 6 days at 100° dissolved 86·8 grms. per sq. m. ; and 79·1 grms. in 10 hrs. at 100° ; 277·6 grms. in 3 hrs. at 200° ; 565·4 grms. in 4 hrs. at 100° ; and acid of sp. gr. 1·725 dissolved 47·0 grms. in 6 hrs. at 100° ; 51·4 grms. in 10 hrs. at 100° ; and 191·9 grms. in 6 hrs. at 200°. The purest soft lead is less acted on by sulphuric acid or nitrated sulphuric acid than any other kind of lead at temp. up to 200°, and if the temp. does not rise beyond that point, it can be safely used in the construction of vitriol chambers ;

tanks, and towers ; and for concentrating pans. The presence of oxygen (oxides) in the lead is always very small and has no appreciable effect on the resistance of lead to sulphuric acid. The presence of 0·2 per cent. of antimony does little or no harm, and since it increases the hardness and tensile strength of the lead it can be used for work in contact with the cold acid. Higher proportions of antimony are inadmissible particularly if the acid be hot. More than 0·2 per cent. of copper is injurious, but between 0·1 and 0·2 per cent. has no appreciable influence with the cold acid, but above 200° has a protective action on lead and reduces its chance of being converted to the sulphate at about 240°. With more conc. sulphuric acid, and 10 hrs.' exposure, the following amounts of lead in grams per sq. metre, dissolved in the acid at 50° :

<div align="center">Nordhausen acid.</div>

SO$_3$ . .	79·30	80·69	81·63	83·49	87·10	88·92	89·90 per cent.
Loss . .	64·0	867·5	1300	1899·6	2008·8	1801·5	1649·7 grms.

The attack thus increases with conc. slowly up to an acid of sp. gr. 1·843, and very rapidly beyond this point. An acid with 99 per cent. H$_2$SO$_4$ should not be in contact with lead, the same remark applies to the fuming acid. A. Frisak's results for the attack on lead by sulphuric acid at different temp. and different conc. of acid are shown in Figs. 17 and 18. F. Kuhlmann said that the attack by conc. sulphuric
FIG. 17.—Solubility of Lead (per cent. Pb) in Sulphuric Acid. (Temperature variable.)
FIG. 18.—Solubility of Lead in Sulphuric Acid. (Concentration Variable.)

acid is imperceptible if the temp. does not exceed 200°–205°. A. Ditte showed that with the hot acid, sulphur dioxide is given off, and R. Hasenclever, and A. Bauer and P. von Mertens observed that by warming 0·2 grm. of lead with 50 c.c. of sulphuric acid of sp. gr. 1·843, at 175°, some gas is given off which increases in amount as the temp. rises to 190° ; at 230°–240°, sulphur dioxide and hydrogen are given off, and there is a separation of sulphur, while the lead is completely transformed into sulphate which dissolves in the acid. Observations were also made by R. R. Tatlock, H. de Hemptinne, A. A. Mallard, A. Lassieur, J. Napier, and F. C. Calvert and R. Johnson. G. Lunge and E. Schmid found that the sudden action of sulphuric acid is slightly retarded by one per cent. of antimony in the lead, and inhibited by 0·2 per cent. of copper. If dil. sulphuric acid be boiled with lead, the acid is concentrated, and the b.p. gradually rises—the sudden conversion of the lead into sulphate occurs at about 280°. H. C. Lancaster found electrolytic lead of 99·998 per cent. purity resists the action of conc. sulphuric acid at 310°. E. Salkowsky found that in the presence of hydrogen dioxide and dil. sulphuric acid, lead is insoluble, and powdered lead is partly converted into lead sulphate. The effect of various foreign metals in lead on its corrosion by sulphuric acid has been studied by F. C. Calvert and R. Johnson, R. Hasenclever, N. Cookson and A. Sanderson, R. W. Hochstetter, L. Pitkin, A. Bauer and P. von Mertens, W. B. Hart, E. L. Rhead, D. W. Jones, W. G. McKellar, J. Mactear, H. van der Planitz, etc. The observations of G. Lunge and E. Schmid on the effect

of copper and antimony have been previously discussed. These confirmed the work of J. Glover, who showed that with each of these metals

Per cent. addition			0·1	0·2	0·3	0·4	0·5
Per cent. loss {Cu			7·1	7·1	7·5	9·1	8·5
{Sb			8·1	9·2	10·9	11·6	11·8

C. E. Barrs found that small proportions of silver, arsenic, sulphur, and tin lessen the action of the acid on lead. H. W. Rowell said that a little zinc in lead accelerates the action of the acid more than is the case with other metals. C. E. Barrs found that zinc and bismuth favour the corrosion. If bismuth and antimony are present together they neutralize one another's activity. Comparing the action of the lead alone and with 0·2 per cent. of different metals, by taking the temp. of the "first action" to be that at which a continuous stream of bubbles rose from the metal, and as temp. of "vigorous action" that at which excessive frothing occurred and the lead was converted to sulphate, C. E. Barrs found

	Pb	Cu	Bi	As	Sb	Zn	Sn	Ag	Te	S
First action .	150°	210°	70°	213°	150°	160°	156°	200°	190°	142°
Vigorous .	220°	315°	135°	260°	220°	200°	232°	262°	316°	238°

D. W. Jones examined the effect with lead containing different proportions of these metals. He found that 0·2 per cent. of copper neutralizes the baneful effect of 0·05 per cent. of bismuth; mercury alloyed with lead has a deleterious effect on its resistance to the acid; sodium and copper were each found to exert a beneficial influence. The subject of lead for making plant to resist sulphuric acid, etc.—the so-called *chemical lead*—was also investigated by T. French. J. A. Wilkinson found that when molten lead is oxidized with **sodium persulphate,** $Na_2S_2O_8$, there is a vigorous reaction, and the whole mass fuses and becomes cherry red, but no luminescence occurs; with **ammonium persulphate,** a bluish-white light appears as the mass becomes solid. M. G. Levi and co-workers obtained lead disulphate by the action of a soln. of alkali persulphate on lead; and F. J. Faktor showed that when a soln. of **sodium thiosulphate** is heated with lead, lead sulphide is formed.

According to L. Arons,[10] when an electric arc is made between lead electrodes in **nitrogen** gas, the metal acquires a film which is probably **lead nitride.** W. R. E. Hodgkinson and N. E. Bellairs found that aq. **ammonia** slowly dissolves lead, and after long contact some lead hydroxide is produced, but no nitrites. H. Endemann found that conc. aq. ammonia dissolved 0·0139 per cent. of lead in three days. A. J. Hale and H. S. Foster observed that a 0·2N-soln. dissolved 0·02 grm. per sq. dm. per day in 7 days and 0·01 grm. per day in 28 days. The solvent action of soln. of ammonium salts has been previously indicated. According to A. Wagner, a soln. of a gram of **ammonium chloride** in 100 c.c. of water dissolved 12 mgrms. from a surface of lead of 11·831 sq. cm. when air free from carbon dioxide was used, and 5 mgrms. with ordinary air. G. Lunge and L. Weibel made observations on this subject. W. G. Whitman and R. P. Russell found that the presence of oxygen favoured the attack of lead by nitric acid. W. R. E. Hodgkinson and A. M. Coote found that molten **ammonium nitrate** attacks lead giving off ammonia and forming lead nitrate; the hydrogen given off at the same time reduces the nitrate to nitrite, and this in contact with the ammonium salt produces nitrogen; an ice-cold soln. of ammonium nitrate attacked lead, forming lead nitrite, and M. M. P. Muir made observations on the solvent action of soln. of this salt—*vide supra.* J. W. Turrentine noted that lead anodes are attacked during the electrolysis of a soln. of **sodium azide,** NaN_3. According to P. Sabatier and J. B. Senderens, **nitrous oxide** slowly oxidizes lead at 300°, and is reduced to nitrogen—no nitrous vapours were observed. They also found that with nitric oxide lead oxide is formed. The production of films on heated lead by nitrous and nitric oxides was studied by E. Schröder and G. Tammann; while E. Müller and H. Barck found that nitric oxide slowly attacks

the metal. B. B. Adhikary showed that with a mixture of nitric oxide and hydrogen (1 : 3) lead acts catalytically, forming ammonia. P. Sabatier and J. B. Senderens showed that **nitrogen peroxide** slowly oxidizes lead at 200°, forming a basic nitrate. R. Weber said that **nitrogen pentoxide** is not decomposed by lead. J. J. Sudborough found that when lead is heated many days in contact with **nitrosyl chloride,** at 100°, a nitrosochloride is formed.

Dil. **nitric acid** is the best solvent for lead, the action of the conc. acid was found by G. Lunge and E. Schmid to be hindered by the formation of a protective film of lead nitrate which is soluble in water and dil. acid but not in conc. acid. According to C. Montemartini, below 15°, nitric acid of all conc. attacks purified lead very slowly, but is quickest with dil. acid. Small quantities of ammonia are formed in amounts which are greatest with the dil. acid. J. J. Acworth and H. E. Armstrong found that comparatively large amounts of nitrous oxide and nitrogen are contained in the gases ; thus, with acid 1 : 2 at 14°, the 10·56 c.c. gas obtained from 0·381 grm. of metal, contained 51·23 per cent. of nitric oxide, 41·47 per cent. nitrous oxide, and 7·30 per cent. of nitrogen. G. O. Higley made observations on this subject. E. Divers said that it is doubtful if hydroxylamine is formed during the action of nitric acid on lead, although a small proportion was once detected, but ammonia was always produced. G. Lunge and E. Schmid found the loss of lead in grams per sq. metre during 30 days at ordinary temp. in acids of different sp. gr., or per cent. HNO_3 :

Sp. gr. .	1·210	1·262	1·305	1·350	1·365	1·371	1·404	1·425	1·458	1·480	1·498
HNO_3 .	33·82	41·64	48·26	52·37	53·45	59·57	65·09	79·98	79·33	86·05	93·10 per cent.
Loss .	3710	1803	900·	552	398	261	195	196	516	733	378

A. J. Hale and H. S. Foster found that $0·2N$-HNO_3 dissolves lead at the rate of 0·36 grm. per sq. dm. per day in 4 hrs., 9·8 grms. per day in 7 days, and 6·3 grms. per day in 28 days. B. C. Banerji and N. R. Dhar found that the presence of ferric chloride or nitrate favours the attack of lead by nitric acid. F. Kuhlmann observed that in the manufacture of sulphuric acid, where the acid vapours pass from one lead chamber to another, when nitric or nitrous acids are present, the lead plates are rapidly corroded. G. Lunge and E. Schmid measured the effect of the nitrous vitriol of different degrees of conc. and with varying proportions of nitric acid on lead. Mixtures of nitric and sulphuric acids vigorously attack lead. They stated that conc. nitrous acid acts more strongly than sulphuric acid at all temp. and upon all descriptions of lead. In the case of dil. acids, say sp. gr. 1·72–1·76, the action of nitrous vitriol is rather less than with sulphuric acid, owing to the formation of a crust of lead sulphate. With still more dil. acids, where the nitroso-sulphuric acid is partly changed into free nitrous and nitric acids, the action is again stronger. If these acids are compared among each other, it is found that those acids act least upon lead at 65°–70°, whose conc. is between sp. gr. 1·6 and 1·5, that is, between the limits which are mostly observed for " chamber acids " ; both more highly conc., and more dil. acids act more upon the lead in the latter case in proportion to the nitric acid present (or formed). P. Sabatier, and P. Pascal and co-workers studied the attack on lead by nitrated sulphuric acid, and found pure lead resists attack provided less than 30 per cent. water is present. H. Braconner attributed the sluggish action of the conc. acid on lead to the formation of a protective film of lead nitrate. V. H. Veley found that at a constant temp. the rate at which lead dissolves increases as the conc. of the acid is increased up to a maximum, and thereafter decreases. This result is unlike that obtained with copper, mercury, and bismuth ; and it is dependent on the decreasing solubility of the lead nitrate with increasing conc. of the acid. Nitrous acid is produced during the reaction, and the amount of metal dissolved in unit time is correlated with the amount of nitrous acid in the soln. The amount of nitrous acid produced is much less than is the case with copper ; the amount increases gradually to a maximum and constant value ; the amount of metal dissolved in

unit time is reduced by the presence of substances like potassium chloride and hydrogen dioxide which destroy nitrous acid. A. Quartaroli added that if the nitric acid be perfectly free from nitrous acid it does not attack lead ; the presence of urea in nitric acid, by inhibiting the formation of nitrous acid, slows down the reaction. Lead is attacked to a less degree by **nitrous acid** or nitric acid taken separately than when mixed together. Expressing the amount of lead dissolved in decimilligrams per sq. mm. per hour, and the conc. of the acids in grams per 15 c.c. at 15°–18°, V. H. Veley found

HNO$_3$ . .	4·5286	14·122	0·8562	1·7062	4·2407	4·1721	0·6840	trace
HNO$_2$ . .	0	0	0·122	0·2219	0·1704	0·5089	0·2754	0·158
Pb dissolved .	2·22	0·015	3·05	2·64	3·67	4·52	15·01	0·8

B. Pelletier [11] found that when **phosphorus** is projected on molten lead, or when lead films are fused with an equal weight of glacial **phosphoric acid,** or lead chloride is treated with phosphorus, a lead phosphide is formed containing less than 15 per cent. of phosphorus. The subject is discussed in connection with lead phosphide. J. Heimann found lead to be soluble in a soln. of **metaphosphoric acid,** B. Reinitzer and H. Goldschmidt found that at 250°, **phosphoryl chloride** is only slightly affected by lead ; and C. Poulenc said that at 180°, **phosphorus trifluochloride** forms phosphorus trifluoride and lead chloride.

FIG. 19.—Velocity of the Reaction between Lead and Nitric Acid of Different Concentrations.

T. Bergman [12] found that when lead is fused with **arsenic,** the lead takes up one-sixth of its weight of arsenic. P. A. Bolley said that when arsenic is alloyed with lead, the union occurs without incandescence, and the product is brittle. W. Spring made the alloys by compressing a mixture of the powdered elements at 65·00 atm. A. Descamps made the alloy by melting arsenic and lead with boric oxide ; W. Heike, with animal charcoal in an evacuated vessel ; K. Friedrich melted the elements together in an atm. of carbon dioxide ; and A. Descamps, and G. A. Koenig, passed the vapour of arsenic into molten lead. J. Fournet reduced lead arsenate in a carbon crucible, and A. Descamps reduced it by fusion with potassium cyanide. The fusion curves of the alloys with 0·34 per cent. of arsenic, by K. Friedrich, are shown in Fig. 20. There is a partial separation of the arsenic as the liquid alloy cools. The fusion curve has two branches with a eutectic at 292° and 2·5–3 per cent. of arsenic. The solid metal contains lead, arsenic, and the eutectic. The fusion curves were also studied by W. Heike, S. F. Schemtschuschny, W. Guertler, and C. T. Heycock and F. H. Neville. K. Friedrich found no sign of the compounds Pb : As=3 : 4, 1 : 1, 4 : 3, and 2 : 1 reported by A. Descamps, or of 3 : 2 reported by W. Spring. I. P. Göbel, and C. O. Thieme discussed the hardening of lead by arsenic ; and I. P. Göbel, the hardness and sp. gr. N. A. Puschin studied the electrical potential of the alloys.

FIG. 20.—Fusion Curves of As–Pb Alloys.

A. Descamps preserved the alloys under air-free water, or under a hydrocarbon, since they are quickly attacked in air. A. Bauer and P. von Mertens found that the alloys are slowly decomposed by sulphuric acid—*vide* lead arsenides. Lead alloyed with a small proportion of arsenic is used to form *shot-metal.* J. Fournet represented the reaction between **arsenic sulphide,** as realgar, and lead by the equation : $2Pb+AsS_2=2PbS+As$; and J. Percy likewise treated **antimony sulphide** with lead.

J. F. Gmelin [13] prepared some alloys of antimony and lead. G. Karsten found

prismatic crystals of an alloy of lead and **antimony** in the hearth of a smelting furnace at Mulden; the composition approximated $Pb_{18}Sb$. A. Brand found the two elements in isomorphous mixture with lead and cuprous sulphides, and with nickel and copper antimonides in the hearth of a lead smelting furnace. Lead and antimony unite when mixed in different proportions and melted. According to W. Spring, the two elements unite even at 265°. Alloys were made by H. Gautier, A. Matthiessen, R. Durrer, M. Kühnel and M. Marzahn, F. de Jussieu, J. E. Stead, C. Pack, Q. Marino and C. Bowen, E. Heyn, A. Riche, R. H. Thurston, W. G. Knox, etc. The equilibrium diagram was studied by H. Gautier, R. Loebe, M. le Gris, C. R. A. Wright and co-workers, A. Saposhnikoff and J. Kaniewsky, G. Charpy, J. E. Stead, A. Gorbow, L. J. Gurevich and J. S. Hromatko, W. Gontermann, M. Wählert, W. Campbell, K. Honda and T. Ishigaki, O. Bertoya, C. C. Bissett, etc. R. S. Dean's, and W. Gontermann's curves are summarized in Fig. 21; the curves are of the V-type with the eutectic at 246° and 87 per cent. of lead, with the possible existence of *lead tetritantimonide*, Pb_4Sb. S. D. Muzaffar could find no compound and no solid soln. in the antimony-lead alloys. V. Fischer studied the equilibrium relations of the liquid alloy.

FIG. 21.—Freezing-point Curves of Mixtures of Antimony and Lead.

The structure of the alloys was investigated by A. Riche, J. Fournet, G. Karsten, A. M. Portevin, H. Behrens, D. Ewen and T. Turner, H. Fowler, F. L. Brady, J. E. Stead, C. C. Bissett, F. de Jussieu, G. Charpy, W. Campbell, P. Siedler, etc.; the grain-growth, by R. S. Dean and W. E. Hudson; the sp. gr., by A. Matthiessen, I. P. Göbel, A. Riche, J. A. Linnavuori, F. C. Calvert and R. Johnson, G. Faunce, E. Maey, J. E. Stead, etc.; A. Matthiessen's results are:

Lead	0	45·9	62·9	77·3	83·6	89·5	94·5	97·7	100 per cent.
Sp. gr.	6·713	8·201	8·989	9·811	10·144	10·586	10·930	11·194	11·376

E. Maey measured the sp. vol. D. Ewen and T. Turner found that the shrinkage of the alloys on cooling diminishes from a maximum with 15 per cent. of antimony to a minimum with 30 per cent. of antimony. M. Dubosc, R. S. Dean and co-workers, and L. Gillet, found that the alloys could be hardened by quenching. The hardness was measured by H. Behrens, E. Heyn and O. Bauer, F. C. Calvert and R. Johnson, C. O. Thieme, I. P. Göbel, P. Ludwik, D. Ewen and T. Turner, A. Saposhnikoff and J. Kaniewsky, L. J. Gurevich and J. S. Hromatko, G. K. Burgess and R. W. Woodward, H. M. Waring, M. Wählert, F. de Jussieu, etc.; the tenacity, by E. Heyn and O. Bauer, H. Behrens, and L. J. Gurevich and J. S. Hromatko, etc.; the elastic constants, by G. Wertheim;
FIG. 22.—The Electrical Conductivity of the Sb–Pb Alloys.
FIG. 23.—The Electromotive Force of Solution of Sb–Pb Alloys.
FIG. 24.—The Thermoelectric Force of Sb–Pb Alloys.

the thermal expansion, by G. Vicentini and D. Omodei; the thermal expansion and the heat conductivity, by F. C. Calvert and R. Johnson; the thermal conductivity, by W. B. Brown; the sp. ht., by H. V. Regnault, H. Kopp,

J. A. Linnavuori, R. Durrer, etc.; the viscosity, by M. Plüss; the shrinkage on solidification, by F. Wüst; the fusion curves, by C. T. Heycock and F. H. Neville, P. Müller, T. Thomson, H. Gautier, etc.—*vide supra*, Fig. 21; F. de Jussieu, the liquation and surfusion, and J. Kallir, the disintegration of these alloys; M. Plüss, the viscosity and sp. gr. of the liquid alloy; the magnetization, by H. Leroux

(Fig. 25), E. Becquerel, W. Rollmann, T. J. Seebeck, E. Rudolfi, A. Naccari and M. Bellati, A. Bettalli, H. Endo, etc.; the thermoelectromotive force, by H. Pélabon, E. Rudolfi, Fig. 24. The curve for the thermal e.m.f. is a straight line for alloys with up to 90 per cent. antimony; and there is then a rapid rise up to the value for antimony alone. The electric conductivity and resistance were measured by A. Matthiessen

FIG. 25.—The Magnetic Susceptibility of Sb–Pb Alloys.

(Fig. 22), P. Müller, W. Guertler, E. Elsässer, G. Vicentini and C. Cattaneo, etc. The curve has a singular point for alloys with about 90 per cent. antimony. The electric potential was measured by N. A. Puschin, and S. D. Muzaffar; the e.m.f., by A. P. Laurie, H. le Chatelier, etc.; and the e.m.f. of dissolution by N. A. Puschin, Fig. 23. The curve is singular for alloys with over 90 per cent. of antimony.

According to S. Zinberg, the greater the proportion of lead in the alloys the more readily are they attacked by air and moisture; and R. Meyer and S. Schuster showed that the mode of casting and subsequent treatment of the alloys affect their tendency to oxidize. B. Kohlmann noted that the white oxide found on type-metal is mostly basic lead carbonate; and R. Moscheles, that the grey film sometimes present is organic matter. W. G. Knox tried covering iron with a protective layer of antimony-lead alloy in place of zinc, but the results were not so good. H. Leroux found that on the oxidation of the alloy the lead oxidizes first and then the antimony; the lead oxide first formed acts as an oxygen carrier to oxidize more antimony. The use of the alloy as anode in the electrodeposition of colloidal clay was patented by the Gesellschaft für Elektro-Osmose. The action of nitric acid was discussed by H. Behrens; of sulphuric acid, by L. Pitkin, H. von der Planitz, and A. Bauer and P. von Mertens; and of hydrochloric acid, by H. Behrens, and H. von der Planitz. J. O. Johnstone found that in contact with lead nitrate, some basic lead nitrite is formed; and C. W. Proctor showed that in acidified soln. of copper sulphate, or sodium cupricyanide, the alloy is coated with copper, and on this, brass or silver can be deposited. J. W. Richards discussed the valuation of these alloys.

Alloys of lead with about 15 per cent. of antimony furnish the so-called *type-metal*. This alloy is fairly fusible, expands on cooling, and is hard, but it does not resist the action of the press, and of the scouring liquids employed in cleaning the type. To overcome these defects, tin or bismuth is also added; in rarer cases, zinc or copper is added. S. Zinberg found type-metal is not attacked by ordinary water, but is readily attacked by distilled water. The alloys are less attacked the more antimony they contain. Analogous alloys are also used for candlesticks, statuettes, and other decorative articles. The keys for flutes and similar parts of other musical instruments are made from a lead alloy with approximately 33 per cent. of antimony.

Lead and **bismuth** were found by F. Rudberg,[14] A. Riche, F. G. A. Wright, H. Endemann, to unite readily in all proportions; W. Spring made the alloy by compressing an intimate mixture of the powders. According to F. Rudberg, the alloy with 40 per cent. of bismuth has only one solidifying temp., 129°, while alloys with other proportions have two solidifying temp. This is very near the result accepted to-day. The f.p. curve, Fig. 26, examined by G. Charpy, D. Mazzotto, W. Herold, A. W. Kapp, A. Gorboff, W. E. Barlow, C. di Capua, A. Stoffel, C. P. Steinmetz, G. Tammann, K. Bornemann, E. S. Shepherd, N. A. Puschin, P. Ludwik, C. T. Heycock and F. H. Neville, E. Dippel, L. Losana, A. Matthiessen

and co-workers, and K. Honda and T. Ishigaki, has a eutectic at 1245°, and 56·5° per cent. bismuth. According to W. Herold, solid soln. are formed, but the region over which these extend is not clearly de-
fined; otherwise the alloys are mechanical mix-
tures of two crystalline phases. The struc-
ture of the alloys was examined by K. Bux,
J. Ewing and W. Rosenhain, A. M. Portevin,
F. L. Brady, W. Herold. R. Arpi measured the
viscosity; G. Wertheim, the elastic constants;
C. di Capua and M. Arnone, the hardness;
G. Vicentini and D. Omodei, and A. Mat-
thiessen, the thermal expansion of these alloys;
M. Jakob, and W. B. Brown, the thermal con-
ductivity; C. C. Person, and D. Mazzotto, the
heat of fusion; J. Taylor, the heat of formation;
the m.p. of specific alloys were reported by
J. W. Döbereiner, C. T. Heycock and F. H. Neville,
E. S. Shepherd, I. P. Göbel, E. Wiedemann,
C. C. Person, F. Rudberg, F. Guthrie, P. Berthier,
and T. Thomson. The sp. gr. was measured by P. van Musschenbroek, A. Riche,
T. Thomson, A. Matthiessen, and C. M. Marx. A. Matthiessen's results are :

FIG. 26.—Freezing-point Curves of Bismuth-Lead Alloys.

Lead	0	4·8	11·2	33·4	66·6	80·0	92·3	100 per cent.
Sp. gr.	9·823	9·893	10·048	10·538	11·141	11·188	11·280	11·376

The last-named reported that the Pb : Bi=1 : 2 alloy does not expand on solidifica-
tion ; the 1 : 3 alloy expands slightly ; while the 1 : 8 alloy expands markedly on solidifying. E. Wiedemann measured the changes of vol. on melting. E. von Maey studied the sp. vol. The hardness curve, Fig. 27, by W. Herold shows an increase in hardness for low and high conc. of bismuth,
and this indicates that solid soln. are formed
at the beginning and end of the series—other-
wise the curve is a straight line. J. Goebel, and
P. Ludwik also measured the hardness of these
alloys. F. Sauerwald studied the viscosity ;
R. Arpi, the thermal expansion ; and O. Richter,
A. Levi, F. A. Schulze, G. Tammann, and
E. Dippel, the sp. ht. of lead-bismuth alloys.
The sp. ht. curve has a maximum, thought to

FIG. 27.—The Hardness of Alloys of Lead and Bismuth.

indicate the formation of a compound or aggregate. The m.p. also depends on whether the alloy is over-heated before cooling, or merely heated a few degrees above the m.p. The sp. ht. is also smaller where the cooling is slower. All these pheno-
mena are supposed to depend on the formation of mol. complexes. A. Magnus and M. Mannheimer observed that cooling occurs when molten lead and bismuth are mixed. E. S. Shepherd, W. Herold, R. Schenck, A. Matthiessen, P. Müller, E. F. Northrup and R. G. Sherwood, R. Kremann and A. Brodar, and W. Guertler, measured the electrical conductivity. F. A. Schulze's values for the thermal and electrical conductivities, Fig. 28, have minima for alloys containing 4–5 per cent. of lead ; this, as well as the initial falls in the curves for alloys with from 0 to 15 per cent. bismuth, also indicates that solid soln. are formed. A. Leduc measured the conductivity of bismuth-lead alloys ; A. Matthiessen and C. Vogt, the effect of temp. and of impurities on the conductivity ; R. Kremann and co-workers found that on electrolysis, the lead accumulates at the cathode, the bismuth at the anode ; C. R. Darling and R. H. Rinaldi, the thermoelectric properties of the alloys against copper ; E. van Aubel, the effect of a magnetic field on the electrical resistance ; A. P. Laurie, R. Kremann and A. Langbauer, H. le Chatelier, and E. S. Shepherd, the e.m.f. of the alloys in a voltaic cell ; S. D. Muzaffar, the electrode

potential; and E. Becquerel, W. Broniewsky, W. Rollmann, and T. J. Seebeck, the thermoelectric properties; A. Battelli's values, Fig. 29, for the thermo-electric force shows a rapid decrease for the addition of small quantities of lead to bismuth. J. Beattie, P. Senepa, H. Endo, W. Rollmann, A. Battelli, G. Spadavecchia, E. van Aubel, and H. Zahn investigated the behaviour of the alloy in a steady magnetic field; T. French, L. Pitkin, and A. Bauer and P. von Mertens studied the action of sulphuric acid ; A. Riche, the action of water ; and A. Vogel discussed the spontaneous disintegration of these alloys. R. H. Thurston, and C. R. A. Wright studied the ternary alloys of lead, bismuth, and antimony; and C. de Capua, the hardness of the ternary alloys Pb–Bi–Sn, and Pb–Bi–Cd.

According to J. F. John,[15] when lead is heated with **carbon,** the metal volatilizes, and forms a sublimate of lead carbide in black lustrous crystals ; but this has not been confirmed—O. Ruff and B. Bergdahl could get only 0·024 per cent. of carbon,
FIG. 28.—The Thermal and Electrical Con-ductivities of Alloys of Lead and Bismuth.
FIG. 29.—The Thermoelectric Force of Alloys of Lead and Bismuth.

in soln. in lead at 1170° ; 0·046 per cent. at 1415° ; and 0·094 per cent. at 1555°— vide lead carbide, **6.** 39, 18. W. Stahl found that the **hydrocarbons** are insoluble in molten lead ; and H. Reckleben and J. Scheiber showed that purified and dried **acetylene** does not act appreciably on lead during 20 months' exposure, while crude and moist acetylene increases the weight of lead less than 1 per cent. Type-metal and lead-antimony solder are scarcely affected by the gas. W. R. E. Hodgkin-son found that acetylene does not change the properties of lead at temp. up to the m.p. of the metal. According to W. Stahl, neither **carbon monoxide** nor **carbon dioxide** is dissolved by molten lead. M. Berthelot found that when lead is heated with carbon monoxide in a sealed tube at 550°, carbon dioxide is formed. A mixture of carbon monoxide and dioxide passed into milk of lime contained in a leaden vessel was found by G. Gore to produce red-lead. The action of aq. soln. of carbon dioxide, or of the moist gas, on lead has been previously discussed. M. Berthelot examined the action of **cyanogen** on lead; and F. H. Rhodes and J. T. Carty, the action of carbon tetrachloride, which produces a slight white film on the metal. G. A. Goyder found that an aq. soln. of **potassium cyanide** acts very slowly on lead without the evolution of gas. The action was examined by A. Brochet and J. Petit. S. G. Sastry said that lead acts on many **chlorinated hydrocarbons**—CCl_4, $CHCl_3$, $C_2H_2Cl_4$, and C_2HCl_5—but not on $C_2H_2Cl_2$. The vapours of the **fatty acids** were shown by A. Mailhe to react with finely divided, reduced lead, forming first a salt of the acid, and then a ketone and carbon dioxide ; the reaction is slow at 300°, but fast at 350°. F. P. Hall showed that lead is attacked by **acetic acid, tartaric acid,** and **citric acid** more strongly when exposed to air than when air is absent. W. G. Whitman and R. P. Russell found that the presence of oxygen favoured the attack on lead by acetic acid. F. Auerbach and H. Weber examined the effect

of the fruit acids, citric and tartaric acids, as well as of **malic, succinic, and benzoic acids.** H. C. Bolton found lead to be attacked by a soln. of citric acid mixed with sodium nitrate. J. C. Thresh examined the action of citric, acetic, benzoic, and tartaric acids, and also of **quinic and formic acids.** O. Sackur said that lead is attacked by dil. acids—acetic acid, **lactic acid,** and hydrochloric acid—only in the presence of oxygen; the velocity of the reaction is nearly independent of the strength and conc. of the acid, but it is dependent on the conc. of the dissolved oxygen, and on the velocity of stirring; otherwise expressed, the rate of reaction is determined by the diffusion velocity of the dissolved oxygen. E. Salkowsky found that in the presence of hydrogen iodide the attack by acetic acid is greatly hastened. H. S. Rawdon said the attack on commercial lead is largely conditioned by intercrystalline impurities which resist attack, and set up electrolytic action—*vide supra.* According to O. P. Watts and N. D. Whipple, with 190 c.c. of N-acetic acid at 37·5° and 60 sq. cms. of metal during 45 hrs., the loss was 0·2019–0·2143 grm.; if 5 c.c. hydrogen dioxide were present, the loss was 6·4026 grms.; with 2 grms. of mercuric chloride and 5 c.c. of hydrogen dioxide present, 6·5596 grms.; with 2 grms. mercuric chloride, 0·8529 grm.; and with 0·25 grm. of sodium arsenate, 0·0490 grm. I. L. C. Eckelt found lead is attacked by **ethylsulphuric acid,** and, added O. Schaal, the more the lead is purified, the slower the reaction. M. Schirmonsky also reported that lead is strongly attacked by **naphthenic acid**—*vide* the electrolysis of soln. of lead salts in organic acids. H. J. Prins studied the action of **nitrobenzene** in acetic acid soln. on lead. The speed of the action is determined by the rate of diffusion of the products of the reaction. C. O. Henke and O. W. Brown, and W. Falta and M. Richter-Quittner found that the reduction of nitrobenzene by hydrogen is catalyzed by lead; J. Tafel, that **ketones** are reduced to hydrocarbons by electrolysis with lead electrodes; V. Thomas, that **methylene iodide** reacts with lead giving off a gas; and F. F. Rupert, that the reaction between hydrogen is accelerated by the presence of lead-foil. L. T. O'Shea studied the adsorption of lead salts by **filter-paper.** O. Schmidt studied the catalytic action of lead in the hydrogenation of organic compounds.

F. Rathgen mentioned that lead medallions were attacked by the organic acid in the **sweat** of the hand; and F. Southerden, by **tanning soln.** H. Baum and R. Seeliger,[16] and T. Sudendorf found that **milk** dissolves lead; D. Klein and A. Berg observed no reaction between lead and soln. of **sugar,** and L. Lindet noticed that lead accelerates the inversion of sugar. J. Aub gave 0·578 grm. per litre for the solubility of lead in **blood serum.** A. Gautier, G. Wölffhügel, P. Schützenberger and E. Boutmy, A. Sander, A. Meyer, A. S. Taylor, N. N. Banerjee, E. Gudeman, T. Sudendorf, M. Rjältschewsky, and E. Spaeth detected the contamination of various **foodstuffs** by contact with lead, and A. Beythein, in **cosmetics.** H. Riesenfeld and F. Taurke noted that when a soln. of cellulose in an ammoniacal soln. of copper carbonate is treated with lead, cellulose and copper are precipitated. J. Tafel observed that **succinimide** is not reduced by contact with spongy lead and dil. sulphuric acid. A. Gawalowsky found that **mash-wort** attacks lead very little. T. Sudendorf examined the solvent action of **wine** on lead, but this fact has been known since the beginning of our era—*vide infra.* P. Grélot found wine which has been treated with sulphur dioxide is particularly liable to attack lead. G. Steifler also found fermenting cider develops acids which attack lead. F. Malmejac found that 95 per cent. **alcohol** in contact with lead in a closed vessel slowly dissolves some lead; but G. Heinzelmann could not detect any reaction between lead and 95–96 per cent. pure or denatured alcohol, although the 90 per cent. alcohol did attack the metal; pyridine was found to be without influence. M. Traube found that the oxidation of lead under absolute alcohol does not occur; oxidation is slow with 90 per cent. alcohol; and in 50 per cent. alcohol it is as fast as in water alone. F. M. Perkin showed that when a current of ozonized air is passed into **ether** containing strips of lead, yellow lead ethoxide, $Pb(OC_2H_5)_2$, is formed. F. C. Mathers and A. B. Leible found that lead adsorbs **ethereal oils** when an aq. soln. of the oil

is shaken with lead.   J. Merrick found that lead is quickly attacked by **turpentine ;** and C. Engler and E. Kneis showed that freshly distilled turpentine dissolved in 2 days, 0·085 per cent. Pb ; in 8 days, 0·265 per cent. ; and in 14 days, 0·715 per cent. ; while old turpentine in the same time dissolved respectively 0·578, 0·982, and 1·851 per cent. Pb ; and **oil of resin** at ordinary temp. dissolved traces of lead in 8 days and 0·024 per cent. in 14 days, and on a water-bath, respectively 0·380 and 0·880 per cent.   W. Fox, A. Gawalowsky, and G. Engler and E. Kneis found that lead is quickly attacked by **petroleum,** and J. Schiel showed that a piece of lead ribbon 1 mm. thick was wholly converted into a yellow oxide when kept 8 weeks under petroleum.   A. Gawalowsky also found that lead is attacked by mineral lubricating oils.   S. Macadam showed that by prolonged contact with **paraffin oils,** lead is considerably attacked.   A. Schneider and F. Jenniger found that **benzene** wash oils corrode lead.   P. Schindler observed that lead is attacked by **oil of sesame,** and **olive oil ;** and A. Livache, by **linseed oil.**   According to I. J. Redwood, with a **mineral oil** lubricant, for a year, sheet lead lost 0·05607 per cent. ; with olive oil, 0·04243 per cent. ; with **rape oil,** 0·19716 per cent. ; with **tallow oil,** 0·16782 per cent. : with **lard oil,** 0·28000 per cent. ; with **cotton seed oil,** 0·07113 per cent. ; with **sperm oil,** 0·28241 per cent. ; with **whale oil,** 0·29502 per cent. ; with **seal oil,** 0·14198 per cent.   U. Ehrhardt and G. Pfeiderer showed that crude **tar oils** containing phenol dissolved 1·1 mgrm. of lead per sq. cm. in four weeks.   C. O. Henke and O. W. Brown studied the catalytic activity of lead in reducing organic compounds ; and A. Benedicenti and S. Rebello-Alves, the effect of lead on soln. of egg-albumen or blood serum.

For the action of **silicon** and **boron** on lead, *vide* borides (**5.** 32, 4), and silicides (**6.** 40, 11).   F. Damm and F. Krafft [17] showed that vitreous **quartz** is attacked by lead vapour.   For the action of the **metals** on lead, *vide infra;* and for salt solutions, *vide supra.*   E. B. Maxted noted the presence of lead reduces the catalytic activity of **platinum ;** and that platinum black adsorbs lead ions from soln. of lead salts.   W. Venator found that a soln. of **sodium hydroxide** quickly corrodes lead, but many plumbiferous alloys are not attacked.   G. Lunge and L. Weibel found that 102·5 grms. of sodium hydroxide in a litre of water dissolve 0·2957 grm. of lead per sq. metre in 7 days at 20°, and 0·1489 grm. in 2 hrs. at 100° ; with 205 grms. of sodium hydroxide per litre, 0·0560 grm. in 7 days at 20°, and 0·0375 grm. in 2 hrs. at 100° ; and with 510 grms. of sodium hydroxide per litre, 0·03004 grm. in 7 days at 20°, and 0·0333 grm. in 2 hrs. at 100°.   Observations were also made by A. Wagner, and R. H. Gaines. A. J. Hale and H. S. Foster found that between 17° and 20°, 0·2N-NaOH dissolved 1·0 grm. of lead per sq. dm. per day during 7 days, and 0·69 grm. per day during 28 days.   According to O. P. Watts and N. D. Whipple, with 190 c.c. of N-NaOH for 45 hrs. at 37·5°, and 60 sq. cm. of metal the loss was 0·1101 grm. ; with 0·25 grm. of sodium arsenate also present the loss was 0·1026 ; with 5 grms. potassium permanganate, 0·0978 grm. ; with 5 grms. potassium nitrate, 0·0938 grm. ; and with 5 grms. sodium chlorate, 0·0942 grm.   O. W. Brown and co-workers, K. Elbs and J. Forssell, and F. Jirsa studied the anodic corrosion of lead during the electrolysis of soln. of sodium hydroxide.   When lead is mixed with an alkali hydroxide and carbon, and heated, carbon dioxide and hydrogen are formed ; similar results were obtained with **alkaline earth hydroxides**—*vide supra,* water. F. Jirsa and J. Fabinger studied the dissolution of lead by alkali-lye during the passage of sinusoidal alternating currents.   G. Lunge and L. Weibel found 4·4 grms. of **sodium sulphide** in a litre of water dissolve 0·0082 grm. of lead per sq. metre in 7 days at 20°, and 0·017 in 2 hrs. at 100°.   P. P. Lebedeff said that a piece of lead wrapped round with platinum wire does not give off hydrogen from a soln. of sodium sulphide.   P. Wenger and D. Midhat studied the electro-reduction of soln. of **potassium dichromate** with lead electrodes ; E. A. von der Burg, the solvent action of soln. of potassium dichromate on cupriferous and ferruginous lead.   Soln. of **molybdates** in hydrochloric acid were found by W. D. Treadwell to be reduced

quantitatively by lead to tervalent molybdenum salts. J. F. Liverseege and A. W. Knapp recommended treating lead pipes with a soln. of **potassium permanganate** whereby they resist better the action of alkaline water. F. Mylius and O. Fromm found copper is precipitated by lead from soln. of **copper salts.** J. B. Senderens found that lead precipitates copper from aq. soln. of cupric nitrate, chloride, or acetate ; but a soln. of cupric sulphate does not give copper because of the formation of a film of lead sulphate on the lead. H. W. Gillett found copper is precipitated from acid soln. of copper phosphate, and of silver phosphate. Molten silver chloride was found by C. Tubandt and S. Eggert to convert lead into lead chloride. F. Mylius and O. Fromm found dil. soln. of **silver salts** precipitate silver when treated with lead. Silver nitrate and acetate, for instance, were found by J. B. Senderens to give a precipitate of silver, whilst a silver sulphate soln. behaves like one of copper sulphate. W. W. Strong found lead gives an imprint on the photographic plate. R. H. Gerke gave for the free energy of the reaction $Pb+2AgCl=PbCl_2+2Ag$, 22,612 cals., and for the thermal value, 25,170 cals. ; with $Pb+2AgI=PbI_2+2Ag$, the numbers are respectively 9852 cals. and 12,231 cals. ; and for $Pb+2HgCl=PbCl_2+2Hg$, 24,717 cals and 22,720 cals. L. Peetz found lead precipitates tin from fused **stannous chloride ;** and W. D. Treadwell, that lead reduces **stannic chloride** to stannous chloride. R. Lorenz and M. Mannheimer studied the equilibrium conditions in the reaction $Pb+SnCl_2 \rightleftharpoons PbCl_2+Sn$. R. Lorenz and co-workers found that when lead, cadmium, and cadmium and lead chlorides are fused together at 600°–700°, equilibrium in the balanced reaction $Cd+PbCl_2 \rightleftharpoons CdCl_2+Pb$, is attained in 10 mins. The system consists of three phases, and with each salt phase of given composition there corresponds a whole series of metal phases. The composition of the equilibrium mixture was independent of the absolute quantities of the phases present and of the direction of the reaction according to the above equation, and nearly independent of the temperature over the interval 600°–700°. The value of $[Pb]/[Cd].[CdCl_2]/[PbCl_2]$ at constant temperature decreased steadily as the cadmium content decreased. Addition of lithium chloride and of mixtures of sodium and potassium chlorides favour the forward reaction in the above equation. Bismuth has no influence on the equilibrium, but antimony favours the reaction from right to left in the equation above. E. B. Spear and K. D. Kahn, and F. Mylius and O. Fromm found **gold or platinum** soln. are precipitated by lead.

Reactions of analytical interest.—A soln. of a soluble **chloride** or of **hydrochloric acid** precipitates lead chloride from moderately conc. soln. of lead nitrate ; about one part of lead chloride per 135 parts of water remains in soln. The precipitate is much more soluble in hot water and crystals of lead chloride separate on cooling the hot soln. Lead chloride is more soluble in conc. hydrochloric acid than it is in water because a soluble complex salt is formed. The complex is decomposed by water so that lead chloride is precipitated by diluting the soln. According to T. G. Wormley,[18] hydrochloric acid enables one part of lead in 500 parts of soln. to be detected ; C. H. Pfaff said that a soln. of one part of lead nitrate in 100 parts of water is the most dil. one in which hydrochloric acid will give a precipitate ; and E. Eegriwe said that a gram of lead in 400 c.c. of water can be detected by hydrochloric acid. The precipitation of orange-yellow lead iodide by **potassium iodide** is a more delicate reaction than is the case with the chloride. According to T. G. Wormley, one part of lead in 21,540 parts of water can be recognized, and F. Jackson said 1 in 8000. E. Eegriwe detected a gram of lead in 85,500 c.c. of water by potassium iodide. The iodide is fairly soluble in hydriodic acid or in a soln. of the alkali iodide, forming complex salts decomposed by water with the deposition of lead iodide. Alkaline, neutral or slightly acid soln. of a lead salt, give with **hydrogen sulphide** a black precipitate of lead sulphide ; with hydrochloric acid soln., an orange-red precipitate of *lead sulphochloride*, PbCl.S.PbCl, is first formed, and this is decomposed by more hydrogen sulphide into black lead sulphide. If the soln. contains much free hydrochloric acid, the red sulphochloride may alone

be formed.   F. Parmentier studied the phenomenon in the presence of lead bromide, and V. Lehner, with lead iodide.   According to M. Martin, if the soln. contains 2·4 per cent. hydrogen chloride, 2·9 per cent. $PbCl_2$ remains in soln.   The reaction between lead chloride and hydrogen sulphide is reversible : $H_2S+PbCl_2 \rightleftharpoons 2HCl+PbS$, because lead sulphide is soluble in conc. hydrochloric acid.   L. Bruner and J. Zawadsky gave for the equilibrium constant, $K=[Pb'\,'][H_2S]/[H\cdot]^2=3\cdot1\times10^{-6}$.   A study of the action of hydrogen sulphide on a 0·001 molar soln. of lead chloride in water at 20° in the presence of hydrochloric acid and of neutral chlorides, by L. Dede and P. Bonin, showed that the precipitation of lead sulphide is completely inhibited by hydrochloric acid alone if present in a concentration of 1·4N.   In the presence of increasing quantities of calcium, ammonium, or potassium chloride, decreasing conc. of hydrochloric acid are sufficient to prevent precipitation entirely.   The conc. of hydrochloric acid required completely to prevent the precipitation of lead sulphide from a soln. containing 20·7 mgrms. of lead per 100 c.c. with different proportions of these three chlorides, are as follow :

Conc. of lead chloride	.	.	.	.	0	0·8	2·8
Conc. HCl $\begin{cases}CaCl_2\\NH_4Cl\\KCl\end{cases}$	.	.	.	.	1·40	0·90	0·20
					1·40	1·00	0·15
					1·40	1·00	0·15

The results with calcium chloride are graphed in Fig. 30.   In the presence of considerably smaller conc. of hydrochloric acid, the precipitation of lead sulphide is incomplete.   At higher temp., the effect of hydrochloric acid in the presence of neutral chlorides is still more marked.   L. Dede and P. Becker found that magnesium and ammonium chlorides also retard the precipitation of lead sulphide from soln. of lead chloride.   The precipitation of lead sulphide is also hampered, although to a less degree, by the presence of perchloric acid. In this case, however, the addition of sodium perchlorate favours precipitation, presumably by depressing the ionization of the acid.   The precipitation of lead chromate in acetic acid soln. is not quantitative in the presence of much chloride ; in ammoniacal soln. this is not the case.   Lead sulphide is decomposed by nitric acid, $3PbS+8HNO_3=3Pb(NO_3)_2+4H_2O+2NO+3S$, but some of the sulphur is at the same time oxidized to sulphuric acid, forming insoluble lead sulphate, and this the more the greater the conc. of the nitric acid.   According to C. H. Pfaff, the brown coloration with hydrogen sulphide is visible when one part of lead nitrate is present in 100,000 parts of water ;   J. L. Lassaigne said 1 in 200,000 ; and P. Harting, 1 in 350,000.   I. M. Kolthoff found the brown colour of lead sulphide is produced in acetic or phosphoric acid soln. when 0·2 mgrm. per litre is present ; and with oxalic acid soln., when 100 mgrms. per litre is present ; N. Schoorl, a milligram per litre.   According to G. Chesneau, a soln. containing eq. proportions of lead and cupric nitrates furnishes more copper than lead when treated with an amount of a one per cent. soln. of hydrogen sulphide insufficient to precipitate both the copper and the lead—*vide infra*, lead sulphide.   M. Berthelot showed that solid lead acetate is not decomposed by dry hydrogen sulphide.   H. Reinsch found that a soln. containing one part of normal lead acetate in 200 parts of water mixed with 5 parts of hydrochloric acid, sp. gr. 1·168, gives with hydrogen sulphide a brown precipitate which soon turns black ; with 10 parts of hydrochloric acid, the precipitate is first red, then brown, and finally black ; with 20 parts of hydrochloric acid, the carmine-red precipitate is gradually formed which retains its colour ; and with 30–50 parts of hydrochloric acid, a slight precipitate is formed only after the

FIG. 30.—Concentration of Hydrochloric Acid required to prevent the Precipitation of Lead Sulphide.

addition of water. If one part of normal lead acetate be dissolved in 112 parts of water and 14 parts of hydrochloric acid, a yellow precipitate is produced by the gas. E. A. Parnell observed that paper saturated with a lead salt and thoroughly dried is not blackened by dried hydrogen sulphide. **Alkali sulphides** precipitate lead sulphide from a soln. of a lead salt, and the black precipitate is insoluble in an excess of the reagent. E. F. Anthon also showed that the sulphides of cadmium, manganese, iron, cobalt, and nickel precipitate lead sulphide from a soln. of lead salts; and, added E. Schürmann, the precipitation by cobalt, nickel, thallium (ous), and zinc sulphides is complete, but with arsenious sulphide only under press. in an autoclave. E. Eegriwe detected one gram of lead in 2,840,000 c.c. of water by means of sodium sulphide.

According to G. S. Jamieson, aq. soln. of **sulphurous acid** or an **alkali sulphite**—$NaHSO_3$, $(NH_4)HSO_3$, etc.—precipitates lead sulphate, the sensitiveness of the reaction is said by W. N. Iwanoff to be $1:20,000,000$, and he added that with one part of lead in 1,000,000 a turbidity is produced in a few minutes—barium, and tin should be absent, copper, silver, nickel, iron, aluminium, magnesium, and calcium may be present. When a soln. of a lead salt is treated with **sulphuric acid,** or a soluble **sulphate,** sparingly soluble lead sulphate is precipitated. According to C. H. Pfaff, and P. Harting, one part of lead nitrate in 200,000 parts of water can be detected by sulphuric acid; T. G. Wormley said $1:21,540$, and F. Jackson, $1:16,000$. J. L. Lassaigne observed an opalescence with one part of lead nitrate in 25,000 parts water, 15 mins. after treatment with sodium sulphate. E. Eegriwe detected a gram of lead in 24,900 c.c. of water by means of sulphuric acid. Lead sulphate is very slightly soluble in water, less so if the water be acidulated with sulphuric acid, and still less so in alcohol. The sulphate is perceptibly soluble in nitric and sulphuric acids; and is readily dissolved by hot conc. hydrochloric acid. Lead sulphate is readily soluble in soln. of the alkali hydroxides, and in the ammonium salts of many organic acids; this latter property enables lead sulphate to be separated from barium sulphate, silica, etc. Ammonium acetate or tartrate is generally used as solvent. N. Tarugi found that **ammonium thioacetate** in cold hydrochloric acid soln. of lead salts gives a reddish precipitate of lead sulphochloride which becomes black when boiled. H. Vohl found that hot conc. soln. with **sodium thiosulphate,** in the presence of ammonium chloride, precipitate lead sulphide quantitatively. The reaction was studied by J. Girard, F. Faktor, and K. A. Hofmann and V. Wölfl.

When a lead salt soln. is treated with **aq. ammonia,** white lead hydroxide is precipitated, insoluble in excess. L. J. Curtman and A. D. St. John detected $1:6500$ by this reaction. A similar precipitate is obtained with **alkali hydroxides,** but with an excess of the reagent, soluble alkali plumbite, say, $Pb(OK)_2$, is formed. The **alkali carbonates** precipitate a basic lead carbonate; and the **alkali hydrocarbonates,** normal lead carbonate. According to J. L. Lassaigne, a soln. of one part of lead nitrate in 50,000 parts of water becomes turbid when treated with sodium carbonate; and $1:100,000$ becomes opalescent in 5 mins.; and $1:200,000$ opalescent in 10 mins. E. Eegriwe detected one gram of lead in 152,000 c.c. of water by means of sodium carbonate. A white lead phosphate, $Pb_3(PO_4)_2$, is precipitated when a lead salt is treated with **sodium phosphate.** E. Eegriwe detected a gram of lead in 284,000 c.c. of water by means of sodium hydrophosphate. The precipitate is insoluble in acetic acid, but soluble in nitric acid or alkali-lye; **sodium arsenate** likewise precipitates lead arsenate; **potassium cyanide** gives a white precipitate which is insoluble in an excess of the reagent; and **oxalic acid** and **alkali oxalates** precipitate lead oxalate which, according to H. W. F. Wackenroder, is produced in soln. containing an excess of acid provided they are dilute. C. H. Pfaff detected one part of lead nitrate in 100,000 parts of water by means of oxalic acid. E. Eegriwe detected a gram of lead in 30,400 c.c. of water by means of ammonium oxalate. A yellow precipitate of lead chromate,

$PbCrO_4$, is produced when an **alkali chromate** is added to a lead salt; the precipitate is insoluble in acetic acid, but soluble in nitric acid and alkali-lye.   P. Harting gave 1 : 70,000 for the limits of this test; T. G. Wormley, 1 : 107,700; S. Harvey, 1 : 350,000; and F. Jackson, 1 : 32,000.   E. Eegriwe detected a gram of lead in 1,050,000 c.c. of water by potassium chromate, and in 2,100,000 c.c. of water by potassium dichromate.   The reaction was studied by C. Reichard, M. Gröger, and O. Mayer.   A white precipitate is produced in a soln. of a lead salt by **potassium ferrocyanide,** according to C. H. Pfaff, when one part of lead salt is present in 8000 parts of water.   E. Eegriwe detected a gram of lead in 56,800 c.c. of water by the ferrocyanide reaction.   **Potassium ferricyanide** gives no precipitate except, according to E. Müller and O. Diefenthäler, in nitrate soln. red crystals of a nitrato-ferricyanide are formed.   J. von Liebig, and R. D. Hall obtained a precipitate with a soln. of **potassium thiocyanate.** No precipitates are produced with soln. of **potassium chlorate** or **bromate.** Lead dioxide is precipitated from soln. of lead salts by **hydrogen dioxide,** by **persulphates,** or by **hypochlorites.**   E. Eegriwe detected a gram of lead in 714,000 c.c. of water by the hydrogen dioxide reaction. According to A. Trillat, an acetic acid soln. of **tetramethyldiamidodiphenylmethane** gives an intense blue coloration with lead dioxide, but not with lead salts.   The reaction is very sensitive in the absence of other oxidizing substances.   E. Eegriwe detected one gram of lead in 8,000,000 parts of water by the blue coloration produced with **ammonium molybdate ;** one gram of lead in 171,000 c.c. of water by a soln. of **cochineal ;** and a gram of lead in 200,000 c.c. of water by a soln. of **hæmatoxyline.**

Physiological action of lead.—There is a reference to the poisonous effects of lead in the medical portion of that collection of writings attributed to Hippocrates of the fifth century before our era.   Dioscorides, in his second-century *De materia medica,* mentioned the delirium produced by lead.   He said:

The drinking of " lead " causes oppression to the stomach, belly, and intestines, with wringing pains; sometimes it even wounds the intestines by its severe pressure; it suppresses the urine, while the body swells and acquires an unsightly leaden hue.

Pliny, in his first-century *Historia naturalis,* mentioned colic as an effect of lead poisoning; Aretæus, in his first-century *De causis et signis acutorum et diuturnorum morborum,* epilepsy ; and Paul of Ægina, in his seventh-century *De re medica,* epilepsy and convulsions.   Vitruvius, in his *De architectura,* written near the beginning of our era, condemned the use of lead pipes for the water supply of Rome because of the risk of poisoning.   Pliny also described how the Romans tested the harshness of wine by immersing in it a sheet of lead, and marking the corrosive action ; they also sweetened some wine by boiling it in leaden vessels.   Pliny does not seem to have thought the practice was attended by any danger.   In the preparation of wine, if the fermentation process be carried too far, the liquor becomes charged with acid.   The ancients probably knew that lead rendered harsh wine milder, and preserved it from acidity.   The process was long used with confidence because the toxic effects were not ascribed to the metal but to some other cause. The deleterious result of sweetening wine with lead compounds was mentioned by M. Citois [10] in 1616, and M. Delamarc in 1696; and J. Zeller and J. Weismann said that the practice was invented in France.   After the poisonous effects of this addition had been recognized, it required the severest of punishments—torture and death—before the use of litharge for this purpose could be stopped.   Even in the eighteenth century, the improvement of wines by litharge was in some quarters taught as a method free from danger—*e.g.* by W. Graham—although J. Beckmann has cited a number of cases near the end of the seventeenth century, where those who treated the wines with lead compounds were very severely punished.   The litharge or white-lead was singularly efficacious in renovating spoilt wine, but its effect on the consumer was disastrous.   According to J. Beckmann,

No adulteration of any article has ever been invented so pernicious to the health, and

at the same time so much practised as that of wine with preparations of lead ; and as the inventor must have been acquainted with its destructive effects, he deserves, for making it known, severer execration than Berthold Schwartz, the supposed inventor of gunpowder. . . . The wine occasions, according as it is used in a great or small quantity, and according to the constitution of the consumer, a speedy or a lingering death, violent colics, obstruc- tions, and other maladies ; so that one may justly doubt whether, at present, Mars, Venus, or Saturn is most destructive to the human race.

Although the noxious character of the fumes given off during the smelting of lead was mentioned by many ancient writers, it was not until 1656 that S. Stock- husen established a definite relation between lead and the so-called colic ; early in the sixteenth century, A. Aetius described the colic frequently associated with the use of certain wines, and in 1757, T. Tronchin discovered that many wines could dissolve the plumbiferous glaze from the earthenware vessels in which the wine was stored. In 1788, J. Hunter described the " dry belly ache " prevalent in the garrison of Jamaica caused by the consumption of rum contaminated with lead. The historical side of lead poisoning has been discussed by G. Meillère, J. Alderson, and by L. Tanqueril des Planches ; and the physiological and pathological effects —*plumbism* or *saturnism*—have been the subject of an extraordinary number of reports and memoirs.[20]

Poisoning by lead compounds may be acute or chronic. Acute poisoning is pro- duced by comparatively large doses of a soluble salt of lead. Recovery has followed after swallowing an ounce, and cases of death are comparatively rare. An astringent metallic taste is perceived ; there is a feeling of constriction in the œsophagus ; and a hot sensation which extends to the stomach. Within half an hour vomiting occurs ; there is a great thirst, and colicky pains in the abdomen which come on in paroxysms. There are prostration, vertigo, numbness, and pains in the head and limbs. There may be a state of drowsiness or one of excitability, and death occurs on the second or third day. There is a sub-acute form in which small but not minute doses of a soluble salt of lead are administered. Chronic lead poisoning is produced by the introduction into the system of minute doses of a lead compound, or lead itself. The sources from which the lead may be derived in chronic lead poisoning are numerous and diverse. There are the so-called *occupational risks* which attend the use of lead or lead compounds in many trades such as painting, plumbing, pottery glazing, glass working, making lead compounds—*e.g.* litharge, red-lead, white-lead, etc.—printing, cutlers, file cutting, making accumulators, making sheet lead and lead piping, smelting metals, enamelling iron, litho-trans- ferring, etc. There are also the so-called *accidental risks* where people in ordinary avocations are in danger from negligence or ignorance owing to the extensive employment of plumbiferous materials for so many purposes in everyday life. Lead is a cumulative poison, and the absorption of a minute quantity at a time but extended over long periods may produce disastrous results. It may be a long time before symptoms of chronic poisoning appear, and in some cases it would require a Dupin to detect the source of the trouble as a preliminary to its elimination.

As indicated previously, lead has been detected in most of the ordinary foods—flour, bread, beer, wines, spirits, cider, tea, vinegar, sugar, confectionery, etc.—in numerous drugs made by the aid of sulphuric acid which, when manufactured by the chamber process, nearly always contains lead ; or in drugs made in leaden vessels—*e.g.* the crystallization of tartaric or citric acid in leaden pans. Lead colic has been reported in a cabman whose first glass of beer every morning at a public-house was drawn from that which had been standing in pipes overnight. The use of old painted wood in a baker's oven, and the subsequent adherence of a film of lead oxide to the outside of the loaves is reported to have caused the illness of 66 people. G. Marmisse mentioned the gate-keeper of a grave-yard at Bordeaux who continually used the remnants of crosses, etc., covered with lead paint to replenish his fires, and who was suffering from lead poisoning. A trace of lead tetraethyl, $Pb(C_2H_5)_4$, in motor spirit prevents " knocking." If carelessly used, accidents may occur owing to the toxic qualities of the exhaust vapours. This was discussed by E. Behrle, and T. Midgley. T. Bancks and R. L. Freer reported that in 1840 about 500 non-fatal cases of acute poisoning were caused by 30 lbs. of sugar of lead having been accidentally mixed with 80 sacks of flour. S. J. Knott mentioned a case of chronic poisoning due to the cleaning of

pewter pots; G. H. Allden, G. A. E. Roberts, and D. Campbell, to the drinking of home-made wine fermented in lead-glazed pans; H. Pillaud, to the use of food prepared in glazed earthenware vessels; E. V. Raumer and E. Spaeth, to the consumption of whortle-berries stored in large glazed earthenware pots; A. S. Taylor, to the wrapping of foods in tin-foil, and the fingering by fishmongers of lead counters covered with brine; G. Johnson, to the handling of vulcanized rubber, etc.—*vide supra*, the action of water, etc., on lead. Chronic lead poisoning has been reported owing to the use of wine bottles cleaned by shaking lead-shot in them; tinned foods; confectionery coloured with lead chromate; tea, and snuff packed in lead-foil; hair-dyes; cosmetics; soda-water syphons with pewter or lead-valves; etc. According to G. Stiefler, the lead poisoning common among the peasants in Lower Austria is due to the cider having dissolved some lead from the containing vessels during its fermentation. There are many other strange reports although in some cases the assigned cause is not the real one, for the lead may have entered the system through another unsuspected channel. H. Masters, G. W. Monier-Williams, and others have discussed the solubility of lead from glazed pottery and enamelled iron. F. H. de Balsac and co-workers reported on lead poisoning in the accumulator industry.

Some people are particularly susceptible to the influence of lead poisoning, while others seem to resist the action of or to tolerate the poison to a marked degree. The possible channels for the *ingestion* of lead are cutaneous absorption, intestinal, and respiratory. The possibility of the cutaneous absorption of lead through the unbroken skin has provoked much controversy; but, in spite of the observations of T. Canuet, M. Drouet, and A. Maneuvrier, T. M. Legge and K. W. Goadby consider that the possibility of the cutaneous absorption has no practical significance. Industrial lead poisoning may occur through compounds of lead finding their way into the alimentary canal *via* the mouth mainly by un-washed hands, by food contaminated with lead dust, and the deposition of lead dust, suspended in air, upon the mucous membrane of the mouth and pharynx, and then swallowed. T. M. Legge and K. W. Goadby consider that this source of contamination is far less dangerous than is that due to the inhalation of dust or fume suspended in air, and that the lung rather than the stomach is the chief channel through which lead finds its way into the system. As a result, the pro-tection of the operatives from dust and fumes by exhaust ventilation and cleanli-ness have produced an extraordinary decrease in occupational plumbism. The *storage* of lead in the system is illustrated by T. Oliver in Table VI, representing

TABLE VI.—THE DISTRIBUTION OF LEAD IN THE VARIOUS ORGANS OF THE BODY.

Organ.	A.	B.	Organ.	A.	B.
Large intestine . .	26·1	—	Spleen	21·9	0·0462
Small intestine . .	9·2	—	Liver	42·4	0·8820
Muscle	3·1	—	Cerebellum . . .	36·9	
Lung	4·9	—	Grey matter (basal ganglia)	53	
Heart	5·3	0·0199	Brain-grey matter cortex .	40·9	0·7070
Mamma	4·8	—	Brain-white matter . .	18·9	—
Kidney. . . .	12·9	0·0253	Spinal cord . . .	1·2	—

the mean analyses of various organs of three lead-workers who had succumbed to lead poisoning. The amount of lead obtained is expressed A in parts per million, and B in grains calculated on the total weight of the organ. Lead is also stored in the bones. The *excretion* of lead from the system is mainly through the kidneys; and lead is often found in the urine of those suffering from lead poisoning. Accord-ing to T. M. Legge and K. W. Goadby, lead is more commonly present in the fæces of lead-workers than in the urine.

The chief symptoms of chronic lead poisoning are general ill-health usually referred to as indigestion; the appetite is lessened; and the bowels constipated. There is a disagreeable taste in the mouth, and the breath is offensive. The skin acquires an unhealthy colour, being at first yellowish and subsequently anæmic. The gums often show a bluish-black line—the *Burtonian line*—produced by lead.

sulphide, and first described by H. Burton.[21] The pulse is slow, and secretions
are diminished. The sexual functions are weakened, and pregnant women have
a tendency to abortion. In addition, there may be lead colic due to recurrent
abdominal pains; pains in the joints; partial paralysis so that when the arms
are held out horizontally, palms downwards, the hands drop and cannot be
raised—wrist-drop; the organs of sight may degenerate, inducing partial or
total blindness; and there may be psychical disturbances commencing by head-
ache, dizziness, and sleeplessness which may further develop to drowsiness or to
excitability or insanity accompanied by hallucinations and wild deliria. In 1831,
R. T. H. Laennec described the pallor of the tissues, and the thinness of the
blood in cases of plumbism; and in 1840, G. Andral and J. Gavarret found that
the proportion of red blood corpuscles during lead poisoning is lower than
normal. To-day, an erythrocite count is a routine clinical procedure in lead
poisoning. The subject has been studied by J. C. Aub and many others. P. Orfila
made experiments on the action of lead compounds on animals; and numerous
other experiments have since been reported. R. V. Tuson stated that seven cows
and one bull had died by eating lead paint; and cattle have been poisoned by
eating grass which has been splashed by the spray from bullets in pastures in the
vicinity of rifle butts. Many observations [22] have also been made on the toxic
effects of lead compounds on plants, yeast, and bacteria.

Some uses of lead.—The pliability of lead and the ease with which it can be
moulded, and soldered or united by autogenous welding have resulted in the metal
being largely used for gutters, spouts, and roofing in buildings; as lead piping for
conveying water, and gases in chemical manufacture, and in the construction of
vessels or plant where resistance to many corrosive acids is needed—*e.g.* evaporating
pans, sulphuric acid chambers, etc.[23] It is also used largely in making accumu-
lators. A great many alloys of lead are used in the arts—shot, solders, pewters,
etc.—*vide infra*. There are methods [24] for coating steel and iron with lead for
pipes and vessels in contact with corrosive liquids—*e.g.* S. Cowper-Coles's electro-
lytic process, or M. A. Schoop's spraying process—earthenware and wood may
also be coated with the metal. The acetate of lead—*liquor plumbi subacetatis*—
is employed medicinally as an astringent in diarrhœa, in gastric ulcers, and in
hæmorrhage of the intestines. The acetate, iodide, and carbonate are used in
conjunction with the oleate for ointments and plasters—*unguentum plumbi
acetatis; unguentum plumbi iodidi; unguentum plumbi carbonatis; diachylon* or
lead oleate or *lead soap;* etc. The basis of Ledoyen's disinfecting fluid is lead
nitrate, and the same salt is used in calico printing; *lead pyrolignite* is used in
dyeing. There are numerous lead pigments, mainly white, yellow, and red. Lead
is used in the preparation of flint glass, pottery glazes, enamels, etc. The oxide is
used to accelerate the hot vulcanization of rubber; and the ethide, as an anti-
knocking agent in explosion engines, etc.[25] The presence of as little as one mol
of lead tetraethide in 200,000 mols of a combustible mixture of petrol and air
exerts a marked effect in the suppression of detonation. Sodium plumbite is
used in the sweetening of gasoline, by removing the sulphides as lead sulphide.[26]

§ 6. The Valency and Atomic Weight of Lead

According to H. E. Roscoe and A. Harden,[1] in a note-book dated March, 1804, J. Dalton wrote 105 for the at. wt. of lead when that of oxygen is 5·5 ; and this number becomes 305 when the at. wt. of oxygen is 16. In his later work, J. Dalton adopted 90 for the at. wt. of lead when that of oxygen is 7, or 206 if oxygen is 16. In 1811, J. J. Berzelius calculated from the ratio $Pb : PbO$, the at. wt. 206·5 when the at. wt. of oxygen is 16 ; from the ratio $PbS : PbSO_4$, 209·9 ; from the ratio $Pb : PbSO_4$, 207·6 ; and from the ratio $PbO : PbSO_4$, 207·98. At first he was not very clear whether to represent what is now called lead monoxide, PbO, by the formula PbO, Pb_2O_3, PbO_2, PbO_3, or PbO_4. After the sp. ht. rule, and the isomorphism rule had been developed, he adopted the now accepted formula PbO. This made the at. wt. of lead approximate 207. Lead ordinarily behaves as a

bivalent element giving salts isomorphous with those of the bivalent alkaline earth metals. So much do the normal lead salts resemble those of the alkaline earths that A. Baudrimont suggested that lead should be included in that family. For the genetic connection of lead with radium which in turn belongs to the alkaline earth family of metals, *vide infra.* Lead can also behave as a *quadrivalent element* as is evidenced by the higher oxide, PbO_2 ; *lead tetramethide,* $Pb(CH_3)_4$, which has a vap. density of 9·52 (air unity) in agreement with the calculated value 9·25 ;. and the isomorphism of the complex fluorides and chlorides—$3KF.HF.PbF_4$ and $3KF.HF.SnF_4$; and R_2PbCl_6 and R_2SnCl_6, where R represents NH_4 or Cs. These observations agree with the position of lead in the tin family in the periodic table. G. Oddo also emphasized the family relations of lead, tin, and germanium. E. W. Wetherell discussed the position of lead in the periodic table.

There is some evidence of *univalent lead—vide* lead suboxide and the subsalts of lead. According to H. G. Denham and A. J. Allmand, in attempting to measure the hydrolysis of lead salts by the hydrogen electrode, abnormally high values are obtained. This is not due to the separation from the soln. of a metal, say silver, more noble than hydrogen ; nor to the deposition of lead on the electrode in such a way that the hydrogen electrode acted as a cathode, nor to the formation of a lead-platinum alloy. The potential depended on the rate at which hydrogen was bubbled through the soln. and it was assumed that the action on the surface film involves a reduction of bivalent lead: $PbCl_2 + H \rightleftharpoons PbCl + HCl$; the faster the stream of hydrogen, the more quickly was the free acid so produced carried into the main bulk of the liquid, and the lower the potential. E. Bose attributed a discrepancy in the silver voltameter to the formation of subvalent ions; and T. W. Richards and co-workers, in the copper voltameter, to the formation of cuprous salts in soln. A hot soln. of a lead salt can dissolve the metal, and give it up again on cooling. A piece of lead in a soln. of lead acetate, maintained at two different temp., forms a thermo-cell; the current flows from the hot soln. to the cold one, and causes a deposition of spongy lead at the cold end of the piece of lead. There is also a series of compounds in which lead appears to act as a *tervalent element,* judging by the analogy of the products prepared by E. Krause, with triphenylmethyl—*vide* valency of carbon. Thus, E. Krause made *lead tricyclohexyl,* $Pb(C_6H_{11})'_3$, by the action of lead chloride on a soln. of magnesium cyclohexyl bromide in dry ether. The corresponding *lead triphenyl,* $Pb(C_6H_5)_3$; *lead tri-o-tolyl,* $Pb(C_7H_7)_3$; *lead tri-p-tolyl,* $Pb(C_7H_7)_3$; and *lead tri-p-xylyl,* $Pb(C_8H_9)_3$, have been examined by E. Krause and G. G. Reissaus. According to W. Esch, lead exhibits a still higher valency in the acid sulphate, $H_2Pb(SO_4)_3$, which may be regarded as *hydrotrisulphatometaplumbic acid.*

The at. wt. of lead calculated from J. J. Berzelius' values for the ratio Pb : PbO, obtained by converting the metal into the nitrate, and calcining the product for the oxide, is 206·5 ; from the ratio PbO : Pb obtained by reducing the heated oxide in hydrogen, 207·06–207·14 ; and from the ratio PbS : $PbSO_4$, obtained by treating the sulphide with aqua regia, he obtained 209·9. T. Anderson's values for $Pb(NO_3)_2$: PbO give 207·360. J. J. Berzelius converted the metal into sulphate, and his values for the ratio Pb : $PbSO_4$, furnish the at. wts. 206·97 and 207·6 ; T. Turner's values, 207·05 ; and J. S. Stas, 206·93. J. J. Berzelius also converted the oxide into sulphate and from the ratio PbO : $PbSO_4$, it follows that the at. wt. is 207·5–207·98; and T. Turner's values gave 207·64. The values of the last-named for the ratio $Pb(NO_3)_2$: $PbSO_4$ gave 204·2, and J. S. Stas', 206·46. From J. S. Stas' value for the ratio Pb : $Pb(NO_3)_2$, the at. wt. is 206·80–206·82. J. J. Berzelius measured the ratio PbO : CO_2, and the results correspond with the at. wt. 206·98. T. Thomson made some observations on the at. wt. of lead. J. C. G. de Marignac converted lead into the chloride, and obtained the ratio Pb : $PbCl_2$, from which the at. wt. is 206·87 ; he also analyzed the chloride for the ratio $PbCl_2$: $2AgCl$, and the results give 206·85, while G. P. Baxter and J. H. Wilson's results give 207·103 ; and G. P. Baxter and F. L. Grover's gave 207·23. From the ratio

$PbBr_2 : 2AgBr$, G. P. Baxter and T. Thorvaldson obtained 207·19. J. C. G. de Marignac's value for the ratio $PbCl_2 : 2Ag$ furnishes the at. wt. 206·80; J. B. A. Dumas' value, 206·88; G. P. Baxter and J. H. Wilson's value, 207·103; and O. Hönigschmid and M. Steinheil, 207·23. From the ratio $2Ag : Pb$, obtained by the electrolysis of a soln. of a lead fluosilicate in hydrofluosilicic acid, while a silver voltameter was in circuit, A. G. Betts and E. F. Kern's data gave 206·73. G. van Dyk obtained 0·0111823 for the electrochemical equivalent of lead; H. Pécheux obtained 206·86–207·09 for the at. wt. by electrolysis. From the ratio $2Ag : Pb$, which L. Meaglia obtained by precipitating silver from a soln. of silver nitrate by lead, 206·866–206·935. J. Thomsen calculated 206·904 for the best representative value of the at. wt. of lead; W. A. Noyes, and J. D. van der Plaats, 206·91; L. Dubreuil, 206·919; F. W. Clarke, 206·970 ±0·0017; T. W. Richards and co-workers, 207·217; and B. Brauner, 207·10. The International Table for 1924 gives 207·20. The **atomic number** is 82. The **electronic structure** on N. Bohr's[2] scheme is (2) (4,4) (6,6,6) (8,8,8,8) (6,6,6) (2,2). J. Beckenkamp, and H. Collins made some speculations on this subject.

The at. wt. problem has assumed another aspect since the study of the end-products of the radioactive degradation of uranium and radium led F. Soddy[3] to question as to whether the lead found in association with uranium is the same as that of ordinary lead.

W. F. Hillebrand noticed the association of lead with uranium in some minerals, and numerous observations have since been made on this subject and on the induced radioactivity of lead. The metal itself is not primarily radioactive. B. B. Boltwood found the ratio of uranium to lead in primary minerals from the same locality to be so nearly constant as to suggest that lead may be the end-product of the degradation of uranium. The rate of radioactive change is so slow that a direct proof of the degradation of uranium to lead cannot be expected. It has been calculated that a gram of uranium yields $1·25 \times 10^{-10}$ grm. of radium-G per annum; and if the gram of uranium be constantly replenished to make up the loss, a gram eq. of radium-G would require 8000 million years for its formation. A. Holmes has shown that with stable minerals of primary origin, where there is no geological or petrological evidence of the presence of lead as a primary product, and no evidence of the loss of any of the constituents by weathering, the age of the mineral can be estimated from the ratio $Pb : U$. The result shows that the age of some precambrian Norwegian minerals, in which this ratio is 0·013, approximates 1000 million years. The trustworthiness of the evidence was discussed by G. Kirsch.

The so-called displacement rule—**4. 26, 11**—enabled F. Soddy, and K. Fajans to calculate the at. wt. of radium-G from that of uranium (238·2) or of radium (226). The result shows that the at. wt. of radium-G is 206·2 or 206·0, while that of ordinary lead approximates 207. R. de M. de Ballore proposed 206·5 for the best representative value of the at. wt. of lead derived from the radioactive uranium minerals. The at. wt. of lead in 24 of the determinations indicated above varies from 206·8 to 207·6. The results of various determinations[4] of the at. wt. of the lead in radioactive minerals, recorded in Table VII, show that the at. wt. of the lead from various uranium minerals approximates 206, and it resembles ordinary lead in all its known chemical reactions. The evidence that lead is accumulating in minerals at the expense of the uranium is purely circumstantial and is as follows : (i) The constancy of the ratio $Pb : U$ in minerals of the same geological age, and its variation in those of different geological age; and (ii) the close approximation of the calculated to the observed values for the at. wt. of lead derived from uranium minerals. R. de Montessus de Ballore proposed 206·5 ±0·05 for the at. wt. of radio-lead.

The genetic connection between thorium and lead is founded on more slender evidence; both B. B. Boltwood,[5] and A. Holmes did not consider it probable that thorium should give lead. The displacement rule gives 208·4 for the at. wt. of thorium-D assumed to be lead produced by the radioactive degradation of uranium,

TABLE VII.—ATOMIC WEIGHT OF LEAD FROM DIFFERENT SOURCES.

at. wt. 232·4 ; and H. N. McCoy's estimate of the ratio of the rates of change makes the production of lead by uranium about three times as fast as would be the case if it were produced by thorium. The observations in Table VII show that the lead derived from thorium minerals has the necessary high at. wt. According to F. W. Clarke, the variations in the at. wt. of different varieties of lead derived from radioactive minerals may be due to the admixture of ordinary lead and an isotopic form of lead, or ordinary lead may be a distinct variety, or a balanced mixture of isotopes derived from uranium and thorium, or an unknown degradation from some lighter parent element. A. Bull ascribed the difference in the at. wts. of different forms of lead to the gravitational attraction being dependent on the electrons which are strained in the radioactive atoms, and the strain becomes less and less as the end-product is approached.

A. S. Russell's analysis of the complexity of the elements gives him the hypothetical conclusion that lead consists of isotopes of at. mass 204, 205, 206, 207, 208, and 210, but F. W. Aston failed to get isotopes by using lead ethide, etc. The attempt by J. Joly and J. H. J. Poole to separate lead isotopes by centrifuging the molten metal was nugatory. T. Dillon and co-workers attempted to separate the isotopes of lead by treating the chlorides with magnesium ethyl halide : $2PbCl_2 + 4MgRX = PbR_4 + 2MgCl_2 + 2MgX_2 + Pb$. The lead and lead ethide so obtained were regarded as two fractions and the whole repeated a number of times on each of the two products separately. The relative values for the at. wts. were 207·1 and 207·4, which shows that there may be here a partial separation of isotopic forms. R. F. Atkinson reported that by melting and cooling about 300 grms. of lead assay foil, fractional crystallization furnished two end-fractions each weighing

about 60 grms. after the purification of each by J. S. Stas' process; the sp. gr. of the fraction at the crystals end was $11 \cdot 345 \pm 0 \cdot 005$, and at the mother-liquid end, $11 \cdot 313 \pm 0 \cdot 005$. Another sample of lead not fractioned, gave, after purification, an intermediate sp. gr. This may have no reference to the isotopes of lead, but may be an effect of purification *per se.* According to T. W. Richards and co-workers, the m.p. of two varieties of lead differing 0·8 in their at. wt. agreed within 0·05°, and the thermoelectric force in the Seebeck effect was zero; the index of refraction, and the solubility of the nitrates of ordinary lead and of lead of at. wt. 206·42 were virtually the same. The sp. gr. of ordinary lead at 20° was 11·377, which is higher than 11·288, that of the lead extracted from Australian radioactive minerals —Table VII. Since at. wts. vary proportionally with densities, the at. vols. of the two forms of lead were the same. M. E. Lembert observed no difference in the m.p. of the chlorides. C. D. and D. Cooksey compared the spectra of lead isotopes. The electrical resistance and the temp. and press. coeff. of the resistance of ordinary and radioactive lead were found by P. W. Bridgman to be the same. The superconductivity of both varieties of lead was found by W. Tuyn and H. K. Onnes to begin at $-265 \cdot 8°$, and to be the same down to $-258 \cdot 8°$. As indicated (4. 26, 11), the spectra of the different varieties of lead were shown by F. Soddy and H. Hyman, O. Hönigschmid and S. Horovitz, B. Perrette, W. D. Harkins and L. Aronberg, and T. R. Merton, to be the same. E. S. Bieler observed a shift of the 4270 band towards the violet in passing from ordinary lead to uranium-lead. O. Hönigschmid and M. Steinheil failed to obtain a separation by fractional distillation; and H. Brennen, by Grignard's reaction : $4(C_2H_5)MgI + 2PbCl_2 = Pb + 4MgICl + Pb(C_2H_5)_4$. T. W. Richards and co-workers observed that no separation of the isotopes could be made with Grignard's reaction or by irreversible volatilization. H. Pettersson and G. Kirsch [6] discussed the **atomic disintegration** of lead atoms when bombarded by α-rays.

L. Naudin [7] reported experiments by P. Schützenberger on the conversion of lead into silver, but there is no confirmation of this statement. W. Ramsay and F. L. Usher's conversion of lead chlorate into carbon monoxide and dioxide by exposing a soln. of that salt to radium emanation has not been confirmed. A. Smits discussed the possibility of transmuting lead into some other metal—mercury and thallium—when used as electrode in a quartz vacuum tube on 30–35 amps. and 80 volts.

§ 7. The Alloys of Lead with the Alkali Metals

W. Guertler[1] studied the affinity of lead for the metals generally. The alloys of lead and *lithium* were partly examined by P. Lebeau, and W. A. Cowan mentioned the hardening of lead by lithium. J. L. Gay Lussac and L. J. Thénard mentioned the alloying of *sodium* with lead when the former is added to molten lead; they said that heat but not light is developed, and C. H. Mathewson added that with 26·4–31·6 per cent. of sodium the rise of temp. is 100°–200°. J. Percy reported the formation of these alloys. G. D. Roos made the alloys by adding lead to sodium melted under vaseline in a current of hydrogen. Several workers—C. T. Vautin, F. Haber, C. E. Acker, J. Walter, L. Hulin, etc.—have noted the formation of these alloys during the electrolysis of molten sodium hydroxide or chloride using a cathode of molten lead; and G. Bredig and F. Haber noted the formation of an alloy during the cathodic spluttering of lead in an aq. soln. of sodium hydroxide. G. S. Sérullas mentioned the formation of an alloy when lead is heated with charred soap; W. H. Greene and W. H. Wahl, by heating a mixture of carbon, lead, and sodium carbonate, or of lead and sodium tartrate; A. Joannis, lead filings and sodammonium; and E. C. Rossiter, by stirring a mixture of sodium hydroxide and wood charcoal in molten lead at 750°, and H. Caron, by reducing lead chloride by sodium.

The f.p. curves of the alloys have been examined by N. S. Kurnakoff, C. H. Mathewson, C. Calingaert and W. J. Boesch, G. Tammann, C. T. Heycock and F. H. Neville, L. Lewin, E. Kordes, and J. Goebel. The freezing curves shown in Fig. 31 represent results by C. H. Mathewson, C. Calingaert and W. J. Boesch. There are four maxima on the f.p. curve: one at 386° and 80 at. per cent. of sodium; one at 400° with 71·4 at. per cent. of sodium; one at 366° with 5 at. per cent. of sodium; and one at 319° with 27·4 at. per cent. of sodium. There are four eutectics: one at 327° and 58·8 at. per cent. of sodium; one at 372° and 76·6 per cent. of sodium; one at 301° with 37·3 at. per cent. of sodium; and one at 307 with 21·1 at. per cent. of sodium. The solid soln. Na-Pb and Na_5Pb_2 are formed with 50–52 at. per cent. of sodium; $NaPb + Na_5Pb_2$ with 70·0–71·4 at. per cent. of sodium; and $Na_4Pb + Na_5Pb_2$ with 71·4–72·4 at. per cent. of sodium. The hemiplumbide decomposes

FIG. 31.—Freezing-point Curves of the Pb–Na Alloys.

at 182°, forming the dipentitaplumbide. The conditions of stability of **sodium tetritaplumbide,** Na_4Pb, are indicated in Fig. 31. C. A. Kraus and H. F. Kurtz observed the formation of this compound in the reduction of lead salts by sodium amalgam. W. H. Greene and W. H. Wahl found that the colour is pale grey; and the sp. gr. 3·81 when the value calculated by the mixture rule was 3·7. The alloy is softer than the finger-nail. N. S. Kurnakoff gave 420° for the m.p. against C. H. Mathewson's 386°. The conditions of stability of **sodium hemiplumbide,** Na_2Pb, are indicated in Fig. 31; the compound was made by W. H. Greene and W. H. Wahl, A. C. Vournasos, A. Joannis, G. Calingaert and W. J. Boesch, as well as by C. H. Mathewson. According to G. Calingaert and W. J. Boesch, the compound which separates from alloys with between 58·8 and 76·6 at. per cent. of sodium is **sodium dipentitaplumbide,** Na_5Pb_2; and not Na_2Pb. The m.p. of the dipentitaplumbide is 400°, alloys with between 58·8 and 71·4 at. per cent. of sodium rearrange at 182° on cooling so that Na_5Pb_2 disappears and the hemiplumbide is formed. The dipentitaplumbide forms solid soln. with both sodium monoplumbide and tetritaplumbide. The pale blue alloy is brittle, and, according

to W. H. Greene and W. H. Wahl, the sp. gr. is 3·61 when the value calculated from the mixture rule is 3·7. The m.p. is 405°, and G. D. Roos found the latent heat of fusion to be 20·0 Cals. per gram when the molar entropy change is 7·5. C. H. Mathewson said that the compound in moist air acquires a brownish-black crust rather more slowly than does the tetritaplumbide. A. Joannis said that the hemiplumbide rapidly oxidizes in air with the evolution of much heat, and it decomposes in water with the separation of brown flocculent lead. It is soluble in liquid ammonia, and, according to C. A. Kraus, when the soln. is electrolyzed, lead separates on the anode, sodium on the cathode. The conditions of stability of **sodium plumbide,** NaPb, are indicated in Fig. 31. W. H. Greene and W. H. Wahl gave for the sp. gr. 6·91 when the value calculated from the mixture rule was 5·6. C. H. Mathewson gave 367° for the m.p. G. D. Roos found the latent heat of fusion to be 16·9 Cals. per gram when the molar change of entropy is 6·1. The conditions of stability of **sodium hemipentaplumbide,** Na_2Pb_5, are given in Fig. 31 ; C. H. Mathewson gave 319° for the m.p., and G. D. Roos found the latent heat of fusion to be 10·9 Cals. per gram when the molar change of entropy is 20·0. N. S. Kurnakoff reported *sodium triplumbide,* $NaPb_3$, m.p. about 316°, but this has not been confirmed. F. H. Smyth found a soln. of sodium in liquid ammonia dissolves lead, and the electrolysis of the soln. and the solubility measurements agree with the assumption that the soln. contains sodium diplumbide, and possibly also a smaller proportion of sodium triplumbide.

W. H. Greene and W. H. Wahl said that alloys with 3 to 31 per cent. of sodium are crystalline, and the brittleness is greater the larger the proportion of sodium. The alloy with 31 per cent. of sodium has a greenish tinge. C. H. Mathewson, H. Hanemann and W. Stockmeyer, and M. Wählert examined the brittleness of these alloys. J. Goebel found that the hardness of lead is increased by sodium from 4·1 when no sodium is present to 28·9 when 2 per cent. is present ; as the proportion of sodium is further increased to 4 per cent., the hardness drops to 18·4. E. S. Sperry, C. O. Thieme, and C. H. Mathewson also examined the hardness of these alloys. An alloy with 1·3 per cent. of sodium is called *noheet metal,* or *tempered lead,* and has been recommended as a bearing metal, and S. K. Patteson claimed that under these conditions some sodium hydroxide is formed, which, with the lubricating oil forms a kind of soap. K. Bornemann and G. von Rauschenplat measured the electrical conductivity of the alloys. M. Sack measured the potential of a lead cathode in 3N-NaOH against a mercury electrode ; and the potential of sodium-lead alloys in a methyl alcohol soln. of lithium chloride at −80°. The curve showing the at. conc. of sodium and the potential of the alloy has breaks corresponding with *sodium diplumbide,* $NaPb_2$; the triplumbide, $NaPb_3$; and *sodium hemi-triplumbide,* Na_2Pb_3. R. Kremann and P. von Reininghaus measured the potential in pyridine soln. of sodium sulphate and iodide. They found evidence of the formation of NaPb, Na_2Pb_5, Na_2Pb, and Na_4Pb. C. H. Mathewson, and W. H. Greene and W. H. Wahl found the greater the proportion of sodium in the alloys, the more readily do they oxidize on exposure to air. According to J. L. Gay Lussac and L. J. Thénard, these alloys are decomposed by water, and L. Lewin, W. H. Greene and W. H. Wahl, and J. Goebel found the alloys are more readily attacked the higher the proportion of sodium, and L. Lewin said much lead passes into soln. According to H. Hanemann and W. Stockmeyer, alloys with 0·5 to 1 per cent. of sodium resist attack by sulphuric acid and tannic acid. They also tried the effect of an addition of magnesium or an alkaline earth metal ; and J. Goebel, the effect of mercury. F. Skaupy tried the alloy as an electrode in electric lamps. G. Tammann studied the electrode potential and chemical properties of these alloys ; and R. Kremann and co-workers found that on electrolysis, sodium accumulates at the cathode, lead at the anode.

J. L. Gay Lussac and L. J. Thénard [2] made alloys of lead and *potassium* by melting the two metals together ; D. P. Smith heated the mixed metals to 600°. L. N. Vauquelin heated a mixture of lead oxide and potassium tartrate and obtained

potassium-lead alloys. J. Percy also made these alloys. J. Walter produced the alloy by electrolyzing molten potassium chloride, using a carbon anode dipping under molten lead. G. Bredig and F. Haber obtained the alloy by the cathodic spluttering of lead in a soln. of potassium hydroxide or carbonate. The f.p. diagram of the lead-potassium alloys obtained by D. P. Smith is shown in Fig. 32. The results show that the m.p. of lead is lowered to 275° by the addition of potassium; the eutectic mixture contains about 8 atoms per cent. of the latter metal. At 295°, **potassium diplumbide**, KPb$_2$, reacts with the fused mass to form **potassium tetraplumbide**, KPb$_4$; KPb$_2$ itself is formed by the interaction of a third compound of unknown composition and the fused mass at 337°. A fourth compound, probably **potassium hemiplumbide**, K$_2$Pb, melts about 568°, and has a transition point at 376°. A. Joannis made what he regarded as **potassium plumbide**, KPb, or K$_2$Pb$_2$, by the action of an excess of

FIG. 32.—Freezing-point Curves of the Pb–K Alloys.

potassioammonium on lead, or by the action of a soln. of potassium amide, KNH$_2$, in liquid ammonia on lead. The impure alloys obtained by J. L. Gay Lussac and L. J. Thénard, L. N. Vauquelin, and G. S. Sérullas were grey and brittle, and were decomposed by water. K. Bornemann and G. von Rauschenplat measured the electrical conductivity of the alloys; and R. Kremann and E. Pressfreund, the potential against a soln. of potassium chloride in pyridine. They found evidence of the formation of K$_2$Pb, and KPb$_4$, but not KPb$_2$. K. Jellinek and co-workers studied the equilibrium of the reaction between alkali metals and their molten chlorides, Na+KCl⇌NaCl+K, by the introduction of a lead phase. Mixtures of sodium and potassium chlorides were heated at 800° with lead-sodium, lead-potassium, or lead-sodium-potassium alloys, and in each experiment the percentage ratio of sodium and potassium in the lead phase was constant, no matter which of the above alloys was used. The law of mass action holds for these salts in the fused state. The chemical affinities of sodium and potassium lie much closer together at high temp. and the heat of reaction becomes very small. The alloy with about 3 per cent. of potassium was recommended by G. H. Worrall as a bearing metal. G. Tammann studied the electrode potential and chemical properties of these alloys.

\

§ 8. The Alloys of Lead with Copper, Silver, and Gold

Alloys of lead and *copper* were described by J. F. Gmelin,[1] P. Berthier, J. H. Croockewit, etc. The so-called manilla gold, according to J. C. Welch, is an alloy consisting principally of these two metals ; and, according to W. Gowland's analysis, a Japanese mirror of the seventeenth or eighteenth century is an alloy of copper and lead with about half per cent. of tin. M. Domingo recommended an alloy with 15·6 per cent. of lead as a hard solder for copper. J. Girardin found a buckle belonging to the Frankish dynasty in Gaul—it contained 72 per cent. copper ; and A. Schertel reported a scaly mass with 63·31 per cent. of copper in a lead-refining furnace. At a red heat, C. T. Heycock and F. H. Neville found that copper readily dissolves in molten lead ; and, according to J. Percy, the alloy obtained by melting the two metals above the m.p. of copper, when well stirred and quickly cooled in an ingot mould, gives an alloy which appears homogeneous ; but if the alloy be kept for a considerable time beyond the m.p. of lead, liquation occurs, lead containing a little copper trickles away, and a more or less spongy mass of copper remains. C. J. B. Karsten found an alloy of lead with 25 per cent. copper gave lead containing from 2·0 to 2·8 per cent. copper, and copper with about 25 per cent. of lead. W. H. Creutzfeldt examined cathode deposits of the alloy from soln. of mixed silver and lead salts.

If a molten mixture of the two metals be very slowly solidified—and F. Reich found that when cupriferous lead is melted, or rather partly melted, the scum, *Abzug*, swimming on the surface contains most of the copper—the proportion of copper retained by the lead increases rapidly as the temp. rises. R. J. Nevil patented a modification of the process for liquating lead-copper alloys to recover the silver. The liquation and limited miscibility of copper-lead alloys has also been discussed by A. Streng, G. Mardus, and W. Baker. As emphasized by E. J. Ball and others, the tendency of the alloy to separate into two different liquids renders it impossible to make uniform alloys with all proportions of copper. W. Hampe said that by rapid cooling he was able to make homogeneous alloys with one per cent. of lead. H. Goldschmidt used the principle of the thermite process for making lead-copper alloys from mixtures of cupric oxide and lead ; and E. Dannert obtained alloys from mixtures of copper, silica, and lead oxide. W. Spring described the preparation of the alloys by compressing an intimate mixture of the powdered elements.

The f.p. curve of these alloys has been investigated by C. T. Heycock and

F. H. Neville, K. Friedrich and A. Leroux, W. C. Roberts-Austen, M. Merle, R. H. Thurston, C. R. A. Wright, H. Gautier, K. Honda and T. Ishigaki, and F. Giolitti and M. Marantonio. The results are summarized in Fig. 33. There is no evidence of the formation of definite compounds. There is a eutectic at 949°, according to C. T. Heycock and F. H. Neville, or 969°, according to F. Giolitti and M. Marantonio, with 60 per cent. of lead ; and conjugate liquids are formed ; there is a sat. soln. of lead in copper and a sat. soln. of copper in lead ; when between 17 and 65 grm. atoms of lead are present per 100 of alloy, the f.p. remains constant at 969° (or 949°). F. C. Calvert and R. Johnson measured the heat conductivity of the copper-lead alloys ; and G. Wertheim, the elastic constants. N. A. Puschin observed no evidence of the formation of a definite compound in his study of the e.m.f. of the cell Pb | N-Pb(NO_3)$_2$ | PbCu$_n$, when n ranged from 15 to 95 at. per cent. G. Tammann and W. Wiederholt studied the cathodic polarization of these alloys.
FIG. 33.—Freezing-point Curves of Lead-Copper Alloys.

A. Guettier made some observations on the effect of a small proportion of lead on the mechanical properties of copper ; and A. Matthiessen and M. Holzmann, on the electrical conductivity of these alloys. G. Lunge and E. Schmid made observations on the oxidizability of these alloys ; and J. Percy said that when the alloy is exposed for a long time to atm. air, at ordinary temp., it becomes oxidized to a considerable depth. X. Rocques found that water and salt soln. act more strongly than on lead. L. Brault and A. B. Poggiale said that if the alloy be heated with conc. sulphuric acid, the copper can be completely dissolved while the lead is scarcely attacked ; and A. Bauer, that an alloy with one per cent. of copper is slowly attacked by sulphuric acid of sp. gr. 1·843, the attack is greater at 250°, and all is dissolved at 280°. G. Mardus discussed the electro-refining of copper-lead alloys with an electrolyte containing fluoborates. F. Mylius and O. Fromm discussed the separation of the metals from dil. soln. D. Coda added an alloy of copper and lead to molten zinciferous alloys in order to concentrate the zinc in a dross from which the zinc is separated by distillation. C. J. Reed patented an alloy with 85 per cent. of lead, 10 per cent. arsenic, and (1 to) 5 per cent. of copper as an anti-friction metal ; alloys of lead, copper, and antimony were discussed by E. J. Ball, H. Schack, W. Hampe, and J. L. Lassaigne ; and alloys of lead, copper, antimony, and arsenic by W. Gowland.

A. Levol [2] said that lead and *silver* can be melted together in all proportions, but the alloys are not homogeneous, since he found that there is a strong tendency to liquefaction as is evidenced by the use of these alloys in H. L. Pattinson's process for desilvering lead ; and the tendency of the silver to concentrate towards the centre of the cast ingots—*vide* 3. 22, 4. C. R. A. Wright, however, said that homogeneous alloys of the two elements can readily be prepared. J. Joly and J. H. J. Poole could not appreciably separate the constituents of the alloy by centrifuging. N. W. Fischer said that a lead-silver alloy is produced when lead is placed in a soln. of silver nitrate. The f.p. diagram, Fig. 34, gives no support to the view that these two elements form chemical compounds. The curves were investigated by G. I. Petrenko, C. T. Heycock and F. H. Neville, R. Kremann and F. Hofmeier, C. R. A. Wright, D. H. Andrews

FIG. 34.—Freezing-point Curves of the Lead-Silver Alloys.

and J. Johnston, H. W. B. Roozeboom, K. Honda and T. Ishigaki, E. Kordes, and K. Friedrich. The V-curves have a eutectic at 303·9° or 304° and 2·5 per cent. of silver. According to G. I. Petrenko, alloys with over 5 per cent. of lead are heterogeneous mixtures of a solid soln. with nearly 5 per cent. of silver, and lead. According to A. Levol, the alloy with Pb : Ag as 1 : 20 is white with a grey fracture; that with 1 : 12 is the colour of platinum with a fine-grained fracture; that with 1 : 10 is greyish-white with a grey fracture; and that with 1 : 4 is bluish-grey, ductile, and quickly attacked by air and hydrogen sulphide. W. C. Brögger described some crystals of an alloy with 27 per cent. of silver which he found in the bottom of a furnace. W. Campbell examined the microstructure of these alloys. A. Matthiessen gave for the sp. gr.:

Lead	.	0	32·4	49·0	65·8	79·4	88·5	95·5	98·0	100 per cent.
Sp. gr.		10·468	10·800	10·925	11·054	11·144	11·196	11·285	11·334	11·367

E. von Maey represented the sp. vol., v, of alloys with p per cent. of silver by $v=0·08791+0·0000760p$. W. C. Roberts-Austen, and G. Wertheim measured the elastic constants; P. Ludwik, the hardness; and W. C. Roberts-Austen, the rate of diffusion of silver in lead. H. Moissan and T. Watanabe heated an alloy with 46·24 per cent. of silver for $2\frac{1}{2}$ mins. in an electric furnace, and found the residue then contained 96·81 per cent. of silver. C. R. Groves and T. Turner also found that when heated in vacuo, the lead volatilizes faster than the silver. A. Matthiessen's values for the electrical conductivity are plotted in Fig. 35. The curve is very steep in the region where solid soln. are formed at between 97 and 100 per cent. of silver; the curve is nearly a straight line with alloys having less than 50 per cent. of silver. This is a characteristic of mechanical mixtures of two crystalline phases. N. A. Puschin found no evidence of chemical combination in his measurements of the e.m.f. of the cells $Pb \mid N\text{-}Pb(NO_3)_2 \mid PbAg_n$. A. P. Laurie, and H. le Chatelier made observations on the e.m.f. of

FIG. 35.—The Electrical Conductivity of Silver-Lead Alloys.

voltaic cells. R. Kremann and O. Benda found that in the electrolysis of lead-silver alloys, the lead accumulates at the anode, the silver at the cathode; and C. G. Fink and L. C. Pan, that lead-silver anodes resisted corrosion in the electrolysis of brine better than lead-mercury alloys. T. J. Seebeck measured the thermoelectric properties. A. Bauer found that when exposed to moist air and carbon dioxide, in the presence of dil. acetic acid, the lead forms a basic carbonate leaving the silver unattacked. F. Mylius and O. Fromm discussed the separation of the metal from dil. soln. K. Friedrich and A. Leroux, and H. Schack studied the ternary system Pb–Cu–Ag; G. Charpy, Pb–Cu–Sb; W. Guertler, Pb–Ag–Sb; and M. Goto, Pb–Bi–Ag.

C. Hatchett[3] prepared a pale yellow alloy of *gold*, with one-twelfth part of lead. He found it to be as brittle as glass; having a fine grained fracture; and sp. gr. 18·08. Even as little as $\frac{1}{1920}$th part of lead was found to reduce appreciably the ductility of gold. L. Nowack studied the effect of lead on gold. The f.p. curves were examined by C. T. Heycock and F. H. Neville, W. C. Roberts-Austen, R. Vogel, E. Kordes, and F. Rinne. The results by R. Vogel are plotted in Fig. 36. There are a eutectic at 215°, and breaks at 254° and 418°, making the f.p. curve consist of four branches. There are two definite compounds, gold hemiplumbide, Au_2Pb, and gold diplumbide, $AuPb_2$. At 211°, the diplumbide

FIG. 36.—Freezing-point Curves of the Lead-Gold Alloys.

undergoes a transformation. The diplumbide forms brittle, long, white, acicular crystals with rounded contours easily distinguished from those of the hemiplumbide. H. Weiss studied the speed of formation of the gold-lead compounds. The microstructure of these alloys was examined by R. Vogel, W. C. Roberts-Austen and F. Osmond, M. Merle, F. Rinne, J. Arnold and J. Jefferson, and T. Andrews. According to A. Matthiessen, the sp. gr. at 0° is :

Gold	.	0	8·7	16·0	19·2	23·9	32·3	48·9	65·4	79·2	100 per cent.
Sp. gr.		11·376	11·841	12·274	12·445	12·737	13·306	14·406	15·603	17·013	19·265

E. von Maey examined the sp. vol. of the alloys. W. C. Roberts-Austen, C. E. van Orstrand and F. P. Dewey, and S. Dushman and I. Langmuir discussed the rate of diffusion of gold in solid and molten lead (q.v.). W. C. Roberts-Austen and F. Osmond gave 6·57 kgrms. for the tensile strength of gold with 0·240 per cent. of lead, and an elongation of 4·9 per cent. on 76 mm. G. Wertheim measured the elastic constants, and A. Matthiessen, the electrical conductivity of these alloys. A. P. Laurie, and H. le Chatelier made observations on the e.m.f. of voltaic cells. E. Matthey examined the liquation of gold-lead alloys. According to A. Bauer, the lead alone oxidizes when the alloys are fused in air, and the lead can be completely removed from the alloys by acetic acid. G. Tammann, and R. Kremann and co-workers studied the electrode potential and the chemical properties of these alloys. F. Mylius and O. Fromm discussed the separation of the alloy from dil. soln. C. Hatchett examined some Au–Pb–Cu alloys ; and M. Goto, Au–Pb–Ag alloys.

§ 9. Alloys of Lead with the Metals of the Alkaline Earths, and of the Magnesium-Zinc Family

H. Caron[1] made an alloy of *calcium* and lead by treating molten calcium chloride with the lead-sodium alloy. H. Moissan found that calcium readily alloys with molten lead, although, as B. Setlik showed, there is a great loss of calcium. L. Donsky recommended working with an atm. as free as possible from oxygen. The union of calcium with molten lead is attended by the evolution of heat and light. L. Hackspill said that the best mode of preparing calcium-lead alloys is by electrolysis of molten calcium chloride, using a molten lead cathode. W. Moldenhauer and J. Andersen added some potassium chloride to the electrolyte, and used a graphite anode. F. M. Perkin and L. Pratt heated lead chloride with calcium, and L. Hackspill used the same process in a crucible lined with magnesia. J. N. Pring, and W. Kroll heated lead oxide with calcium carbide, and N. Tarugi also recommended reducing lead salts with calcium carbide at 400° ; and W. Kroll heated a salt of calcium with a lead-sodium alloy. K. Jellinek and co-workers obtained alloys of lead with the alkaline earth metals by fusing a mixture of the alkaline earth chloride and a sodium-lead alloy, and they studied the equilibrium relations in the electrolysis of the mixtures of the alkaline earth metals and sodium chloride : $M + 2NaCl \rightleftharpoons MCl_2 + 2Na$; and $Ba + CaCl_2 \rightleftharpoons BaCl_2 + Ca$ with lead electrodes. H. Moissan, and F. von Kügelgen made alloys by direct fusion of the constituent elements. E. Kordes studied the eutectic mixtures. The f.p. curves of the lead-calcium system were investigated by L. Donsky, and N. Baar.

The results are summarized in Fig. 37. There are maxima at 649° and 1105° corresponding respectively with the f.p. of **calcium triplumbide**, $CaPb_3$, and **calcium hemiplumbide**, Ca_2Pb : another less stable compound, **calcium plumbide**, $CaPb$, is formed at 950°. The eutectic point at 625° corresponds with 10 per cent. calcium, and that at 701°, with 58 per cent. of calcium. L. Hackspill claimed to have made **calcium hemitriplumbide**, Ca_2Pb_3, by heating a mixture of lead-calcium alloy with 21 per cent. of calcium and twice its weight of lead at 950°–1100° in vacuo for $1\frac{1}{2}$ hrs. The sp. gr. at 19° was 7·6, and the m.p. 775°. The individuality of this product has not been established. C. A. Kraus and H. F. Kurtz obtained indications of the formation of calcium hemitriplumbide, Ca_2Pb_3, in the reduction of lead salts by calcium amalgam.

FIG. 37.—Freezing-point Curves of the Lead-Calcium Alloys.

B. Setlick said that the alloys are crystalline and brittle; L. Hackspill found that they are harder than lead. L. Donsky, C. O. Thieme, A. Hart, and F. C. Frary and S. N. Temple also made observations on the hardness of these alloys. When remelted, the alloys are liable to lose some calcium. O. Ruff and H. Hartman studied the absorption of nitrogen by lead-calcium alloys. M. Wählert recommended alloys with 3 per cent. calcium as bearing metals. Alloys with less than 10 per cent. calcium can be preserved unchanged in a desiccator, but L. Donsky found that the others gradually break down into black powders in air. W. Moldenhauer and J. Andersen found the alloy with 82 per cent. of calcium acquires a black layer when kept a week under paraffin. H. Caron said the alloy with 17 per cent. of calcium does not decompose when strongly heated in a carbon crucible. L. Hackspill found that an alloy with 21 per cent. of calcium is not much altered when kept for 20 mins. in vacuo at 900°–1000° ; but if heated in air, a crust of calcium oxide and nitride is formed. E. A. Ashcroft found that moist air and water do not act so rapidly on the lead-calcium as on the lead-magnesium alloy. L. Hackspill said that cold water acts on the lead-calcium alloys slowly, while boiling water acts rapidly, forming calcium hydroxide and powdered lead. C. V. Burton said that carbon is dissolved by the alloy with one per cent. of calcium, and it can be separated, in the form of what was thought to be the diamond, by the action of steam at a red heat. G. Tammann studied the electrode potential and chemical properties of these alloys.

The alloys of lead and *strontium* have been examined only in a cursory manner. The Metallbank und Metallurgische Gesellschaft said that alloys with less than
FIG. 38.—Freezing-point Curve of Mixtures of Lead and Strontium.
FIG. 39.—Freezing-point Curve of Some Barium-Lead Alloys.

10 per cent. of strontium are softer than those of barium, but harder than those of calcium. E. Piwowarsky found that strontium is quite insoluble in solid lead, and the two elements form one compound, **strontium triplumbide**, Pb_3Sr, m.p. 676°, Fig. 38 ; the eutectic containing very little strontium melts at the same temp. as

lead. W. Kroll heated mixtures of lead oxide and barium or strontium carbide. J. Czochralsky and E. Rassow made alloys of *barium* and lead by fusing a mixture of the constituent elements; H. Goldschmidt made them from the oxides by the thermite process; and the Metallbank und Metallurgische Gesellschaft, by the electrolysis of fused barium chloride using a molten lead cathode. E. Kordes studied the eutectic mixtures. J. Czochralsky and E. Rassow obtained the portion of the system of f.p. curves indicated in Fig. 39; they also reported **barium triplumbide**, $BaPb_3$, to be formed, but no mixed crystals. W. Mathesius gave 250° for the m.p. of the triplumbide; and W. A. Cowan and co-workers found that the microstructure of alloys with 4·5-6 per cent. of barium shows rod-like crystals of the triplumbide to be present. Alloys with about 8 per cent. of barium decompose in air, forming a grey powder. Water decomposes the alloys at ordinary temp. Acid liquids and vapours attack them superficially. E. Scheurer found that filings of the alloy with 3 per cent. barium may inflame paper. The so-called *ulco-metal* is an alloy containing 98–99 per cent. of lead plus barium or calcium, and it was used during the Great War as a substitute for antimonial lead in making shrapnel balls. One of these alloys was described by R. T. Rolfe, and W. A. Cowan and co-workers, J. Czochralsky and co-workers, E. Heyn, and W. Mathesius. Alloys of lead, calcium, and barium or strontium were investigated by W. Cowan and co-workers, W. Mathesius, and L. Filipoff.

J. Parkinson [2] made alloys of *magnesium* and lead by melting together the constituent elements in an atm. of hydrogen. They were also made directly by E. A. Ashcroft, W. Guertler, G. Tammann, N. S. Kurnakoff and N. J. Stepanoff, and G. Grube. G. Massing obtained the alloys by compressing a mixture of the finely divided constituents; C. Winkler, by the action of magnesium on lead oxide; and E. A. Ashcroft, E. Beck, and the United Lead Co., by the electrolysis of fused magnesium chloride using a molten lead cathode. The f.p. curves were investigated by C. T. Heycock and F. H. Neville, A. von Vegesack, N. S. Kurnakoff and N. J. Stepanoff, E. Kordes, and G. Grube. The results of the last-named are summarized in Fig. 40. There are two eutectics, one at 459·2° or 460° and 67 at. per cent. of lead, and the other at 246·9° or 250° corresponding with 97 at. per cent. of lead. One compound, **magnesium hemiplumbide**, Mg_2Pb, is formed, provided the temp. does not exceed 750°. This compound freezes at 551·3°. It is brittle, and steel-blue in colour; the sp. gr. is 5·5416 and the sp. vol. 0·1805; the compound is stable in dry air, but in moist air it quickly forms a black powder from which a hydrate, $PbO.2MgO.3H_2O$, is produced. A. J. Berry said the compound probably dissociates into its constituents when melted. A. Sacklowsky found that the X-radiogram agrees with a face centered cubic lattice, and J. B. Friauf calculated the unit cubic cell has an edge 6·78 A., and contains four molecules. The positions of the atoms correspond with the calcium fluoride arrangement.

FIG. 40.—Freezing-point Curves of the Lead-Magnesium Alloys.

J. Parkinson said that the magnesium-lead alloys are crystalline, and brittle. According to P. Ludwik, magnesium hardens lead more than does bismuth, antimony, tin, cadmium, or silver. H. Hanemann and W. Stockmeyer also found that magnesium hardens and toughens lead more than does antimony; and D. Stenquist patented 0·01-0·1 per cent. of magnesium as a hardening agent for lead. I. P. Göbel also examined the hardness of these alloys. A. J. Berry found that at 680°, in vacuo, magnesium distils from these alloys carrying over only a trace of lead. N. J. Stepanoff's measurements of the electrical conductivity of these alloys are plotted in Fig. 41. The conductivity decreases rapidly with

increasing proportions of lead until about 5 per cent. of lead is present. At the conc. corresponding with the hemiplumbide, the electrical conductivity passes

through a minimum. The temp. coeff. of the conductivity also indicates the existence of the same compound. W. Jenge measured the e.m.f. of the alloys in N-$MgSO_4$ against silver in a sat. soln. of silver nitrate, with N-Na_2SO_4 as intermediate electrolyte. G. Tammann, and W. Jenge studied the electrode potential and chemical properties of these alloys; and R. Kremann and J. Gmachl-Pammer found evidence of Mg_2Pb in the electrochemical behaviour of these alloys. H. Hanemann and W. Stockmeyer said that alloys with less than 4 per cent. of magnesium are not attacked by air and water, and only slowly by acids. I. P. Göbel said that all alloys containing the free hemiplumbide corrode rapidly. G. Grube, and E. A. Ashcroft studied the oxidation of these
FIG. 41.—The Electrical Conductivity of Lead-Magnesium Alloys.

alloys by moist air. E. Beck found the nitride is formed when nitrogen is bubbled through the molten alloy with 46 per cent. magnesium. J. Parkinson, and G. Grube found that glass is attacked by the molten alloys. C. O. Thieme discussed the hardness of some Pb–Mg–Sb alloys.

J. F. Gmelin [3] stated that lead readily unites with *zinc*, thereby becoming harder, but its ductility is not impaired by any proportion of zinc. When the two elements are melted together, and the molten mixture is allowed to cool slowly, nearly complete separation occurs, the zinc solidifies first, forming the upper layer, which can be removed as a crust from the molten lead below. The f.p. curve has been studied by C. T. Heycock and F. H. Neville, P. T. Arnemann, R. Kremann and F. Hofmeier, B. E. Curry, P. Müller, G. Tammann, F. Novak, F. Mylius and

co-workers, A. V. Tidblom, P. Müller, I. P. Göbel, and W. Spring and L. Romanoff; the results are summarized in Fig. 42. There is no evidence of the formation of a definite compound. Mixtures containing from 0·5 to 97 per cent. of lead separate into two conjugate liquids. The m.p. of zinc falls as lead is introduced, becoming 418° with 0·5 per cent., and then remains constant until 96·6 per cent. is present. Further additions of lead cause the m.p. to fall to 317°, which is the eutectic with 98·8 per cent. of lead. The m.p. then rises to 327° that of lead alone. Alloys with 0–98·8 per cent. of lead have zinc and eutectic, and those with more
FIG. 42.—Freezing-point Curves of the Lead-Zinc Alloys.

lead show lead and eutectic. All these alloys are soft enough to be cut with a knife. The solubility of zinc in lead and of lead in zinc was worked out by W. Spring and L. Romanoff. The percentage amounts of zinc in the upper and lower layers at different temp. are :

	334°	419°	450°	475°	514°	584°	650°	740°	800°	900°
Upper . .	—	98·5	—	98·0	97·0	95·0	93·0	90·0	86·0	74·5
Lower . .	1·2	—	8·0	9·0	11·0	14·0	17·0	21·0	25·0	41·0

The two solubility curves meet at about 940°—the critical soln. temp.—so that above that temp. the two metals are mutually soluble in all proportions. W. Heike gave for the percentage solubility of zinc in lead, 2·20 at 425°, 3·30 at 500°, and 7·38 at 600°. According to J. Fournet, when an alloy of zinc and lead is heated white-hot in a charcoal crucible, the zinc all distils away from the lead. If silver is present in the system it divides itself between the two layers, but by far the

larger proportion accumulates with the lighter zinc layer, for silver at about 540° is 300 times more soluble in zinc than in lead. This subject was investigated by C. R. A. Wright and C. Thompson, C. R. A. Wright, F. Reich, D. Mazzotto, B. Bogitch, W. Alexéef, A. Guettier, and G. N. Potdar. Segregation phenomena were studied by O. Bauer and H. Arndt. The fact is at the base of A. Parkes' process for the desilveration of lead, first indicated by C. J. B. Karsten—*vide* **3. 22, 4.** W. Spring prepared the alloy by compressing an intimate mixture of the powdered elements. The structure of the alloys was examined by W. Campbell, H. Behrens, F. A. Schulze, B. E. Curry, P. T. Arnemann, and S. Konno ; and the liquation of the molten alloys by a centrifuge, by F. Hoffmann ; the sp. gr. and sp. vol., by E. von Maey—between 0° and 17°, the sp. vol. is $0 \cdot 083-0 \cdot 000520p$, where p denotes the percentage amount of zinc. I. P. Göbel, P. Ludwik, M. Levi-Malvano and O. ·Ceccarelli, and A. Guettier investigated the hardness of these alloys. G. Wertheim, R. Hoyt, P. T. Arnemann, and E. H. Schulz investigated the elastic properties ; J. Tayler, the heat of formation ; E. Matthey, the liquation of Pb–Zn–Au, Pb–Zn–Au–Ag, and Pb–Zn–Au–Ag–Cu alloys ; A. P. Laurie, N. Hesehus and N. Georgiewsky, and G. Tammann and W. Wiederholt, the electrochemical behaviour of these alloys ; S. Konno, P. Müller, and H. Rainy and R. D. Clackson, the electrical conductivity ; P. Fuchs, R. Kremann and J. Gmachl-Pammer, the electrochemical behaviour ; and W. Rollmann, and A. V. Tidblom, the thermoelectric properties. The action of acids was studied by M. Centnerswer, P. T. Arnemann, F. Novak, L. Pitkin, and F. Osmond and J. Werth. Applications of the alloys were discussed by G. T. Key, J. and T. Hall, R. Hoyt, J. S. Rae, C. Mark, Lohmann Co., G. Tammann and O. Dahl. C. R. A. Wright and C. Thompson studied the ternary system Pb–Zn–Sb. The alloys of zinc, lead, and copper—the so-called lead-brass—have been discussed by A. Arche and C. Hassack, H. Behrens, W. Flight, L. Guillet, W. N. Hartley, J. Percy, J. J. Rein, and V. A. Skinder ; and alloys of zinc, lead, copper, and antimony, by M. Beuling. The ternary system Cu–Zn–Pb was investigated by H. Niclassen, and N. Parravano and co-workers ; Ag–Zn–Pb, by C. R. A. Wright and C. Thompson, W. D. Bancroft, G. K. Williams, and R. Kremann and T. Hofmeier. G. N. Potdar studied the partition of silver between zinc and lead. R. Kremann and R. Knabl measured the electrode potentials of the Zn–Pb–Sb ternary alloys. The ternary diagram is broken up into five systems ; Pb–Zn–Ag_2Zn_5 ; Pb–Ag_2Zn_5–Ag_2Zn_3 ; Pb–Ag_2Zn_3–AgZn ; Pb–AgZn–Ag_3Zn_2 ; and Pb–Ag_3Zn_2–Ag. The lead field is a very small one. Lead does not form solid soln. in any part of the system. In the zinc process for desilverizing lead, the quantity of zinc added is so small that the region of immiscible liquids is not usually entered. The removal of zinc also removes silver hemipentazincide. G. Tammann and P. Schafmeister measured the partition of copper, silver, gold, cadmium, tin, nickel, and antimony between zinc and lead ; and W. A. Naish, that of silver between zinc and lead. F. Doeblin, and G. Tammann and O. Dahl investigated the ternary system Pb–Zn–Sb. W. Heike studied the Pb–Zn–Ag and the Pb–Zn–Ag–Cu alloys.

The alloys of *cadmium* and lead are in marked contrast with those of zinc and lead, and are not what would be anticipated in view of the close analogy between zinc and cadmium. The alloys were examined by B. Wood, and C. R. A. Wright.[4] G. Tammann and W. Wiederholt measured the diffusion of cadmium in lead. The f.p. diagram was investigated by A. W. Kapp, C. T. Heycock and F. H. Neville, E. Jänecke, M. Wählert, F. Mylius and R. Funk, G. P. Luckey, I. P. Göbel, C. W. Hill, G. Tammann and W. Wiederholt, C. di Capua, W. C. Barlow, A. Matthiessen, K. Honda and T. Ishigaki, and A. Stoffel, and the results are summarized in Fig. 43. No compounds were observed, and mixed crystals within the limits indicated in the diagram are formed. A. M. Portevin studied the microstructure of the eutectic. A. Matthiessen found the sp. gr. of the alloys to be :

Lead .	0	22·8	31·8	48·2	65·0	78·8	88·2	91·7	100·0 per cent.
Sp. gr.	8·655	9·160	9·353	·9·755	10·246	10·656	10·950	11·044	11·376

J. Göbel, and F. Sauerwald also measured the sp. gr. E. von Maey represented the sp. vol., v, of alloys of lead with p per cent. of cadmium by $v=0.08791 +0.0002673p$. A. Magnus and M. Mannheimer observed a rise of temp. occurs when molten lead and cadmium are mixed. I. P. Göbel, F. L. Brady, and P. Ludwik measured the hardness of these alloys. A. Matthiessen investigated the thermal expansion; H. le Chatelier, R. Kremann and A. Langbauer, N. W. Taylor, and A. P. Laurie, the electromotive force of cells; A. Battelli, the thermoelectric properties; D. Mazzotti, the thermal phenomena accompanying the formation of these alloys. The electrical conductivity determined by A. Matthiessen, W. Guertler, G. Tammann and K. Dahl, A. Schulze, and A. Matthiessen and C. Vogt, Fig. 44, is a linear function of the conc. There are no critical points on the curve
FIG. 43.—Freezing-point Curves of the Lead-Cadmium Alloys.
FIG. 44.—Electrical Conductivity of the Lead-Cadmium Alloys.

in the region between 95 and 100 per cent. of lead in which solid soln. are known to be formed. B. Beckman examined the effect of press. on the conductivity. P. Müller, M. Herschkowitsch, and P. Fuchs measured the e.m.f. of cadmium-lead alloys in N-$CdSO_4$ against cadmium. R. Kremann and co-workers found that on electrolysis, the lead accumulates at the anode, the cadmium at the cathode. F. Mylius and O. Fromm examined the precipitation of the metal from dil. soln. L. Pitkin, and the Accumulatoren-Fabrik examined the effects of acids on the alloys. Some uses of the alloys were examined by W. Kaiser, G. P. Luckey, C. W. Hill, etc. E. Becquerel measured the thermoelectric force of lead-, zinc-antimony alloys. C. G. Fink and L. C. Pan found that in the electrolysis of brine, lead-cadmium anodes do not resist corrosion so well as lead-silver alloys. W. Stockmeyer and H. Hane-
FIG. 45. — Freezing-point Curves of the Ternary System: Cd–Pb–Bi.

mann made lead, magnesium, potassium, and lead, magnesium, sodium alloys; W. Mathesius, lead, cadmium, and calcium alloys; the Metallbank und Metallurgische Gesellschaft made lead and magnesium alloys with the metals of the alkaline earths; and M. Cook studied the system Pb–Zn–Cd; and E. Becquerel, Pb–Zn–Cd–Sb. W. E. Barlow investigated the ternary system Cd–Pb–Bi; and the results are summarized in Fig. 45. There is a ternary eutectic at 91·5°, and no compounds are formed. Observations on these alloys were also made by B. Wood, C. von Hauer, C. P. Steinmetz, C. W. Hill, F. Novak, J. Tomes, C. S. Tomes, A. Kirby, T. B. Hitchcock, T. Fletcher, A. Witzel, C. R. A. Wright, and R. Kremann and A. Langsbauer; and C. R. A. Wright, the Cd–Pb–Zn alloys; C. T. Heycock and F. H. Neville examined the ternary alloys Pb–Cd–Ag, and Pb–Cd–Au.

The alloys of lead and *mercury* are readily obtained by triturating lead filings with mercury, or by agitating molten lead with mercury. They were examined by S. Lucas,[5] W. Kettembeil, J. H. Croockewit, etc. According to J. F. Daniell, a bar of lead immersed for 10 days in cold mercury, though it remains ductile, is covered at the surface with soft feathery crystals. J. Henry found that when a bar of lead is bent in the form of a syphon, and placed with one end in the mercury,

in due course the mercury will flow out at the other and lower end. With a bar made of non-hammered lead, the first drop of mercury appeared in 24 hrs., and when made of hammered lead, in 10 days. J. Nicklès found lead is more permeable than silver and less so than zinc. E. N. Horsford measured the rate of ascent of mercury in rods of lead; W. J. Humphreys, the diffusion of lead, and of lead-cadmium, and lead-tin alloys in mercury; and A. Gouy, the solubility of lead in mercury. J. Regnauld found the union of mercury with lead is accompanied by an absorption of heat, and D. Mazzotto found the maximum absorption occurs with 1 vol. of lead and 2 vols. of mercury. J. Schumann obtained the amalgam by stirring molten lead into heated mercury; R. Lacau, by pouring mercury into molten lead on the point of freezing, and afterwards heating the product a little to make it homogeneous. J. P. Joule dissolved the lead in mercury, forced out the excess by press., and obtained an amalgam corresponding with Pb_2Hg. R. Böttger obtained lead amalgam by immersing sodium amalgam in a soln. of lead acetate; A. C. Becquerel, by the action of mercurous chloride and water on lead-foil; J. Schumann, by the electrolysis of a soln. of lead nitrate with a mercury cathode; and G. Vortmann, by the electrolysis of a mixed soln. of lead and mercuric acetates or tartrates.

The f.p. curves of the binary system have been investigated by H. Fay and E. North, P. T. Bachmetjeff and J. Wsharoff, K. Bornemann, G. Tammann, D. Mazzotto, G. W. Gressman, N. A. Puschin, E. Jänecke, and K. Honda and T. Ishigaki, and the results are summarized in Fig. 46. As empha-sized by G. McP. Smith, and N. A. Puschin, there is no sign of the formation of a chemical compound. There are two kinds of solid soln. which E. Jänecke designates α-PbHg and β-PbHg, or α-amalgam and β-amalgam.

FIG. 46.—Freezing-point Curves of the Lead-Mercury Alloys.

Chemical compounds have been reported without satisfactory evidence of their individuality; thus, A. Bauer, and J. P. Joule reported *lead hemitrimercuride*, Pb_2Hg_3, a white crystalline mass of sp. gr. 12·49 at 17°; J. H. Croockewit, and J. Schumann, *lead mercuride*, $PbHg$; J. P. Joule, and H. Fay and E. North, *lead hemimercuride*, Pb_2Hg, in crystals isomorphous with lead, and of sp. gr. 12·11; and L. Schüz, *lead tritamercuride*, Pb_3Hg.

According to H. Fay and E. North, the amalgams of lead become more and more like a mush as the proportion of lead increases, and when the proportion has reached 65 per cent., the amalgam is quite solid. A. Battelli said that when the proportion of Hg : Pb is greater than 12 : 1, the amalgam is liquid, and solid when the proportion is less than 2 : 1. C. von Simson found that the X-radiograms corresponded with the same face-centred lattice as that of lead itself. J. Schumann, and N. A. Puschin examined the microstructure of these amalgams. H. Fay and E. North found the crystals to be like those of lead; A. C. Becquerel said that the crystals belong to the cubic system. A. Matthiessen gave for the sp. gr. of the amalgams Hg : Pb=2 : 1, 12·815 at 15·5°; 1 : 1, 12·484 at 15·7°; and 1 : 2, 11·979 at 15·9°. Observations were also made by A. T. Kupffer, J. P. Joule, C. Cattaneo, and T. W. Richards and R. N. Garrod-Thomas. E. von Maey represented the sp. vol., v, of amalgams with p per cent. of lead by $v=0·07368+0·0001422p$. G. Tammann and Q. A. Mansuri, and J. Göbel measured the hardness of these alloys. W. C. Roberts-Austen, and H. Feninger investigated the diffusion of mercury and lead. R. Lacau, and C. O. Thieme reported that lead is hardened by association with 2–5 per cent. of mercury. N. A. Puschin also noted the increased hardness imparted to lead by mercury, but the metal becomes quite brittle as the proportion of mercury approaches 20 per cent. L. Schüz found the amalgams with Hg : Pb between 1 : 1 and 2 : 7 are quite brittle. G. Meyer, and F. Schmidt
measured the surface tension of dil. lead amalgams ; and E. von Schweidler found the viscosity, at different temp., of amalgams with 1 per cent. of lead ; H. Feninger also measured the viscosity.   O. Bauer and H. Arndt studied the liquation of these alloys.   N. S. Kurnakoff and S. F. Schemtschuschny measured the press. required to make the amalgam flow.   C. Cattaneo measured the thermal expansion ; W. Ramsay measured the effect of lead on the vap. press. of mercury, and showed the results agree with the assumption that the lead is present in the amalgams in the at. state.   J. H. Hildebrand and co-workers gave for the vap. press., p, of lead amalgams at $324°$: $\log (p/p_0) = \log N + 0.252/(0.31 + 0.31n)^2$, where n denotes the number of mols of mercury per mol of lead ; N, the molar fraction of mercury ; and p_0, the vap. press. of mercury at $324°$.   L. Schüz gave 0.03458 for the sp. ht. of the 1 : 1 amalgam, and H. V. Regnault, 0.03827 between $20°$ and $100°$; L. Schüz found for the Hg : Pb=1 : 2 amalgam, 0.3348 ; for the 10 : 11, 0.03372 ; and for 2 : 7, 0.03050.   G. Tammann and E. Ohler measured the at. heat of soln. of lead in mercury, and found -1658 cals. at $14°$, and -2172 at $97°$.   The heat of soln. is the same for a gold amalgam presumably because the gold mercurides are dissociated in soln.   R. H. Gerke obtained -134 cals. for the molar free energy of lead in its mercuride.   G. Tammann and W. Jander measured the vap. press. curves of lead amalgams.   The electrical conductivity or electrical resistance of these amalgams was measured by H. Feninger, A. Lohr, A. Matthiessen and C. Vogt, G. G. Gerosa, E. von Schweidler, etc.   According to C. L. Weber, the sp. conductivities of amalgams with p parts of lead per 1000 parts of mercury, referred to the conductivity of mercury at the same temp. $15.9°$–$18°$, are :

p	0.302	1.214	2.700	6.946	10.197	13.730	17.290
Cond.	1.0020	1.0079	1.0171	1.0406	1.0568	1.0724	1.0773

The conductivity is increased by raising the temp. ; thus, with an amalgam having $p=6.95$, the conductivity at $16.8°$ was 1.0405, and at $80°$, 1.0424 ; when $p=17.29$, the conductivity at $26°$ was 1.0876, and at $83.2°$, 1.0924.   G. W. Gressman made observations at temp. down to $-50°$.   The effect of temp. on the conductivity was also examined by A. Larsen, C. Michaelis, R. Sabine, A. Battelli, and G. Vicentini and C. Cattaneo.   N. A. Puschin measured the e.m.f. of the cells, Pb | N-Pb(NO$_3$)$_2$ | HgPb$_n$, and found no evidence of chemical combination.   Observations on the electrode potentials of lead amalgams were made by S. Lindeck, G. Gore, J. F. Spencer, F. C. Henrici, V. Rothmund, G. Meyer, J. Roszkowsky, F. J. Mellencamp, F. Haber, J. H. Hildebrand, T. W. Richards and R. N. Garrod-Thomas, C. Hockin and H. A. Taylor, A. Oberbeck and J. Edler, etc.   R. Kremann and A. Kapaun found that on electrolysis of the lead amalgams, the lead accumulates about the cathode.   The thermoelectric properties were examined by C. L. Weber.   A. Coehn and A. Lotz found lead amalgam electropositive towards glass.

According to E. de Souza, the lead amalgams retain their mercury at $360°$, but not at $440°$; and by heating the amalgams in a bath of boiling sulphur, the residue had the composition Hg : Pb=1 : 8.   V. Merz and W. Weith found that after 7 hrs. in a bath of boiling sulphur only a trace of mercury was retained, and none after 12 hrs.' heating.   According to M. N. Bannerjee, mercury cannot be completely separated from lead amalgam by distillation in vacuo, but if the amalgam be repeatedly rubbed with garlic juice, lead sulphide is formed, and in this way, mercury can be purified from lead.   The amalgams are stable in dry air, but in moist air, as P. A. von Bonsdorff, S. Lucas, and G. Vortmann showed, a black powder is formed.   G. S. Sérullas found that potassium amalgam and water separate lead from the liquid amalgam.   When lead amalgam is shaken with a violet soln. of iodine, H. Gautier and G. Charpy found that mercurous iodide is formed, and with a brown soln. of iodine, mercuric iodide.   This reaction was also examined by E. Beckmann and A. Stock.   M. G. Mellon studied the displacement

of lead by copper when lead amalgam is placed in a soln. of copper nitrate ; and K. Someya, the reducing action of the amalgam on titanic sulphate, uranyl sulphate, molybdic acid, and tungstic acid. A. S. Russell and D. C. Evans studied the reducing efficiency of lead amalgam on soln. of ferric sulphate, potassium permanganate, and uranyl sulphate in dil. sulphuric acid, and interpreted the results in terms of overvoltages. J. L. Jordan prepared ternary alloys of lead, mercury, and antimony ; and H. Davy, I. P. Göbel, F. Orioli, and J. W. Döbereiner, lead, mercury, and bismuth. E. Englisch measured the electrical conductivity of alloys of lead, bismuth, and mercury. I. P. Göbel examined the lead, mercury, and sodium alloys ; and W. D. Bancroft, the zinc, lead, and mercury alloys. C. Hockin and H. A. Taylor measured the e.m.f. of the cell Pb | dil.H_2SO_4 | PbZnHg$_n$. R. B. Boulton patented a cadmium, lead, and mercury alloy ; ·E. Jänecke studied the ternary system Pb–Hg–Cd in some detail. There were six phases—lead, cadmium, and four sets of solid soln.: α-HgPb, β-HgPb, α-HgCd, and β-HgCd. The results are summarized in Fig. 47. C. Hockin and H. A. Taylor studied the ternary alloys Pb–Hg–Cu, and Pb–Hg–Zn. R. Kremann and co-workers studied the electrical properties of the Pb–Cd–Hg alloys. G. Tammann and W. Jander measured the vap. press. curves of lead-silver, and lead-gold amalgams.
FIG. 47. — Freezing - point Curves of the Ternary System : Pb–Hg–Cd.

§ 10. Alloys of Lead with Aluminium, Indium, Thallium, and Tin

H. St. C. Deville [1] said that lead and *aluminium* have so small a tendency to form alloys that any small piece of lead which may have dropped into the metal may be recovered intact at the bottom of an ingot of the aluminium. A. J. Rogers made an alloy by the electrolysis of molten cryolite and sodium aluminium tetrachloride with a lead cathode; and C. Tissier, by reducing lead oxide with aluminium —the reaction proceeds with explosive violence. These products are not alloys in the usual sense of the term, for if the two metals be melted together, or lead added to molten aluminium, alloys may exist at certain temp., but on cooling, the aluminium separates, and chilling first, floats on the surface of the molten lead. Similar observations were made by C. R. A. Wright, C. H. Hirzel, W. Campbell and J. A. Mathews, H. Schirmeister, etc. S. Mierzinsky said that this property would render it possible to use aluminium in place of zinc for desilverizing bullion, provided the cost was not too great. According to H. Pécheux, homogeneous alloys with 2-7 per cent. of lead can be obtained if they are rapidly chilled, but if more than 10 per cent. of lead be present, three layers are formed—the bottom layer consisting of lead, the top layer of aluminium, and a middle layer with 90-97 per cent. aluminium. J. W. Richards said that by cooling an ingot of the alloy slowly, he observed 94·49 per cent. lead in the lower part of the ingot, and 9·78 per cent. in the upper part. C. R. A. Wright found only 0·07 per cent. aluminium in the lower layer and 1·92 per cent. of lead in the upper layer. C. T. Heycock and F. H. Neville observed no lowering of the m.p. of aluminium by lead. According to A. G. C. Gwyer, the two metals are immiscible, and the cooling curves give two fixed points corresponding respectively with the m.p. of aluminium and of lead, Fig. 48. The reports of the presence of aluminium in the lead layer and of lead in the aluminium layer are due to the formation of a kind of emulsion, or to the mechanical entanglement of the one metal in the other. The dotted lines in the diagram are intended to indicate that above the m.p. of aluminium the two metals become mutually soluble in one another, and this the more the higher the temp. The presence of antimony is said to make the lead dissolve more aluminium, and alloys of lead, aluminium, and antimony have been patented by I. H. Johannes, C. B. Miller, and T. MacKellar. W. Campbell and co-workers studied the microstructure of these alloys. According to H. Pécheux, the colour of alloys with 2-7 per cent. of lead is very little different from that of aluminium; the sp. gr. of the alloy with 2 per cent. lead is 2·600; with 4 per cent., 2·671; with 5 per cent., 2·674; with 6 per cent., 2·691; with 7 per cent., 2·745; and with 8 per cent., 2·765. P. Ludwik measured the hardness of these alloys, and it appears to be less than that of aluminium. H. Schirmeister found the tensile strength of aluminium falls from 10·5 kgrms. per sq. mm. to 10·0 kgrms. per sq. mm. when 4 per cent. of lead

Fig. 48.—Freezing-point Curves of Lead-Aluminium Alloys.

is present. H. Pécheux measured the thermoelectric force of the alloy against copper, and found at 100° with lead alone 211·96 microvolts; with 94 per cent. aluminium, 113·55 microvolts, and with aluminium alone, 162·75 microvolts. H. Schirmeister said that alloys with 4 per cent. of lead are stable. According to H. Pécheux, each alloy is merely a mol. juxtaposition of the two metals, for on melting and drawing into rods of much smaller diameter the composition is altered, the alloy becoming richer in lead; thus, from the three alloys containing respectively 93, 95, and 98 per cent. of aluminium, three new ones were obtained containing 92, 94, and 96 per cent. of aluminium. The alloys are not acted on by moist air; hydrochloric acid dissolves the aluminium at 13°; conc. sulphuric acid dissolves both metals, liberating hydrogen at 13° and sulphur dioxide on heating; conc. nitric acid has very little action at the ordinary temp., but an energetic one on heating; the dil. acid has little or no action; conc. potassium hydroxide or aqua regia dissolves them readily in the cold; hydrogen sulphide blackens the alloys containing 92-93 per cent. of aluminium, and distilled water is without action even at 100°. The United Lead Co., and H. Hanemann and W. Stockmeyer respectively patented alloys of lead with calcium, and with magnesium. C. R. A. Wright, and W. D. Bancroft examined the ternary alloys Ag–Al–Pb; C. R. A. Wright, Al–Pb–Sb and Al–Pb–Bi alloys; and C. R. A. Wright, T. A. Bayliss, and B. G. Clark, and C. A. J. H. and H. E. R. Schroeder, Al–Zn–Pb alloys. G. Tammann and P. Schafmeister measured the partition coeff. of copper, silver, gold, magnesium, tin, and antimony between aluminium and lead.

Lead and *indium* form an ismorphous mixture in all proportions and the solid soln. crystallize in the cubic system. J. L. Haughton and G. W. Ford [2] showed that the two constituents do not crystallize in the same habit, but that the tetragonal lattice of indium differs from the face-centred cube of lead only by an elongation of 6 per cent. in the direction of one of the axes. N. S. Kurnakoff and N. A. Puschin found that the addition of 10 at. per cent. of lead to indium has very little effect on the m.p. of the latter, Fig. 49, but further additions give almost a straight line
FIG. 49.—Freezing-point Curve of Mixtures of Lead and Indium.
FIG. 50.—The Pressure required to produce a Flow of the Lead-Indium Alloys.

in the direction of the m.p. of lead. The press. necessary to cause these alloys to flow was measured by N. S. Kurnakoff and S. F. Schemtschuschny, and the results are shown in Fig. 50. They also measured the electrical conductivity, Fig. 51, and the temp. coeff. of alloys which form a continuous series of solid soln. G. Borelius also measured the electrical conductivity of the solid lead-indium alloys; and J. A. M. van Liempt, the X-radiograms.

The alloys of *thallium* and lead were examined by L. Rolla,[3] D. Mazzotto, L. Guillet, N. S. Kurnakoff and N. A. Puschin, W. Crookes, E. Carstanjen, and K. Lewkonja. The f.p. curve, Fig. 52, has a transition point at 309° or 309·5° corresponding with 5-5·5 at. per cent. of lead; in this region solid soln. are formed containing 0-5·5 at. per cent. of lead, and they crystallize in the same form as thallium. The f.p. curve then rises to a maximum at 374° (K. Lewkonja), or 380° (N. S. Kurnakoff and N. A. Puschin), and then falls to 327·7°, the m.p. of lead. The solid phase here deposited consists of solid soln. with 25-100 at. per cent. of lead, and crystallizes in octahedra belonging to the cubic system. P. Fuchs said that solid soln. are formed only beyond the limit 73 at. per cent. of thallium. The transformation temp. of the sat. solid soln. is 144·5°. The at.

ratio of lead to thallium corresponding with the maximum temp. varies from 1 : 1·67 to 1 : 1·83 for different preparations of lead and thallium, and this is taken by N. S. Kurnakoff and N. A. Puschin to indicate the existence of a solid indefinite compound. H. Endo also studied this diagram. K. Lewkonja interprets
FIG. 51.—The Electrical Conductivity of Lead-Indium Alloys.
FIG. 52.—Freezing-point Curves of Lead-Thallium Alloys.

the maximum to be the f.p. of **thallium hemiplumbide,** Tl_2Pb. The existence of this compound is not definitely established. L. Rolla showed that the curves of the sp. vol., hardness, electrical conductivity, and thermoelectric power afford no evidence of a compound. C. di Capua measured the hardness of these alloys. The alloys are very soft and easily oxidized. He found that with as little as 0·5 per cent. of lead, the transition point of thallium is no longer appreciable. G. D. Roos gave 7·6 cals. per gram for the heat of formation. C. T. Heycock and F. H. Neville measured the lowering of the f.p. of lead by thallium ; and A. W. Smith, the thermal conductivity. N. S. Kurnakoff and co-worker's measurements of the resistance offered by these alloys to flow, Fig. 53, and of the electrical conductivity, Fig. 54, and of the effect of temp. on the conductivity show singular
FIG. 53.—The Pressure of Flow of the Thallium-Lead Alloys.
FIG. 54.—Electrical Conductivity of the Thallium-Lead Alloys.

points where the lead and thallium form isomorphous mixtures. The addition of lead to thallium causes a decrease in the electrical conductivity and in the temp. coeff. of the resistance ; this decrease is followed by an increase which extends to the conc. at which the soln. is sat. with lead. The straight line portion of the curve between 5 and 25 per cent. of lead indicates where the alloys are mechanical mixtures of two crystalline phases. W. Guertler and A. Schulze found no evidence of a compound in their study of the electrical conductivity of these alloys. G. Tammann and W. Wiederholt, W. Jenge, E. Bekier, and R. Kremann and A. Lobinger studied the electrode potential and chemical behaviour of these alloys ; and H. Endo, the magnetic susceptibility. R. Kremann and A. Lobinger found no evidence of the formation of a compound, but rather of solid soln., in their study of the electrochemical behaviour of these alloys. C. C. Fink and C. H. Eldridge studied the corrosive action of acid soln. of cupric sulphate. E. Carstanjen studied the Pb–Tl–Bi alloys ; and C. di Capua, the Pb–Tl–Cd alloys.

Lead and *tin* can be alloyed in all proportions, and are easily made by fusing the

two metals together in the desired proportions. The alloys were made and used by the Romans. They were mentioned in the first century of our era by Pliny in his *Historia naturalis* (**34**. 17, 48) ; and in the second century, G. Galen, in his *De antiodotis epitomis* (**1**. 175), drew attention to the danger attending the use of tin adulterated with lead. The early alloys were discussed by R. Weber.[4] The tin-lead alloys were examined by J. L. Proust, L. N. Vauquelin, A. Gummi, C. H. Pfaff, J. W. Richards, D. Mazzotto, G. Nannes, J. Pohl, F. Rudberg, A. Matthiessen, K. Honda, S. Konno, L. Peetz, R. C. Besley, D. Silow, R. H. Thurston, P. Bolley, J. H. Croockewit, W. Richter, A. P. Laurie, C. R. A. Wright, C. Pack, M. L. Lissberger, H. Stegmann, etc. C. H. Proctor, and W. Blum and H. E. Haring made the alloy by electrodeposition from fluoborate soln. ; and W. Spring, by strongly compressing an intimate mixture of the powdered elements ; the two solids form an alloy in a few hours at 150°–200°. The alloying of a mixture of the powdered metals by press. was discussed by W. Hallock, and W. Rosenhain and P. A. Tucker. When lead stannate is reduced by carbon (R. C. Besley), or when tin is heated with lead oxide, with stannous chloride, or with an alkali plumbate (L. Peetz), the alloy is formed. S. Bodforss and P. Frölich, and M. Kutscheroff prepared a **colloidal solution** of the tin-lead alloy. The f.p. curves have been studied by E. Wiedemann, H. Gautier, R. Gnehm, C. T. Heycock and F. H. Neville, F. Rudberg, E. S. Shepherd, F. C. Weld, B. Wiesengrund, P. N. Degens, K. L. Meissner, W. Guertler, A. Stoffel, W. C. Roberts-Austen, A. W. Kapp, L. Guillet, D. Mazzotto, C. R. A. Wright and co-workers, W. Spring and L. Romanoff, A. P. Laurie, A. von Vegesack, F. Guthrie, M. Plüss, M. Wählert, C. P. Steinmetz, E. Heyn and O. Bauer, K. Bornemann, L. Losana, J. Göbel, N. S. Kurnakoff, N. Parravano and co-workers, P. Ludwik, M. Dullo, P. Müller, K. Heine, A. Pleischl, K. Honda and T. Ishigaki, H. Stegmann, L. Sterner-Rainer, H. von Jüptner, D. Silow, J. Alexander, W. Rosenhain and P. A. Tucker, etc. The results are summarized in Fig. 55. There is no evidence of the formation of a definite compound, but P. N. Degens observed a transformation at 146° with all alloys containing between 0 and 88 at. per cent. of lead ; the transformation is attended by the appearance of a constituent distributed through the lead, and it is suggested that a compound is formed at this temp. from the tin and lead in the solid state. W. Rosenhain and P. A. Tucker place the temp. at which heat is evolved with alloys containing 18–63 per cent. of tin at 149°, and rather less with alloys containing 8–18 per cent. of tin. The transformation is attributed to the passage of the solid soln. from what is called the β-form to the α-form, and it is attended by the rejection of part of the tin. The alloy with 8 per cent. of tin can remain in the β-form down to the temp. of liquid air. G. H. Gulliver calculated the difference in the relative proportions of solid (primary crystals) and liquid between the eutectic and the liquidus curves for very slow and very rapid rates of cooling. The transformation at 161° is due to the contained tin. The f.p. curve is of the V-type with the eutectic at 181° and 76 at. per cent. of tin ; according to W. Rosenhain and P. A. Tucker, the eutectic is at 180° with 62·93 per cent. of tin. P. N. Degens said that at 181° tin retains only 0·21 at. per cent. of lead in solid soln., and lead, 12 at. per cent. or more of tin. N. Parravano and A. Scortecci found for the percentage solubility of tin in lead :
FIG. 55.—Freezing-point Curves of Lead-Tin Alloys.

	175°	170°	162°	150°	100°	75°	50°	25°
Sn	14·5	13·5	12·5	10·0	6·5	5·0	3·0	1·5

The subject was studied by D. H. Andrews and J. Johnston. The facility with

which the plumber can "wipe a joint" with solder, containing about 66 per cent. of lead, depends on the two f.p., *A*, *B*, Fig. 55, of these alloys. The "pasty" condition occurs when the freezing alloy has granules of solid lead in a liquid matrix.

The microstructure of the alloys was investigated by W. Campbell, W. Guertler, G. Charpy, A. M. Portevin, H. Behrens, K. Bux, W. Rosenhain and P. A. Tucker, J. E. Stead, J. A. Ewing and W. Rosenhain, C. H. Green, and H. von Jüptner. Figs. 56, 57, and 58 represent some results by W. Rosenhain and P. A. Tucker with
FIGS. 56, 57, 58.—Microstructure of Lead-Tin Alloys respectively with 10, 20, and 55 per cent. of Lead.

alloys containing 10, 20, and 55 per cent. of lead respectively. By means of the X-radiograms, W. C Phebus and F. C. Blake found that lead and tin form solid soln. at room temp. ; with from 0 to 3·6 per cent. of tin the lead space-lattice decreases from $a=4·942$ to 4·931 ; and with 10–93 per cent. of tin, both tin and lead lattices are present without the tin lattice being appreciably distorted. The sp. gr. was examined by F. C. Calvert and R. Johnson, G. Pillichody, S. Grimaldi, C. Long, T. Thomson, O. Kleinstück, G. Vicentini and D. Omodei, K. Gilbert, A. T. Kupffer, P. Bolley, J. Pohl, H. Kopp, A. Riche, J. H. Croockewit, H. V. Regnault, A. Matthiessen, and B. Wiesengrund ; and C. Long gave :

| Pb | . | 0 | 23·0 | 31·0 | 47·3 | 64·2 | 78·2 | 87·8 | 91·5 | 100 per cent. |
| Sp. gr. | | 7·924 | 7·927 | 8·188 | 8·779 | 9·460 | 10·080 | 10·590 | 10·815 | 11·376 |

According to E. von Maey, for alloys containing *p* per cent. of tin, the sp. vol. is $0·08811+0·0004900p$. The shrinkage vol. on freezing was measured by C. M. Marx, E. Wiedemann, and B. Wiesengrund ; the vol. changes during the formation of the alloy, by K. Karmarsch, D. Mazzotto, F. Wüst, K. Gilbert, J. Pohl, F. Hoffmann, H. Kopp, and B. Kosmann ; the hardness, by A. Saposhnikoff, D. Stenquist, F. L. Brady, K. Gilbert, I. P. Göbel, P. Ludwik, L. Sterner-Rainer, E. Heyn and O. Bauer, and F. C. Calvert and R. Johnson ; L. Guillet, M. Dubosc, and R. S. Dean and co-workers, the hardening of the alloys by quenching ; the diffusion of tin in lead, by W. C. Roberts-Austen ; the difficulty of thoroughly mixing the molten metals, by H. Kopp ; the viscosity and sp. gr. of the liquid alloy, by M. Plüss, and R. Arpi ; the elastic constants, by G. Wertheim, L. Sterner-Rainer, E. S. Sperry, E. Heyn and O. Bauer, I. P. Göbel, E. N. da C. Andrade, A. E. Dunstan, Z. Carrière, and J. Dewar ; the coeff. of thermal

expansion, by A. Matthiessen, and G. Vicentini and D. Omodei ; H. Moissan and A. J. P. O'Farrelly found lead can be almost completely distilled from alloys in the electric furnace ; J. Joly and J. H. J. Poole separated the constituents to a small extent by centrifuging. A. Magnus and M. Mannheimer observed that a rise of temp. occurs when molten lead and tin are mixed. The thermal conductivity was measured by F. C. Calvert and R. Johnson, W. B. Brown, and A. W. Smith ; the sp. ht., by E. van Aubel, U. Behn, H. Kopp, H. V. Regnault, A. Saposhnikoff, W. Spring, and F. Rudberg ; the phenomenon of surfusion, by D. Mazzotto, B. Wiesengrund and W. C. Roberts-Austen ; the heat of fusion, by W. Spring, and D. Mazzotto ; the heat of formation, by J. Tayler ; and the electrical conductivity, by E. Elsässer, W. H. Preece, W. Harris, S. Konno, P. W. Bridgman, W. Guertler, A. Matthiessen and co-workers, W. C. Roberts-Austen, E. J. Cuy, N. Parravano and A. Scortecci, C. L. Weber, P. Müller, K. Bornemann and G. von Rauschenplat, H. Rainy and R. D. Clackson, E. F. A. Obach, and G. Vicentini and B. Omodei. The results by W. C. Roberts-Austen are plotted in Fig. 59. The straight line is in agreement with the fact that the alloys are heterogeneous mixtures of the components. A. Matthiessen and C. Vogt examined the effect of temp., and of foreign metals on the conductivity ; and H. Rainy and R. D. Clackson, the change of conductivity at the m.p. J. Trowbridge and E. Stevens, S. D. Muzaffar, N. A. Puschin, H. le Chatelier, A. P. Laurie, and O. Sackur measured the electrode potential of the alloys in different soln. W. Rollmann, J. L. Haughton, P. H. Dowling, H. Pélabon, and A. Battelli measured the thermoelectric properties, and the results by E. Rudolfi are plotted in Fig. 60. P. H. Dowling found no change
FIG. 59.—Electrical Conductivity of the Tin-Lead Alloys.
FIG. 60.—Thermoelectric Power of the Tin-Lead Alloys.

in the e.m.f. of contact of a solid and molten lead-tin alloy with 25 per cent. lead. R. Kremann and P. G. von Rehenburg found that on electrolyzing these alloys the tin accumulates about the cathode, the lead at the anode. P. H. Dowling studied the change in the contact e.m.f. of a lead-tin alloy, and Wood's metal with a nickel surface when the alloy is solid and when fused. The magnetic susceptibility curve, Fig. 61, by K. Honda is nearly a straight line, but with alloys containing 0–10 per cent. of lead there is a slight curvature corresponding with the presence of solid soln. E. L. Dupuy also investigated this property. M. Loutchinsky found the magnetic susceptibility of the hammered alloy less than where it is crystallized.

J. Fordos, L. Bessnou, H. Reckleben and J. Scheiber, A. Scala, F. Knapp, and L. Peetz examined the influence of oxygen, air, and other gases on the alloys. H. E. Armstrong, G. Charpy, J. Pohl, A. Bauer and P. von Mertens, and L. Pitkin investigated the action of acids on the

FIG. 61.—Magnetic Susceptibility of the Tin-Lead Alloys.

lead-tin alloys ; O. Bauer, the action of sulphuric acid ; F. P. Hall, C. H. Pfaff, J. Pohl, Z. Roussin, A. Pleischl, A. Gummi, J. L. Proust, O. Sackur, F. Knapp, and R. Weber, the action of acetic, citric, tartaric, and lactic acids ; A. Scala, the

action of distilled water; and F. Knapp, and C. Reichelt, the action of soln. of sodium chloride—*vide* the action of natural waters on lead.

The technical uses of the tin-lead alloys were discussed by A. Guettier, N. Braun-schweiger, M. von Schwarz, L. Hartmann, O. and A. Neumann, W. Kaiser, etc. E. Seel and K. Hils observed that 1·27–4·44 per cent. of lead was found in some tins used for canned foods. *Solders* usually consist of tin and lead in various pro-portions, and when a still more fusible solder is needed, bismuth is added. Accord-ing to Pliny's *Historia naturalis* (**34**. 17, 48), the so-called *tertiarium* of the Romans contained twice as much lead as tin, and was used as a solder. It contained very nearly the eutectic proportion. W. Gowland found that a sample dating from 300 A.D., unearthed at Silchester, contained 61·93 per cent. of lead, and 28·01 per cent. of tin. An alloy containing equal parts of tin and lead was the *argentarium* of Romans, and it is a common solder of to-day. The standard *tinman's solder* has 1 part tin and 2 parts lead, and its fusibility is indicated by the line AB, Fig. 55. The solders were discussed by G. Strahl, M. von Schwarz, F. M. Feldhaus, M. Wählert, M. L. Lissberger, J. Rothe, J. Novel, F. Singer and H. Barthel, W. Kaiser, E. Johanson, P. Yanushewsky, and A. H. Munday and co-workers. The effect of a small proportion of bismuth, antimony, arsenic, copper, silver, zinc, cadmium, aluminium, or mercury was examined by C. O. Bannister, and H. J. Tabor and H. D. Smith. *Pewter* or *latten ware*—from the French *laiton*, brass or tin-plate—is an alloy of tin and lead, 4 : 1, which came into use near the middle of the seventeenth century, and was used in making measures for wine and ale; by a Royal decree, the pewter vessels were stamped. The Pewterers' Company, incor-porated in 1474, attempted to regulate the quality of pewter by permitting enough lead to bring the sp. gr. to that of tin; persons who departed from the regulations were liable to expulsion from the guild, but the rule was disregarded so much that it had little effect in keeping up the standard. Unalloyed tin is largely used in place of pewter being not only whiter, but also safer for domestic purposes on account of the poisonous nature of lead (*q.v.*). The pewter with 18 per cent. of lead is said to be harmless when used for vessels for wine and vinegar. Other pewters contain small proportions of other metals—*e.g.* zinc, copper, antimony, etc. Alloys of tin and lead are used for toys—*e.g.* toy soldiers—and an alloy of lead and tin in the proportions 3 : 5 is used for tinning certain articles of copper. The so-called *Fahlum brilliants*, used for stage jewellery, contain lead and tin nearly in the proportions 2 : 3; the molten alloy is cast in mould facetted like cut diamonds. Thin sheets of steel coated with an alloy of tin and lead (1 : 3) are used in packing dry goods and for roofing, and called *terne plates*. C. Baskerville described a cheaper substitute made by coating iron with antimony, and depositing lead thereupon. The uses of these alloys in making domestic utensils was discussed by F. Knapp.

The ternary **Pb–Sn–As alloys** were investigated by W. Zimmer, and H. J. Roast and C. F. Pascoe; the **Pb–Sn–Sb alloys** by H. Behrens and H. Baucke, W. Hommel, A. H. Munday and co-workers, R. W. Irwin, G. Charpy, H. Kopp, O. W. Ellis, W. Campbell and F. C. Elder, J. d'Arcet, L. J. Chaudet, F. Rudberg, J. W. Döbereiner, Isaac Newton, G. A. Erman, R. Loebe, G. H. Gulliver, C. O. Thieme, A. M. Portevin, R. H. Thurston, G. Wertheim, J. Hoyle, J. Czochralsky, J. C. Work, E. Heyn and O. Bauer, C. Pack, M. Wählert, A. Halfmann, M. le Gris, J. E. Stead, M. Dreifuss, G. H. Clamer, G. von Hanffstengel, L. E. Eckelmann, R. Meyer and S. Schuster, S. Zinberg, R. W. Irwin, and R. Weber. The alloys for stereotype work have lead 72–82 per cent.; tin, 3–10; and antimony, 15–19. The applications of these alloys were discussed by W. Campbell, E. Heyn and O. Bauer, A. Hague, J. Czochralsky, A. Halfmann, W. Kaiser, T. Goldschmidt, L. Revillon, H. M. Waring, C. F. Beyer, P. Yanushewsky, R. J. Shoemaker, C. Fischer, J. J. Watts and S. Harton, M. von Schwarz, F. Varrentrapp, and S. K. Patteson. M. Dubosc, R. S. Dean and co-workers, and L. Guillet, studied the hardening of the alloys by quenching. The **Pb–Sn–Bi alloys** were investigated by E. van Aubel, G. Charpy, M. Dullo, C. M. Marx, J. Würschmidt, K. Bux, H. Kopp, K. Gilbert, D. Mazzotto, H. Rainy and R. D. Clackson, P. T. Bachmetjeff and J. Wsharoff, C. Cattaneo, J. W. Döbereiner, C. Drewitz, G. A. Erman, G. Gore, C. C. Person, H. V. Regnault, W. C. Roberts-Austen, L. Schüz, W. Spring, C. L. Weber, G. Wiedemann, E. Heyn and O. Bauer, R. H. Thurston, G. Wertheim, M. Merle, T. J. See-beek, H. von Löbell, H. Stegmann, E. S. Shepherd, F. Guthrie, P. Goerens, C. P. Steinmetz,

F. Hauser, K. Bux, E. Wiedemann, H. Behrens, G. W. A. Kahlbaum and E. Sturm, J. Faé, J. Johnston and L. H. Adams, K. Heine, C. von Hauer, J. M. Belin, L. Brennan, F. Wüst, L. Grunmach, J. Würschmidt, J. Joly and J. H. J. Poole, C. Schaefer, F. Faktor, etc. G. Charpy found that no compounds are formed, but there is a sharply defined ternary eutectic at 96°, as shown in Fig. 62. F. Wüst found that the alloy with 49·88 per cent. bismuth ; 32·47, lead ; and 17·38, tin, expands on cooling. The applications of these alloys were discussed by C. Drewitz, M. von Schwarz, R. Clayton, R. R. Maddison, C. W. Harrison, E. Lenssen, G. Homberg, W. Kaiser, W. F. Siemens and E. F. A. Obach, E. von Bibra, O. Trossin, L. Brennan, R. Jobson and R. J. Ransome, C. von Hauer, D. Mazzotto, H. V. Regnault, C. C. Person, W. Spring, G. W. A. Kahlbaum and E. Sturm, E. Jannettaz and co-workers, H. Grissel and T. Redwood, C. Cattaneo, J. Würschmidt, and H. Behrens.

The ternary **Pb–Sn–K alloys** were examined by W. Stockmeyer and H. Hanemann ; the **Pb–Sn–Na alloys,** by J. Göbel, and W. Stockmeyer and H. Hanemann ; the **Pb–Sn–Ca alloys,** by C. G. Carroll and W. H. Adams ; the **Pb–Sn–Ba alloys,** by Metallbank und Metallurgische Gesellschaft ; and the **Pb–Sn–Cu alloys,** by R. E. Lee and F. B. Trace, and R. H. Thurston ; A. French, G. Charpy, and E. J. Ball—these ternary alloys were found by F. Giolitti and M. Marantonio to contain either Cu₄Sn or Cu₃Sn. N. Parravano studied the **Pb–Sn–Ag alloys ;** A. von Vegesack, C. O. Thieme, and W. Stockmeyer and H. Hanemann, the **Pb–Sn–Mg alloys ;** W. Hommel, A. and L. Svanberg, C. R. A. Wright and co-workers, F. Rudberg, J. Czochralsky, A. H. Munday and co-workers, A. Guettier, G. Wertheim, S. Fox and J. W. Slater, W. Sharman, F. Osmond and J. Werth, M. Levi-Malvano and O. Ceccarelli, C. F. Grimm, C. Pope, H. Grissell and T. Redwood, G. Wegner, W. E. Day, A. M. Ayala, J. R. Kinder, and A. Hanszel, the **Pb–Sn–Zn alloys ;** M. Levi-Malvano and O. Ceccarelli obtained no compounds in the ternary system, and the ternary eutectic occurred at 177° with an alloy containing 71 per cent. of tin, 24 of lead, and 5 of zinc. A. K. Aster, W. J. Humphreys, A. Stoffel, E. S. Sperry, C. P. Steinmetz, M. Wählert, W. Hommel, B. Wood, C. W. Hill, C. von Hauer, K. Heine, L. J. Gurevich and R. W. Woodward, S. W. Stratton, F. Halla and A. Hoffmann, J. Scoffern, W. Kaiser, A. Lassieur, and P. Speier studied the **Pb–Sn–Cd** alloys. A. Stoffel observed that no compounds were formed, and that there is a ternary eutectic at 143°, as indicated in Fig. 63. F. Weld, and
FIG. 62.—Fusion Curves of the Ternary System : Pb–Sn–Bi.
FIG. 63.—Fusion Curves of the Ternary System : Pb–Sn–Cd.

W. J. Humphreys studied the **Pb–Sn–Hg alloys ;** C. R. A. Wright and co-workers, W. D. Bancroft, and J. Cayorca, the **Pb–Sn–Al alloys ;** and C. G. Fink and C. H. Eldridge, the **Pb–Sn–Tl alloys.**

The so-called *fusible alloys*—discussed by K. Heine, N. F. Budgen, L. Losana, E. F. Davis, G. K. Burgess and P. D. Merica, A. Lassieur, and many others—contain tin and lead with one or more metals—bismuth, cadmium, mercury—in addition. They are used for obtaining casts of delicate objects which would be damaged at a high temp.— e.g. casts of portions of post-mortem specimens can be obtained by adding $\frac{1}{16}$th of its weight of mercury to say bismuth 2, tin 1, and lead 1. The fusible alloys are used for very soft solders. Fusible safety plugs, are used for boilers, etc. An alloy for fusible teaspoons is composed of bismuth 8, tin 3, lead 5, and mercury 1–2. The composition of some well-known fusible alloys is represented in Table VIII. The so-called *G. C. Lichtenberg's alloy* is really that given by Isaac Newton ; and that often quoted as I. Newton's alloy (3 : 5 : 8, m.p. 94·5°) was not given by him at all.

The quaternary **Pb–Sn–Sb–P alloys** were studied by J. T. Dwyer ; the **Pb–Sn–Sb–As alloys,** by J. E. Stead and L. J. Spencer ; the **Pb–Sn–Sb–Na alloys,** by P. S. Braucher ; the **Pb–Sn–Sb–Al alloys,** by the Dellinger Hüttenwerke, and the Allgemeine Elektrizitäts-Gesellschaft ; the **Pb–Sn–Bi–Sb alloys,** by S. Singley, P. Bolley, R. Clayton, W. Kaiser, and E. Heyn and O. Bauer ; the **Pb–Sn–Bi–Na and Pb–Sn–Bi–K alloys,** by G. Bredig and F. Haber ; the **Pb–Sn–Zn–P alloys,** by S. R. Bailey, and J. F. Gross ; the **Pb–Sn–Zn–Sb alloys,** by J. U. V. de Strubing, J. Segura, B. Kohlmann, K. Küppers, S. M. Meyer and W. James, and T. Lambert and H. C. Soper ; and the **Pb–Sn–Bi–Cd alloys,** by A. Gouy, G. Gore, J. Faé, W. Campbell, D. Mazzotto, W. Spring, F. Guthrie, L. Losana ; E. Wiede-

TABLE VIII.—THE COMPOSITION OF SOME FUSIBLE ALLOYS.

Alloy.	Tin.	Lead.	Bismuth.	Cadmium.	Melting-point.
B. Wood's	2	4	5–8	1–2	60°–72°
V. Rose's	3	8	8	–	93·7°
J. d'Arcet's	1	1	2	–	79°
Isaac Newton's	3	2	5	–	91·5°
A. Lipowitz's	4	8	15	3	70°

mann, H. Behrens, G. Strahl, J. H. Gladstone and W. Hibbert, C. von Hauer, J. Roszkowsky, C. L. Weber, B. Wood, E. van Aubel, C. Cattaneo, W. Hallock, H. Stegmann, G. W. A. Kahlbaum and E. Sturm, L. Grunmach, C. Friedel, C. P. Steinmetz, A. Lipowitz, M. Wählert, C. Schäfer, J. Dewar, N. Parravano and G. Sirovich found that no compounds are formed and that the most fusible alloy of the series contains 27·27 per cent. of lead, 13·13 of tin, 10·10 of cadmium, and 49·50 of bismuth. The uses of these alloys were discussed by R. Pearson, R. Threlfall, O. Troosin, etc. The Pb–Sn–Bi–Hg alloys were studied by T. J. Seebeck, A. Gory, and G. Gore; the Pb–Sn–Bi–Al alloys, by A. B. Clarke and H. H. Gregg, D. J. Millard, and W. J. Crawford and T. B. Turley; the Pb–Sn–Zn–Cu alloys, by A. Guettier, W. Broniewsky, H. F. Staley and C. P. Carr, H. Kopp, and J. Czochralsky; and the Pb–Sn–Zn–Al alloys, by A. W. King, F. Jackman and co-workers, W. R. Mitchell and J. B. Vigo, C. H. Frantz, C. C. Wells, and J. G. Kelly and co-workers. The so-called *babbitt metals* are quaternary Pb–Sn–Cu–Sb alloys with tin 20–80 per cent.; lead, 0–63·5; copper, 1·5–3·0; and antimony, 10–15. They are used as bearing metals, and were investigated by A. H. Mundey and co-workers, E. G. Mahin and J. F. Brocker, L. D. Staplin, J. R. Freeman, etc. W. Hommel studied the Pb–Sn–Cd–Bi alloys; and the Pb–Sn–Hg–Bi alloys, by F. C. Weld.

The quinquinary Pb–Sn–Zn–Sb–Bi alloys were studied by O. Holden, and B. D. Webster and J. Horsfall; the Pb–Sn–Zn–Sb–Al alloys, by R. L. Weatherford; the Pb–Sn–Zn–Sb–Cr alloys, by C. R. Erkens; the Pb–Sn–Cd–Sb–Bi alloys, by T. Goldschmidt; Pb–Sn–Cd–Zn–Al alloys, by O. Nicolai and F. Börner, and W. R. Mitchell and J. B. Vigo.

C. Hatchett [5] suggested that a systematic examination of all possible alloys of all the metals be made proceeding from the binary to the more complicated ternary and quaternary alloys. Supposing this were done, and that one proportion of each of thirty metals were taken, there would be 435 binary, 4060 ternary, and 27,405 quaternary alloys to be examined; and if four proportions of each of thirty metals were employed, 6655 binary, 247,660 ternary, and 1,013,985 quaternary alloys would have to be examined.

§ 11. Lead Suboxide, or Hemioxide

The grey film which is first formed when lead is heated below its m.p. in air was regarded by J. J. Berzelius [1] as **lead suboxide or hemioxide**, Pb_2O. P. Bolley also made it from spongy lead, and he stated that lead is not present in the hemioxide because the product gives up no lead to mercury ; and that when heated in a glass tube, it forms lead and ordinary lead oxide. F. J. Brislee showed that there is no break in the hyperbolic curve representing the increase in weight at different periods when lead is heated in oxygen ; but there is a definite break in the time-reduction curve with carbon monoxide—*vide infra*. F. Glaser found that lead oxide in hydrogen at 211° forms grey lead suboxide ; and P. Sabatier and L. Espil obtained a similar result at 190°, or more quickly at 240° ; red-lead passes into the hemioxide under similar conditions at 250° ; G. Bischof worked at 250°–300°, and H. G. Denham showed that lead oxide prepared in different ways requires different temp. for the reduction in hydrogen. A. Salmony saw that the product obtained by the partial reduction of lead oxide is impure. P. L. Dulong, J. B. J. D. Boussingault, and J. Pelouze obtained the hemioxide by cautiously heating lead oxalate in a retort from which air was excluded. The retort was kept at a temp. not exceeding 300° until gas ceased to be evolved. The retort and contents are cooled before the black powder is removed. L. Gutersohn made the suboxide by heating lead oxalate, or a mixture of litharge or red-lead with oxalic acid, sucrose, or starch to 250°–300° in the absence of air.

G. C. Winkelblech regarded the suboxide as a mixture of lead and lead monoxide ; and S. M. Tanatar, as a mixture of lead and lead hemioxide. R. W. E. McIvor said that as fast as the carbon monoxide is formed it should be swept from the apparatus by carbon dioxide and the temp. should not exceed 300°. J. B. J. D. Boussingault, and J. Pelouze said that the suboxide contains no metallic lead, because mercury extracts nothing from it either dry or under water ; and no lead monoxide is present because a boiling soln. of lead acetate does not extract any lead oxide from it. S. M. Tanatar recommended making the hemioxide by heating lead oxalate at as low and as uniform a temp. as possible in a current of carbon dioxide until no more gas is given off. H. G. Denham said that when carbon dioxide is used

traces of a horn-like substance, possibly subcarbonate, are formed; and that if nitrogen be used, the time must be prolonged—say a week at 300°. He recommended mixing the oxalate with four times its weight of silica, and heating the mixtures at 270°–275° while removing the gaseous products by suction at about 50 mm. press.; and when the press. becomes very small, raising the temp. to 335°. E. Puxeddu said that lead dioxide reacts instantly and vigorously with phenylhydrazine, yielding lead and its monoxide and hemioxide; and red-lead gives the same products when heated with phenylhydrazine. G. Shimadzu described a large-scale process for making a mixture of the suboxide with finely divided lead.

The greyish-black or greyish-brown lead hemioxide was stated by R. W. E. McIvor to be stable in dry air. L. Gutersohn found that in moist air it becomes covered with a film of hydroxide. The greyish-green product with a sp. gr. 9·973–9·979 is considered by S. M. Tanatar to be a decomposition product, for the hemioxide itself has a sp. gr. 8·3404 to 8·3475. S. M. Tanatar gave for the heat of the reaction $Pb_2O = Pb + PbO + 5·452$ cals. F. Aufenast and H. Terrey found the heat of dissolution in acetic acid to be very close to the value for litharge. H. G. Denham, H. G. Denham and A. J. Allmand, and M. M. Bell cited evidence in favour of the possible existence of ions of subvalent lead in soln. A. E. van Arkel observed that the X-radiogram of lead suboxide shows that it is a mixture of tetragonal lead oxide and the metal.

H. G. Denham said that the hemioxide can be heated in vacuo at 375° without decomposition, but it is paler and does not react so readily as the hemioxide which has not been heated to so high a temp. J. B. J. D. Boussingault, and J. Pelouze said that when heated to dull redness out of contact with air, it forms a greenish-yellow mixture of lead and yellow oxide from which the lead can be extracted with mercury, and the lead oxide by a soln. of lead acetate or acetic acid; M. Herschkowitsch said that heat is evolved when lead hemioxide decomposes into lead and lead monoxide. When heated in air, lead hemioxide ignites and oxidizes with a glimmering light. P. Sabatier and L. Espil said that dry hydrogen reduces it to the metal slowly at 250°, and rapidly at 300°. I. W. Fay and co-workers found that reduction can be detected at 202° when the suboxide is heated in ammonia or methane for 6 hrs. S. M. Tanatar said that it is insoluble in and not decomposed by water; but if the moist suboxide be exposed to air, S. M. Tanatar, J. B. J. D. Boussingault, and J. Pelouze found that oxygen is rapidly absorbed and the ordinary hydroxide is formed, the reaction being accompanied by a rise of temp. They also stated that dil. sulphuric, nitric, hydrochloric, or acetic acid transforms the hemioxide into a salt of the acid and a little finely divided lead. A similar result is obtained with a soln. of sodium hydroxide; and, according to J. Pelouze, with a cold soln. of lead nitrate, while with a hot soln., the whole of the suboxide is dissolved and basic lead nitrite is formed. In the method of making white-lead by G. Bischof's process, the suboxide is supposed to be first formed, and subsequently converted by direct hydration and oxidation into the ordinary hydroxide, which in turn is carbonated for white-lead. H. G. Denham showed that ethyl chloride at 311° transformed the suboxide into *lead subchloride*, PbCl; ethyl bromide at 261° into *lead subbromide*, PbBr; and methyl iodide at 250°–262° into *lead subiodide*, PbI. According to E. A. Ashcroft, when an alloy of magnesium with 85 per cent. of lead is exposed to moist air, oxidation of both the magnesium and lead proceeds so rapidly that a lump of the alloy swells up and falls to a black powder in a couple of hours. It is assumed that magnesium hydroxide and **lead subhydroxide,** or **lead monohydroxide,** PbOH, are formed, and when exposed for a still longer time, ordinary lead hydroxide is formed. The second stage of the oxidation requires more time than the first stage. The oxidation of the subhydroxide can be accelerated by adding water to the powder. Some hydrogen is evolved. By shaking the oxidized alloy with an aq. soln. of carbonic acid, white lead is produced. L. Kahlenberg and W. J. Trautmann found that lead hemioxide is but little affected when heated with

powdered silicon, even in the electric arc. A. V. Blom used lead suboxide as a pigment with linseed oil.

§ 12. Lead Monoxide

Dioscorides, in his *De materia medica*, and Pliny, in his *Historia naturalis*—both written in the first century of our era—referred to preparations of lead which were impure litharge. The λιθάργυρος of Dioscorides was made from a plumbiferous silver, from lead, and from a plumbiferous sand. He said that there were three grades—the best grade, *chrystis*, had a yellow colour and came from Greece ; the second grade, *argyritis* had a silver-white colour, and came from Spain ; while the poorest grade, *lauritis*, was made from silver, and came from Puteoli, Campania, and Sicily. Pliny (**33**. 35) referred to the first two preparations, but called the poorest grade *molybditis*. The *molybdæna* of both Pliny and Dioscorides was of a somewhat shining gold colour, and free from metallic lead ; it became reddish-yellow when powdered, and was found in gold and silver (cupellation) furnaces, as well as in the native condition. The σκωρία ἀργύρον, the ἔλκυμα, or the ἔγκανμα of Dioscorides, and the *scoria argenti* or *spuma argenti* of Pliny ; the σκωρία μολύβδον of Dioscorides or the *scoria plumbi* of Pliny ; and the λίθος μολυβδοειδης of Dioscorides or the *lapis plumbaris* of Pliny were impure preparations of litharge. Pliny described the production of litharge during the process of cupellation.

Lead monoxide has been reported to occur naturally in quite a number of places, but some of the reports are not considered to be well established. J. G. Wallerius [1] referred to the yellow oxide as *terra plumbaria citrina*, and the red oxide —red-lead—as *terra plumbaria rubia*. J. B. L. Romé de l'Isle referred to the yellow and red oxides as *mine de plomb terreuse ;* R. J. Haüy mentioned the same oxides. J. G. Lehmann showed that the yellow oxide reported from the Harz was considered by J. G. Lehmann to come from the remains of an old silver-works, and that reported by J. F. John from Breinig, near Stolberg, was shown by J. J. Nöggerath to be an old furnace product.

A. G. Werner's *lead-earth* was a carbonate. L. A. Emmerling, and C. C. von Leonhard both described the yellow oxide as a mineral. The *lead-ochre* of M. Bauer, F. Klockmann, and P. Groth were regarded as lead monoxide ; and that of E. F. Glocker, and C. Hartmann as red-lead. E. F. Glocker in 1839 applied the term *Bleiglätte* for massicot ; A. d'Achiardi used the term *massicottite*, and A. Weisbach, *chrysitine*.

J. D. Dana reported lead oxide from the lead-slags of the Laurium, Greece ; A. Pelloux, from Sardinia ; C. A. Tenne and S. y C. del Rio Calderon, in Mertola, Portugal, and Murcia, Spain ; A. Lacroix, in various departments of France—Gard, Haute-Loire, Isère, Ruy-de-Dôme, Rhône, Vosges, and Haute-Marne. J. D. Dana, F. A. Quenstedt, M. Bauer,

C. Koch, G. A. Kenngott, V. R. von Zepharovich, in Germany—Baden, Nassau, and Siebenbürgen ; V. R. von Zepharovich, at Dubrava, Hungary ; E. S. Larsen, in Austria —in crystals ; A. Scott, Zarshuran, Persia—red tetragonal crystals ; J. B. Dana, in Virginia ; E. S. Larsen, in California—in crystals ; F. von Gerolt, J. J. Nöggerath, L. W. Bailey, C. F. de Landero, E. Pugh, in various parts of Mexico—Ixtacihuatl, Popacatepetl, Chihuahua, Cohahuila, and Zomclahhuacan ; I. Domeyko, in Caracoles, Bolivia ; W. F. Petterd, in Dundas, Tasmania. The occurrence of lead oxide as a furnace product, etc., was mentioned by E. Mitscherlich, J. J. Nöggerath, J. D. Dana, C. M. Marx, F. Sandberger, W. J. Grailich, J. S. S. Brame, etc.

All varieties of ordinary lead oxide, *i.e.* lead monoxide, are called **litharge,** although many confine the term to the fused and crystalline oxide, and they call the oxide which has not been fused **massicot.** J. B. L. Romé de l'Isle [2] said : *a mésure que la chaux grise de plomb se combine avec l'acide igné, sa couleur change ;* the yellow oxide is called *massicot,* and the *verre de plomb* which has crystallized is called *litharge.* The so-called amorphous lead oxide is pulverulent like massicot, and is not necessarily non-crystalline. Lead oxide is formed by the direct oxidation of lead, and is therefore liable to contain the impurities originally associated with the lead. Modifications by oxidizing molten lead spray were made by W. P. Thompson,[3] and G. Shimadzu ; or finely divided lead in a tube furnace, by G. Shimadzu ; by air under press., or air mixed with steam, by L. Kühler. Many other modifications have been patented by H. M. Gabel, G. Shimadzu, etc. Commercial litharge is usually fairly pure, and is seldom adulterated. It contains a little iron, copper, silver, antimony and silica, and metallic lead. Sometimes a little sulphate and carbonate are present, and maybe a little red-lead. The purification has been described by G. Bischof, E. F. Anthon, R. H. Bradford, etc. It is difficult to make the amorphous monoxide by oxidizing lead because, as J. F. Sacher showed, if the temp. is too low, red-lead is produced, and if too high, the lead oxide fuses and crystallizes on cooling. Lead is vaporized by making an electric arc with a lead electrode, and the vapour oxidized as described by V. Kohlschütter and coworkers, and T. Goldschmidt. W. N. Hartley oxidized the vapour in the induction spark between lead electrodes. The so-called *flores plumbi* or flowers of lead, and the so-called *lead-ash* are examples the mode of preparation of which was indicated in connection with the action of oxygen on lead. Lead oxide is a by-product in the cupellation of lead. If the lead employed is impure, the litharge produced at the beginning is impure, that last formed contains silver, while the middle portion is collected in pots in a fused condition. Exfoliation occurs during solidification, forming a friable mass which is broken up, screened, and sold as *flake litharge ;* the knottings on the screen are ground in water, and the sludge collected in settling tanks is dried and sold as *levigated litharge.* Lead oxide is usually prepared by drossing lead in a small reverberatory furnace ; as the oxide is formed, it is pushed back with an iron rabble so as to expose a fresh surface of metal to the air. Pigs of lead are added as required, and the operation continued until sufficient oxide has accumulated. The product is then ground and the finely powdered product levigated in water ; or collected by pneumatic separation. Modifications of the calcination process have been suggested by H. A. Hünicke, W. Eckford, A. Salmony, G. Shimadzu, T. Goldschmidt, C. A. Hall, etc. The so-called *sublimed litharge* is obtained as a by-product in the fume from the manufacture of litharge by hearth or cupellation process. It is a very fine grained sulphur-yellow material. G. T. Lewis made lead oxide by boiling the fumes from lead smelting furnaces in a soln. of sodium hydroxide or carbonate for about an hour, then allowing to settle, washing the precipitate (carbonate and hydrated oxide of lead) to free it from sodium sulphate and roasting to form litharge or red-lead. If the fumes contain zinc the latter must first be dissolved out with sulphuric acid.

The hydroxide decomposes when heated, forming the oxide, and, according to J. B. A. Dumas, 2 or 3 per cent. of oxygen are given off at the same time. S. Glasstone made litharge by this process. J. Milbaur said the decomposition is complete at about 130° in vacuo. V. Kohlschütter and co-workers found that at 110°, red

oxide is formed, and at 650°, the yellow oxide.   T. Carnelley and J. Walker obtained
lead oxide by heating red-lead to 520°–530° ; at 521°, said W. Reinders and
L. Hamburger, the decomposition is incomplete.   J. E. Mackenzie, and W. Mosto-
witsch said that lead dioxide decomposes at 800°–820°, forming the monoxide.
Formerly, lead oxide was obtained of a high degree of purity by calcining the
oxalate.   J. J. Berzelius obtained the oxide by heating lead nitrate ; the reaction,
said H. C. Cooper and co-workers, is complete at 357°.   C. R. A. Wright and
A. P. Luff used this process, and added that the lead nitrate should not be melted.
G. Gore obtained the oxide by reducing lead carbonate with carbon monoxide ;
J. Riban, V. Kohlschütter and H. Röseti heated lead carbonate to 400° in air,
and obtained the red oxide by heating the resulting basic carbonate in nitrogen
at 450°, and the lemon-yellow oxide at 650° ; W. Dominik, reduced the car-
bonate at 300° with steam ; H. S. Reed and H. L. Purlow manufactured lead
oxide by heating the basic carbonate in air at 310° in a rotating tube furnace, and
afterwards at 600°–650° in the absence of air ; J. Riban, by calcining the acetate ;
A. Leclerc, by heating the nitrato-oxalate, and V. A. Kroll, by melting electrolytic
lead dioxide.   According to V. Thomas, lead oxide is formed during the action
of nitrogen peroxide on lead iodide.   G. Kassner obtained litharge by heating
powdered lead with calcium plumbate, or by stirring together molten calcium
plumbate and lead.   R. Kayser obtained lead oxide by heating a mixture of lead
sulphate and sodium nitrate to dull redness and washing the product ; M. Liebig
gradually added lead to molten sodium nitrate at about 300° ; and subsequently
washed the sodium nitrite from the lead oxide.   Lead oxide is produced during
the electrolysis of soln. of sulphates (C. Pollak), oxalates (L. Lejeune), hydroxides
(C. Luckow), and phosphates (F. Fischer), using lead electrodes.   A. C. Becquerel
obtained cubic or tabular crystals of lead oxide by fusing a mixture of lead oxide
with 4–6 times its weight of potassium hydroxide in a silver crucible at a dull red
heat, and washing the alkali away with water.   L. Michel obtained some red-
coloured lead oxide and some lead dioxide at the same time.   F. C. Calvert said
that if sodium hydroxide be employed the red-coloured " amorphous " oxide is
produced which becomes brownish-red if heated between 300° and 400°, but if
heated above 400°, the cold mass is sulphur-yellow.   G. Grube, A. Geuther, and
V. Kohlschütter and co-workers also obtained yellowish-green crystals by heating
the hydroxide with a conc. soln. of potassium or sodium hydroxide—say $8N$- to
$12N$-KOH.   According to J. J. Houton-Labillardière, if a hot soln. of sodium or
potassium hydroxide be sat. with lead oxide, and the soln. kept in a stoppered
bottle all through the winter, small, white, rhombic dodecahedra are formed.
E. Mitscherlich added that a boiling conc. soln. of potassium hydroxide sat. with
lead oxide gives yellow scales of lead oxide on cooling ; if the soln. be not fully
sat., or if the mother-liquor from the preceding operation be allowed to stand in a
cool place, red scales of lead oxide are formed.   The red crystals are soluble in
acetic acid showing the absence of red-lead, and when heated, they become yellow
on cooling.   A. G. Fell destroyed any higher oxides present in a soln. of lead oxide
in alkali-lye, by allowing the liquid to stand in contact with spongy or finely
divided lead for a short time.   F. C. Calvert dissolved lead hydroxide in boiling
soda-lye of sp. gr. 1·38–1·39, and, on cooling, obtained rose-red crystals of lead
oxide which lose about 0·1 per cent. of water at 400° and turn black ; at low redness,
the crystals become sulphur-yellow without changing their form.   A. C. Becquerel
prepared greenish crystals of lead oxide by wrapping copper about a piece of lead,
placed in a soln. of silica or alumina in potash- or soda-lye.   E. Frémy showed
that when lead hydroxide is boiled with a quantity of alkali-lye not sufficient to
dissolve it all, the undissolved part is converted into the crystalline, anhydrous
oxide, and the dissolved portion is obtained as crystals by evaporating the liquid.
According to A. Ditte, when potash-lye is added with continual agitation to lead
hydrate, $Pb(OH)_2$, suspended in water at 25°, the amount of lead oxide dissolved
increases with the quantity of alkali added until the latter amounts to 300 grams

per litre of water. At this point, the amount of lead oxide dissolved decreases slightly, but afterwards increases as more alkali is added, and, at the same time, the amorphous hydrate is converted into transparent, microscopic crystals. When the quantity of alkali added reaches 400 grms. per litre of water, the amount of lead oxide dissolved again suddenly diminishes, but afterwards increases as more and more alkali is added. The hydroxide, $Pb(OH)_2$, dissolves at first in the dil. potash-lye, but as the conc. of the latter increases, it is converted into the hydrate $3PbO.H_2O$, and this, in its turn, is converted into the anhydrous oxide when the conc. of the alkali passes a certain point. The same changes take place at all temp., but more readily the higher the temp. The hydrate, $3PbO.H_2O$, separates out in the form of transparent, white, flattened, hexagonal prisms (sp. gr. at $0° = 7.592$), when a soln. of alkali containing 100–300 grms. per litre of water is sat. with lead hydrate at a temp. insufficient for its decomposition, and allowed to cool. The anhydrous oxide is obtained in several different forms depending on the temp. and the conc. of the potash-lye. When the hydrate is heated with a soln. of about 130 grms. of potash in a litre of water, the oxide is obtained in small plates, with a greenish-yellow tinge ; sp. gr. at $0° = 9.1699$. With 230 grms. potash in a litre of water, the oxide forms brilliant sulphur-yellow crystals ; sp. gr. at $0° = 9.2089$. With 300 grms. potash in a litre of water, the oxide separates out on cooling in small, compact, heavy, brownish-yellow needles ; sp. gr. at $0° = 9.8835$. If potash is added gradually to lead hydrate suspended in water at $20°$ until it amounts to 400 grms. per litre of water, the anhydrous lead oxide separates out after several days in the form of a hard, compact, greyish-green crust, composed of large, brilliant laminæ ; sp. gr. at $0° = 9.5605$. When a hot soln. of 185 grms. potash in a litre of water is sat. with lead oxide, the latter separates out on cooling in long, dark green, almost black needles ; sp. gr. at $0° = 9.4223$. All these different varieties of the oxide are formed of small, thin, transparent crystals, the colour varying with the thickness of the plates, which are rhombic, the ratio of the diagonals being about 1 : 3. All the crystals become red when heated, and sulphur-yellow on cooling ; their sp. gr. increases the more they are heated.

Lead oxide is obtained by treating lead salts with aq. ammonia·or soln. of alkali or alkaline earth hydroxides—assisted by light or heat. If the soln. be heated, the anhydrous oxide is precipitated, and if cold, the hydroxide. V. Zotier obtained red, microscopic crystals by slowly heating at $160°$ a mush of lead nitrate and water with twice its weight of a 50 per cent. soln. of sodium hydroxide. A. Geuther obtained the red oxide by heating to $170°$ basic lead nitrate, and shaking the product in a stoppered cylinder with a soln. of sodium hydroxide (1 : 10–20). W. Reinders and L. Hamburger boiled lead nitrate with an excess of a 40–50 per cent. soln. of sodium hydroxide. Analogous processes by using lead acetate were described by V. Kohlschütter and H. Rösti, and S. Glasstone ; M. Pleissner found the precipitate obtained with baryta-water and lead nitrate always contains a trace of nitrate. A. Ditte found the hydrated oxide, $3PbO.H_2O$, is converted into the anhydrous oxide by exposure to light or heat ; and the basic chloride, $Pb_3O_2Cl_2$, passes into the anhydrous oxide when treated with potash-lye. C. E. A. Wichmann obtained the yellowish-red oxide by the action of a boiling aq. soln. of sodium hydroxide, sp. gr. 1.25, on lead sulphate ; with a more conc. alkaline soln., the product is redder. A. G. Fell patented a method of making lead oxide by heating the basic sulphate with alkali hydroxide. V. Kohlschütter and H. Rösti heated the sulphate, or chloride with $10N$-$NaOH$; and M. Lachaud and C. Lepierre, the chromate with 45 per cent. potassium hydroxide soln. A. Wohl obtained the sulphur-yellow oxide by the action of alkali-lye or lime-water on basic lead carbonate. The recovery of lead oxide from saccharate soln. has been discussed by G. Kassner, J. L. Babé and W. Witter, and A. Wohl.

J. Tünnermann exposed a soln. of lead acetate containing an excess of ammonia to sunlight for a few days, and obtained olive-green crystals of the anhydrous oxide ; W. Behrens added sufficient ammonia to a soln. of lead acetate to dissolve

the precipitate first formed, and exposed the filtered soln. in a stoppered vessel to sunlight for a few hours. Colourless crystals first separate out, and these become yellow and yellowish-grey in a few hours. The white powder becomes dark brown after long trituration. According to A. Payen, when 4 vols. of an aq. soln. of lead acetate, sat. at 30°, are mixed with 100 vols. of boiling water, and then with 45 vols. of aq. ammonia, the anhydrous oxide separates out, in delicate, yellowish-white, rhomboidal laminæ. These can be separated by levigation from the crystalline granules of hydroxide which form at the same time, washed with boiling water, and dried in vacuo. When ignited, the crystals give off only a trace of water with decrepitation. The crystals can be obtained without the hydroxide by boiling 100 vols. of a sat. soln. of the basic acetate, $Pb_3O(C_2H_3O_2)_2H_2O$, with 50 vols. of water, adding 50 vols. of water at 80° and 8 vols. of aq. ammonia, and heating the mixture on a water-bath. G. C. Winkelblech obtained reddish-yellow spangles by mixing boiling soln. of two mols of lead acetate and 3 mols of potassium hydroxide (1 : 10). M. Pleissner obtained an oxide of a high degree of purity by the action of 150 c.c. of a boiling soln. 4 per cent. soln. of barium hydroxide on 36 c.c. of a boiling soln. of lead acetate (1 : 6). The greyish-yellow plates of oxide were washed with boiling water. According to F. Brendecke, if a soln. of lead acetate be dropped with constant stirring into a conc. soln. of calcium hydroxide at 88°, until crystalline scales appear, and a little more be added, the scaly crystals continue separating as the liquid cools. When dry, they are yellowish-white, with a silvery lustre, and feel like talc ; when heated, they become red without loss of weight, but on cooling regain their original colour and appearance. N. Kromer agitated a mixture of powdered lead acetate, $Pb(C_2H_3O_2)_2.3H_2O$, and barium hydroxide, $Ba(OH)_2.8H_2O$—or strontium or calcium hydroxides, $Sr(OH)_2.8H_2O$, or $Ca(OH)_2.H_2O$—and yellow crystalline lead oxide was formed, which became red in about a month.

Lead oxide appears as a product in many chemical processes—*vide supra* in connection with the action of aerated water, etc., on lead. Thus, in the action of an aq. soln. of oxygen on lead, M. Pleissner showed that lead oxide is produced provided the soln. is kept sat. with oxygen ; if only a limited supply of oxygen is available, the lead is converted into the hydroxide. P. Yorke obtained lead oxide by placing a piece of lead and some water inside a leaden vessel exposed to air. White flecks of hydrocarbonate are first formed, and then grey, mica-like crystals of lead oxide. These become orange when heated. T. Benfield patented a process for making lead oxide by shaking granular lead with water in presence of air or oxidizing gases. H. V. Regnault obtained lead oxide as a product of the action of steam on lead at a white heat, but, according to P. A. von Bonsdorff, not at a red heat. According to A. Bergmann and co-workers, the conversion of lead into litharge is effected by mechanically agitating the lead in a closed vessel in the presence of hot air and superheated steam, and so projecting the molten metal against a distribution plate as to reduce it to an impalpable powder. Under the action of the mixture of air and superheated steam this is immediately and quantitatively converted into litharge, which is carried forward by the current of air into deposition chambers. By suitable regulation of the temp. of the mixture of air and steam, red litharge (at 250°–300°) or yellow litharge (at 300°–400°) may be obtained. Several modifications have been suggested by the original inventors, E. Barthelmess, etc. To convert galena into lead oxide, T. Huntington and F. Heberlein recommended that the mineral be mixed with sufficient lime or other alkaline earth to react with the sulphur present, and that the mixture be heated to bright redness (about 700°) in a reverberatory or other furnace. It is then cooled to a dull red heat (about 500°) and transferred to a vessel in which it is exposed to a current of air, which may be preheated, and which is introduced by means of a blower. Under these conditions rapid oxidation takes place, sulphur dioxide is evolved (and may be utilized) ; much heat is generated, and the mixture fuses and gradually settles down to a mass of oxide of lead with the gangue of

the ore. W. S. Kilpatrick roasted the galena in order to obtain a mixture of lead oxide and sulphate; heated the product with an eq. proportion of a carbonate of the alkalies, alkaline earths, magnesium, or zinc; and removed the sulphate by elutriation or by washing. T. Goldschmidt volatilized lead oxide from lead, lead sulphide, carbonate, or red-lead in a current of air.

Analyses by P. Berthier,[4] T. Thomson, J. B. Trommsdorff, J. L. Proust, J. W. Döbereiner, L. N. Vauquelin, J. Davy, J. J. Berzelius, and C. F. Bucholz established the composition of lead oxide. The brownish-yellow colour of commercial litharge, said R. Ruer, is not due to the presence of the higher oxides of lead, but to the presence of other impurities. Analyses of the purest obtainable commercial lead oxide by W. Mostowitsch showed the presence of 99·2 per cent. PbO, some silica and some iron; E. J. Kohlmeyer reported 0·9 per cent. carbon dioxide; J. Gaudin, some Pb_3O_4; J. Löwy, and L. Michel, silver, gold, and platinum; J. S. Remington and R. F. Hartley, metallic lead, iron, copper, and carbonate; F. C. Schlagdenhausen, some calcium sulphate; M. Liebig, 0·006 per cent. chlorine. C. A. Klein gave the following as typical analyses of commercial samples of lead monoxide (the insoluble matter refers to acetic acid as solvent):

	Pb	Cu	Bi	Sb	Fe	Insoluble
Process oxide . . .	—	<0·0070	0·0081	0·0066	0·019	0·079
Fused litharge . . .	0·4	0·0064	0·0005	0·0015	0·007	0·650

V. Kohlschütter and J. L. Tüscher obtained highly dispersed lead oxide by vaporizing the metal in the electric arc, and passing a current of air through the vapour.

§ 13. The Physical Properties of Lead Monoxide

As indicated in connection with the different modes of preparation, the **colour** of lead monoxide may be yellowish-white, greyish-yellow, greenish-yellow, sulphur-yellow, reddish-yellow, red, or reddish-brown. The yellow massicot form is also called *argyritis*, or *Silberglätte*, and the red form *chrysitis* or *Goldglätte*. E. Mitscherlich [1] showed that the colour of the red form is not due to the presence of red-lead because it is wholly soluble in acetic acid. F. le Blanc attributed the difference to a variation in the physical structure, and not in the chemical composition, since either form may be obtained by regulating the temp. and the rate of cooling—the red variety, which is specifically lighter than the yellow, is formed most abundantly when the cooling is slow. According to E. Mitscherlich, and F. C. Calvert, the red form passes into the yellow when heated ; and, according to N. Kromer, and R. Ruer, the yellow becomes red by long-continued action of light at ordinary temp., or, according to W. Behrens, R. Ruer, and A. Geuther, by prolonged trituration—R. Ruer did not change the yellow to the red form by a press. of 2000 atm.

A. Geuther found that below 105°, only the yellow form is produced in a boiling aq. soln. of potassium or sodium hydroxide ; and at 110°–130°, only the red form. R. Ruer, however, showed that the temp. is dependent on the conc. of the alkali-lye ; in a sealed tube with 7·10 per cent. sodium hydroxide soln., at 150°, the red oxide remains red, and the yellow oxide, yellow. A. Ditte, R. Ruer, and H. C. Germs consider that two enantiotropic forms of lead monoxide are here involved, the red form being more stable at ordinary temp., and at all temp. up to the **transition point** which has not been precisely determined. R. Ruer found that at ordinary temp. the yellow form is not stable, but is stable above 620°, so that the transition temp. is near 620° because the reddish-brown form when heated to this temp. assumes the yellow form—the red oxide required a temp. of 720° for the conversion. The reverse change was induced only by grinding or by heating with conc. alkali-lye. H. C. Germs, emphasizing the difference in the colour, sp. gr., and solubility of the two forms, concluded that the transition point is 587°. The rate of conversion at this temp. was found to be very slow, but the speed increases as the temp. rises. It was not found possible to change the yellow to the red form except by dissolving the oxide in molten alkali. S. Glasstone found that the heating curve showed no signs of a transition temp., and that no visible change was observed by keeping the red form at 540° for 4 hrs., although W. Reinders and L. Hamburger observed a slow change at this temp. S. Glasstone added that measurements of the potential $Pb \mid PbO, N\text{-NaOH}$ show no signs of a transition ; that no definite difference in sp. gr. or crystal form has been established ; and that the solubilities of lead oxide made by different methods are always the same and independent of the colour. He therefore attributed the difference to a difference in the state of aggregation of the particles. The yellow agglomerated form produces a reddish-brown powder on trituration owing to the production of smaller particles ; and it is assumed that the red particles are of an intermediate state of subdivision. He showed that the passage from the red to the yellow form on heating is not due to the intermediate formation of red-lead ; at 200°–450° the reaction is symbolized : $6PbO + O_2 = 2Pb_3O_4$; and at 600° by $2Pb_3O_4 = 6PbO + O_2$—the change occurs in an atm. of nitrogen.

On the other hand, R. Ruer said that the solubility of the two forms in water is different, the value for the yellow oxide being $1·00 \times 10^{-4}$ gram-eq. per litre, and for the red form, $0·56 \times 10^{-4}$ gram-eq. per litre. F. le Blanc, A. Geuther, and R. Ruer found the red form to be specifically lighter than the yellow form, whereas M. P. Applebey and R. D. Reid found the yellow to be specifically lighter than the red. It is assumed that S. Glasstone's preparations were mixtures of both red and yellow forms because M. P. Applebey and R. D. Reid obtained both oxides in definite crystals by the action of conc. soln. of potassium hydroxide at a temp. near the b.p.—which form is produced depends on the conc. of the alkali—highly conc. soln. produce the red variety ; soln. of moderate conc. give the yellow form ; and dil. soln. give a black or steel-grey variety with the same crystalline form as the yellow variety. For example, uniaxial and negative, square, tetragonal plates of the red form were obtained with $15N$-KOH ; biaxial and positive, needle-like, rhombic bipyramids of the yellow form were obtained with $10N$-KOH ; and steel-black crystals, otherwise resembling the yellow crystals, were obtained with $3N$-KOH. With conc. intermediate between 10 and $15N$-KOH, mixed red and yellow crystals were produced, and with 3–$10N$-KOH, crystals of various shades of green were obtained. The differences in the properties of the two forms were very marked at 20°. Thus,

	Red oxide.	Yellow oxide.
Crystalline form	Tetragonal	Rhombic
Optical properties	Uniaxial, negative	Biaxial, positive
Sp. gr.	9·27	8·70
Potential $Pb \mid PbO, N\text{-NaOH}$ . . .	0·5668	0·5594 volts
Solubility gram-eq. per litre . .	$0·90 \times 10^{-15}$	$1·80 \times 10^{-15}$
Solubility product $[Pb''][OH']^2$ . .	$0·47 \times 10^{-15}$	$0·91 \times 10^{-15}$
Ionization constant of acid H_2PbO_2 .	$0·33 \times 10^{-11}$	$0·39 \times 10^{-11}$

It is therefore assumed that the yellow and red forms exhibit a true case of dimorphism. J. F. G. Hicks, H. Hélier, and V. Kohlschütter and H. Rösti regarded the red and yellow forms as polymerized varieties of lead monoxide ; and V. Kohlschütter and P. Scherrer claimed that this view is supported by the difference in the X-radiograms of the two forms. A. Geuther suggested the hypothesis that the yellow form is Pb_3O_3, and the red form Pb_6O_6, this view is favoured by E. J. Wade, D. I. Mendeléef, and G. Kassner, but the evidence is valueless.

E. Mitscherlich,[2] A. E. Nordenskjöld, C. F. Rammelsberg, and W. J. Grailich described the **crystals** of lead oxide as belonging to the rhombic system, and C. M. Marx, and F. S. Beudant and A. C. Becquerel described them as belonging to the cubic system, but J. L. F. Hausmann showed that the latter are really aggregates of rhombic crystals. The pseudocubic form of these crystals was confirmed by P. Termier. O. Luedecke found that while the yellow form furnishes rhombic bipyramidal crystals, the red form is tetragonal. A. Scott showed the optical characters of a native red litharge from Zarshuran, Persia, to be in conformity with the tetragonal form. L. Michel found the red crystals to be optically negative ; and E. S. Larsen said that the yellow form is always biaxial and positive while the red form is uniaxial and negative. According to A. E. Nordenskjöld, the axial ratios of the yellow, rhombic crystals of lead oxide are $a : b : c = 0.6706 : 1 : 0.9764$. E. S. Larsen found the central portion of plates of native litharge to consist of the yellow rhombic modification, and the borders of the red tetragonal form. According to T. V. Barker :

The colour of the red form is extremely variable, passing from red through brown to light yellow. It crystallizes in square plates which exhibit a negative uniaxial figure in convergent light, and the system is therefore presumably tetragonal. The yellow modification, which is uniformly yellow when freshly prepared, crystallizes in elongated, strongly doubly refracting plates with straight extinction. The ray vibrating parallel to the direction of elongation has the greater refractive index, so that even if the system be tetragonal (which is in doubt) the sign of the double refraction is positive. The two forms, then, exhibit distinctly different optical properties and must be held to present a true case of dimorphism.

R. G. Dickinson and J. B. Friauf found the **X-radiograms** correspond with the tetragonal lattice with two PbO-mols per unit cell with the dimensions (100), 3.99 A. ; and (001), 5.01 A. The oxygen atoms are at (000) and $(\frac{1}{2}\frac{1}{2}0)$, and the lead atoms at $(0\frac{1}{2}u)$ and $(\frac{1}{2}0u)$. G. R. Levi showed that stannous oxide and red plumbous oxide are isomorphous, and he gave for the axial ratio $a : c$ of red lead monoxide $1 : 0.900$; and for the dimensions of the tetragonal cell, $a = 5.55$ A., and $c = 5.00$ A. A. E. van Arkel gave for the base of the tetragonal cell 3.87 A., and for the height, 5.02 A. E. von Federoff studied the symmetry of the crystals, and V. Kohlschütter and H. Rösti described pseudomorphs after lead chloride. A. Sommerfeld discussed the electronic structure of the oxide. The **specific gravity** of lead oxide has been determined by C. J. B. Karsten,[3] who obtained 9.2092 ; W. Herapath, 9.277 at 17.5° ; E. Filhol, 9.361 ; P. F. G. Boullay, 9.500 ; L. Playfair and J. P. Joule, 9.363 at 3.9° ; and G. R. Levi, 9.51. A. Ditte found the sp. gr. depended on the mode of preparation, one sample with a sp. gr. 9.1699, after heating to 160° became lemon-yellow, and had a sp. gr. of 9.4342. S. Glasstone obtained numbers ranging from 9.20 to 9.53 according to the mode of preparation ; and he found that no definite conclusion could be drawn as to the relation between the sp. gr. and colour. The following oxides were prepared by boiling the hydroxide with potash-lye : a greenish-yellow oxide, 9.1699 ; yellow, 9.2089 ; brownish-yellow, 9.8835 ; grey, 9.5605 ; and dark green, 9.4223. A. Geuther found that the yellow oxide prepared in the wet way had a sp. gr. 9.28–9.36, at 14°–15° ; while the red oxide had a sp. gr. 8.74–9.126, at 14°–15°. R. Ruer gave 9.52 at 20°/4° for the yellow oxide, and 9.28 at 20°/4° for the red oxide. H. C. Germs found that the yellow forms always have a higher sp. gr. than the red ; while M. P. Applebey and R. D. Reid obtained

results in the opposite direction. Samples of a high degree of purity with all the occluded air removed in vacuo, had a sp. gr. 9·27 when red, and 8·70 when yellow. The oxide which had been fused and finally powdered was found by E. J. Kohlmeyer to have a sp. gr. 9·514; while A. le Royer and J. B. A. Dumas gave 8·01 for a glassy sample which had been melted in a fireclay crucible, and which must, as pointed out by J. N. von Fuchs, and E. Biewend, have contained some silica; a similar remark applies to the crystalline sample of a furnace product which W. J. Grailich found to have a sp. gr. of 8·02. According to E. Biewend, the solidification of molten lead oxide into a crystalline mass is attended by expansion. E. Pugh gave 7·83–7·98 for the sp. gr. of the native oxide from Mexico. O. W. Brown and co-workers showed that the apparent sp. gr. (i.e. the weight of oxide occupying a given vol.) of heavy crystalline lead oxide is diminished initially by grinding, and after reaching a minimum value, increases to a constant value—greater than the initial value. A. Balandin studied the mol. vol., 23·45. The initial decrease is not shown by the light amorphous oxide. The **hardness** on Moh's scale is 2·0. S. Motylewsky found the drop weight of the molten oxide near the m.p. to be 161, when that of water at 0° is 100.

L. Playfair and J. P. Joule gave 0·0000795 for the coeff. of **thermal expansion** (cubic). H. V. Regnault[4] gave 0·05118 for the **specific heat** of crystalline lead monoxide between 22° and 98°, and 0·05089 for the sp. heat of the fused monoxide prepared from red lead. H. Kopp obtained 0·0553 for the sp. ht. between 19° and 50°. The first two of the following values for the sp. ht. and **molecular heat** of lead oxide are by A. Magnus, the last two are by W. Nernst and F. Schwers, and the others are by A. S. Russell:

	144°	58°	2°	−73·9°	−80·3°	−190·3°	−251·7°
Sp. ht.	0·0523	0·05078	0·0517	0·0459	0·0349	0	0
Mol. ht.	11·64	11·34	11·57	10·26	7·75	6·42	1·55

E. J. Kohlmeyer[5] found that lead oxide sinters strongly at 830°, and, according to C. M. Marx, it fuses at a red heat, and, on cooling, forms a mass of crystalline plates; but, as J. N. von Fuchs, and E. Biewend showed, if a very small proportion of silica be present, the molten oxide forms a glass as it cools. G. Tammann and Q. A. Mansuri said that lead monoxide sinters together at 410°. According to R. Ruer, the **melting point** of lead oxide is 835°; J. W. Mellor and co-workers, 877°; F. O. Döltz and W. Mostowitsch, 906°; W. Mostowitsch, 883°; F. O. Döltz and C. A. Graumann, 900°; H. C. Cooper and co-workers, 888°; F. M. Jäger and H. C. Germs, 875°; L. Belladen, 870°; R. Schenck and W. Rassbach, 879°; J. C. J. Cunningham, 875°; S. Hilpert and P. Weiller, 776°; and H. le Chatelier, 830°. The last-named also said that an allotropic transformation of lead monoxide occurs at 580°. R. Lorenz and W. Herz studied the relation between the transition temp. and the m.p. According to J. Fournet,[6] lead oxide volatilizes at a white heat, but less readily than lead itself. C. Zenghelis said that lead monoxide volatilizes at ordinary temp. because if silver-leaf be suspended over a layer of lead oxide, it begins to acquire a yellowish colour after a longer or shorter time, and may be detected in the silver. The presence of moisture, or of a reducing substance like hydrogen or alcohol vapour, favours the action; and so does the partial exhaustion of the containing vessel. T. W. Hogg cited the following experiment to show that the **volatilization** of lead monoxide occurs at a scarcely visible red heat—presumably near 530°:

If a plate of glass be written upon, using lead oxide as a pigment, and another plate, preferably of some dark blue or ruby tinted glass, be placed immediately over it but prevented from actual contact by suitable means—if these be then heated for about an hour to a temp. of scarcely visible redness, the upper glass always has its polish so altered that a distinct reverse of the writing appears upon it, more or less sharp according to the distance between the two surfaces.

F. O. Doeltz and C. A. Graumann found that lead oxide lost 0·1 per cent. in weight

when heated for 1 hour at 700°; 0·2 per cent. at 800°; 2 per cent. at 900°; 5 per cent. at 950°; and 10 per cent. at 1000°. E. J. Kohlmeyer found only a small loss in weight at 1170° when the ratio of the mass to the surface exposed is large. The volatilization is reduced when the lead oxide is fixed by silica or iron oxide. For the observations of M. Störmer, O. Andersen, W. Thomason, S. Hilpert, etc., on the volatilization of lead oxide from lead silicates, *vide* lead silicates, **6**. 40, 50. Alumina inhibits the volatilization. W. R. Mott gave 870° for the **boiling point** of lead oxide, but, as E. P. Dewey pointed out, the estimate is far too low.

G. H. Bailey and W. P. Hopkins said that lead monoxide seems to be reduced to a lower oxide at high temp. T. Carnelley and J. Walker found that lead oxide is stable over 815°, and A. A. Read, that it is not decomposed at 1750°. According to W. Stahl, the **dissociation pressure** of the reaction $2PbO \rightleftharpoons 2Pb + O_2$ is equal to 0·21 atm.—the partial press. of oxygen in the atm.—at 2075°; and he calculated the oxygen press., p, mm., in the system:

	500°	700°	900°	1100°	1300°	1500°
p	$3 \cdot 1 \times 10^{-38}$	$2 \cdot 1 \times 10^{-25}$	$3 \cdot 2 \times 10^{-18}$	$1 \cdot 3 \times 10^{-13}$	$2 \cdot 1 \times 10^{-10}$	$4 \cdot 8 \times 10^{-8}$
				1700°	1900°	2000°
				$3 \cdot 2 \times 10^{-6}$	$8 \cdot 9 \times 10^{5}$	$3 \cdot 7 \times 10^{-4}$

S. Glasstone calculated the dissociation press. from Nernst's formula (**1**. 13, 11), using 100,600 cals. for the heat of formation per mol of oxygen, and obtained $1 \cdot 9 \times 10^{-67}$ atm. at 25°, a result in agreement with $4 \cdot 2 \times 10^{-67}$ atm. calculated from the e.m.f. of the cell Pb | PbO,N-NaOH,H_2 | Pt, *viz.* 0·247 volt; he also estimated that the oxide would be completely dissociated if heated to 2600° in air; and showed that if $Q = 100,600$ cals., and the ratio PbO : Pb be constant, $R \log_e p = -QT^{-1} + 32$, where p denotes the partial press. of the oxygen at the absolute temp. $T°$. Hence, at 2587°, the partial press. of oxygen is 0·21 atm. On the other hand, F. Damm and F. Krafft found that at 750° lead oxide gives a metallic mirror when heated in the vacuum of the cathode light. J. Thomsen gave for the **heat of formation** of lead monoxide $Pb + O = PbO + 50 \cdot 3$ Cals.; M. Berthelot gave 50·8 Cals.; W. D. Treadwell gave $Pb + \frac{1}{2}O_2 = PbO + 50 \cdot 4$ Cals.; G. Chaudron, 50·2 Cals.; and S. Glasstone calculated from the e.m.f. of the cell Pb | PbO$_{red}$,N-NaOH,H_2 | Pt, 49·61 Cals. for the heat of formation of the red-coloured monoxide at 25°; and D. F. Smith and H. K. Woods, 45,050 cals. at 25° for the **free energy** of formation of lead monoxide. A. L. Marshall and B. Bruzs gave 19·41 Cals. per mol. for the heat of soln. of lead oxide in nitric acid, 50 per cent. by vol. Values approximating 15·6 Cals. were also obtained by J. Svéda, M. Herschkowitsch, S. M. Tanatar, and F. Aufenast and H. Terrey.

The **optical properties** of the crystals of lead monoxide were examined by P. Termier,[7] and L. Michel. E. S. Larsen found that the birefringence in both forms is very strong; the optical character of the biaxial rhombic form is positive, and that of the uniaxial tetragonal form is negative. The **index of refraction** given by E. S. Larsen is $\beta = 2 \cdot 61$ for the yellow rhombic variety; and $\omega = 2 \cdot 64$ for the red tetragonal form. According to W. W. Coblentz, the **ultra-red emission spectrum** gives a curve with a depression at $3 \cdot 3\mu$, and a possible band at $5 \cdot 5\mu$. G. A. Dima examined the photoelectric effect with lead monoxide (*vide* lead dioxide). J. Ewles found a whitish **cathodoluminescence** with lead oxide; and E. L. Nichols and D. T. Wilber, the feeble **luminescence** of the oxide sublimed in the electric arc.

According to M. Faraday,[8] molten lead monoxide conducts electricity; F. Beijerinck said the **electrical conductivity** of the natural oxide is smaller than that of the artificial lead oxide; and C. Fritsch made some observations on this subject. G. Tammann and H. Bredemeier studied the conductivity of thin films of the oxide. F. Horton measured the effect of temp. on the electrical resistance

(ohms) and electrical conductivity (mhos) of lead monoxide melted in an atm. of oxygen and cast into a slab.

	384°	462°	600°	687°	700°	757°	787°
Ohms .	7×10^{8}	65×10^{4}	45000	4050	2870	730	330
Mhos .	$3 \cdot 86 \times 10^{-8}$	$4 \cdot 15 \times 10^{-7}$	$6 \cdot 00 \times 10^{-6}$	$6 \cdot 67 \times 10^{-5}$	$9 \cdot 39 \times 10^{-5}$	$3 \cdot 695 \times 10^{-4}$	$8 \cdot 175 \times 10^{-4}$

There was evidence of a slight electrolysis during the passage of the current. F. Streintz said that the pressed powder does not conduct electricity; and J. Rosenthal found that the conductivity of the powder pressed at 108° is too small to measure; at 228°, 0·070; at 271°, 0·229; at 357°, 5·536. After strongly heating the mixture the conductivity was increased because of *eine Molekular-umwandlung*. G. von Hevesey said that the conductivity of lead monoxide is partly electrolytic. E. Baur and co-workers found the **electromotive force** of the cell PbO,Pb|electrolyte|C, and obtained 1·0 volt at 1200°; and for the cell PbO,Pb|electrolyte|CuO,Cu$_2$O, 0·44 volt at 990°. W. D. Treadwell measured the potential of lead oxide against molten silver sat. with oxygen, and found for the cell Pb,PbO|electrolyte|O$_2$.Ag, 0·478 volt. M. P. Applebey and R. D. Reid measured the e.m.f. of the cell Hg|HgO in N-NaOH; PbO$_{red}$ in N-NaOH|Pb, and obtained 0·6808 volt, and with yellow lead oxide, 0·6734 volt. D. S. Smith and H. K. Woods measured the e.m.f. of the cell H$_2$|0·0766M—0·2242M|Ba(OH)$_2$|PbO; and G. Tammann, of litharge against the normal hydrogen electrode. S. Glasstone measured the **electrode potential** for Pb|PbO,N-NaOH with different forms of lead monoxide and obtained for the yellow form —0·5512 to —0·5514 volt at 0°, and —0·5597 to —0·5599 volt at 25°; and for the red form, —0·5536 to —0·5538 volt at 0°, and —0·5619 to —0·5621 volt at 25°. C. M. Newton gave for the e.m.f. cell ZnO|PbO in NaOH|Fe, 0·69 volt. G. Tammann also measured the electrode potential of litharge in soln. of various salts. The **dielectric constant** was found by C. B. Thwing to be 25·9, and J. Dewar and J. A. Fleming gave 78·5 at —197·4°; 90 at —184·8°; and 93 at —159·2° to —128·3°. S. Meyer gave —0·31×10^{-6} to —0·449×10^{-6} for the **magnetic susceptibility;** and —0·024×10^{-6} for the mol. magnetism of the sulphur-yellow oxide.

§ 14. The Chemical Properties of Lead Monoxide

A. Ditte [1] reported that in sunlight, the honey-yellow needles of lead monoxide (in contact with their own mother-liquor) gradually become greenish and finally

black. The action of light, trituration, and press. has been discussed in connection with the red and yellow forms of lead monoxide. According to G. Kassner, if lead monoxide be exposed to sunlight and air for about a year, some red-lead is formed provided moisture be present; with air dried by phosphorus pentoxide, no red-lead is formed. The action of light was found by G. A. Dima to be stronger than with other oxides reduced with greater difficulty; the action increases with press. up to a maximum and then decreases. M. P. Applebey and R. D. Reid said that the yellow form is converted into the grey form when exposed to light in air or in vacuo so that the presence of oxygen is not necessary for the change. According to C. Renz, when lead oxide is exposed to light under water, a partial reduction to metallic lead occurs, whilst the oxygen set free oxidizes part of the lead oxide to dioxide, and this in turn combines with lead oxide to form plumbate. The metallic lead is reoxidized by air contained in the water. The formation of metallic lead is proved by exposing to light a mixture of lead oxide and lead chloride which had been boiled with hydrochloric acid. When the product is treated with dil. nitric acid, lead is dissolved with evolution of hydrogen and a slight residue of dioxide remains.

According to J. J. Berzelius,[2] the first stage in the reduction of heated lead monoxide by **hydrogen** is lead suboxide (q.v.). According to G. C. Winkelblech, the crystalline oxide obtained by the action of potash-lye on a hot soln. of lead acetate is reduced by hydrogen at a temp. not much above 100°. W. Müller said that the reduction to lead begins at 310°–311°; and, added S. Hilpert and P. Weiller, there is a perceptible reduction at 240°; while C. R. A. Wright and A. P. Luff said reduction begins at 190°–195°. W. Mostowitsch said that grey lead suboxide is formed between 290° and 300°, and at 410°, small beads of lead are formed. F. Glaser said the reduction to the suboxide occurs at 211°, and to the metal, above 235°. H. Hélier said that lead monoxide becomes brown in hydrogen at 350°. I. W. Fay and co-workers detected signs of reduction after heating for 6 hrs. in hydrogen at 190°; S. Hauser placed the temp. a little higher. W. Ipatjeff and W. Werchowsky said that hydrogen reduces with difficulty lead monoxide which is confined under water at a temp. in the vicinity of 200° and 180 atm. press. H. Mennicke showed that lead oxide suspended in a mixture of zinc and hydrochloric acid is quickly reduced to lead, particularly if a little platinum be present. The hydrogen developed at the cathode during electrolysis also reduces lead monoxide. F. Paneth and co-workers made *lead hydride* by passing activated hydrogen over powdered lead. A. de Hemptinne also found that in the silent electric discharge, lead monoxide is quickly reduced, but not so rapidly as is lead dioxide. G. Tammann investigated the exchange of ions on the surface of lead. H. Moissan found lead oxide to be reduced by **potassium hydride** at a gentle heat; and F. M. Perkin and L. Pratt, by **calcium hydride.** For the action of **oxygen,** *vide* the higher oxides of lead. C. W. Scheele[3] said that lead oxide dissolves in **water,** but J. Tünnermann, F. Siebold, J. E. Herberger, and F. Brendecke reported that lead oxide is insoluble in water; although the last-named said that the moist oxide turns red litmus blue. P. A. von Bonsdorff said that a litre of water can dissolve 0·13 grm. of lead oxide; and P. Yorke, 0·083 grm. of this oxide. The latter added that the aq. soln. slightly reddens turmeric, and turns red litmus blue; it becomes turbid when shaken up with air, or when boiled; when electrolyzed it deposits lead at the cathode, and lead dioxide at the anode; it gives a brownish-black precipitate with hydrogen sulphide; is rendered turbid by carbon dioxide not in excess, or by sulphuric acid or soluble sulphates; and gives a yellow precipitate with potassium iodide, and with potassium chromate. If soluble sulphates or carbonates are present in the water, L. B. G. de Morveau, R. Christison, F. Clowes, and G. Wetzlar showed that the amount of lead oxide dissolved is very much reduced; hence the reports of the insolubility of the oxide in water are probably due to the dissolution and subsequent precipitation of the oxide by the action of the carbon dioxide of the air.

From conductivity measurements, M. Pleissner calculated the solubility of lead oxide in water at 18° to be from 0.077×10^{-3} to 0.403×10^{-3} mol per litre; R. Ruer gave 0.28×10^{-4} and 0.50×10^{-4} mol per litre at 22°; S. Glasstone, 0.26×10^{-3} at 25°; A. C. Cumming gave 3.8×10^{-6} mol PbO per litre; and W. Böttger, 0.80×10^{-4} to 1.22×10^{-4} grm. eq. per litre, or $0.0128-0.026$ grm. per litre at 19.96°. H. Remy and A. Kuhlmann found that a litre of water dissolved 12.36 mgrms. of lead oxide. The results are based on conductivity determinations, and depend on the unknown degree of ionization of the lead oxide in water. A. Bineau's value 0.143 grm. PbO per litre was directly determined by precipitation. He said that if the litharge has been previously fused, it does not dissolve in water; J. Percy, however, showed that this is not the case. S. Glasstone gave 1.7×10^{-15} for the solubility product, $[Pb''][OH']^2$; while M. P. Applebey and R. D. Reid gave 0.47×10^{-15} for the red-coloured oxide, and 0.91×10^{-15} for the yellow.

C. W. G. Kastner found lead oxide to be readily dissolved by a hot aq. soln. of **potassium hydroxide,** forming a yellow, non-crystallizable liquid. A. Ditte said the amount of lead oxide dissolved increases regularly with the conc. of the alkali. According to M. P. Applebey and R. D. Reid, at 20°, a normal soln. of **sodium hydroxide** dissolves 0.0237 mol per litre of the yellow oxide, and 0.0140 mol per litre of the red—*vide infra*, plumbites. E. Berl and G. Austerwell said that the solubility of lead oxide in soln. of sodium hydroxide, **sodium carbonate,** and **potassium carbonate** corresponds with that in potassium hydroxide; the product in dil. sodium hydroxide is said to be sodium hydroplumbite, $NaHPbO_2$, and in a conc. soln., sodium plumbite, Na_2PbO_2 (*q.v.*). P. Bechtereff found lead oxide to be readily soluble in molten sodium hydroxide.

H. Moissan [4] found that the cold **fluorine** does not attack lead oxide, but that when heated, a yellow compound is formed, probably an oxyfluoride. R. Weber found dry **chlorine** quickly converts lead oxide into lead chloride, but C. F. Cross and S. Suguira said that an oxychloride, $Pb_4O.Cl_7$, is formed, and with a mixture of air and chlorine, the composition of the product ranges from Pb_8OCl_{16} to $Pb_{12}O_4Cl_{21}$. C. Löwig found that an aq. soln. of chlorine forms lead dioxide and chloride; A. Michael and A. Murphy also showed that the same products are formed by the action of a soln. of chlorine in carbon tetrachloride. C. F. Cross and S. Suguira found that in the presence of air, **bromine** forms the oxybromides, $Pb_4O_2Br_5$ and $Pb_7O_2Br_{11}$. C. Löwig obtained a mixture of lead dioxide and bromide by the action of an aq. soln. of bromine. C. F. Cross and S. Suguira obtained $Pb_9O_8I_2$ and $Pb_9O_6I_4$ by the action of a mixture of air and **iodine** vapour. J. B. Moyer found that lead oxide is completely converted into lead chloride at ordinary temp. by **hydrogen chloride;** and A. E. Atkinson said that when **hydrogen bromide** is passed over heated lead oxide, it forms an oxybromide. Lead monoxide readily unites with acids forming salts, and the solubility of the oxide in acids, say **hydrochloric acid,** is therefore determined by the solubility of the resulting salt in the acid (*vide* the salts). A. Jäger said that the oxide is not dissolved by conc. **hydrofluoric acid,** but is very slightly soluble in the dil. acid, and air.

According to F. Isambert, when **ammonium chloride** and lead oxide are triturated together at ordinary temp., there is a slow endothermal reaction, and an oxychloride is formed. The press. of the ammonia at different temp. is:

	17°	24.2°	29.7°	36.3°	42°	48.9°
Press.	296	377	469	599	733	926 mm.

W. O. de Coninck and L. Arzalier obtained lead bromide in a similar manner from a mixture of lead oxide and **ammonium bromide;** and lead iodide, when **ammonium iodide** is used in place of the bromide. For the action of **potassium iodide,** *vide* the lead oxyiodides. O. Schott, and H. Houben showed that lead oxide is slightly soluble in fused **sodium chloride,** and on cooling the soln., the lead oxide separates in globules. C. W. Scheele discovered that sodium chloride in aq. soln. reacts with lead oxide, forming sodium hydroxide; and L. N. Vauquelin reported on this

reaction in his *Reflexions sur la décomposition du muriate de soude par l'oxide de plomb*. In dil. soln., E. Berl and G. Austerwell found that for equilibrium at 18°, the ratio OH' : Cl' is 1·02 ; at 48°, 0·75 ; and at 74°, 0·58. The subject was also examined by W. Dominik, and J. F. G. Hicks and W. Craig. According to A. Jäger, lead oxide reacts with the **alkali halides** until equilibrium is attained with the free alkali depending on the solubility of the lead halides ; complex compounds with the lead halides appear to be formed. W. Bersch showed that lead oxide decomposes in alkali halides, forming alkali hydroxide ; if the lead halide be insoluble, and an excess of lead oxide is present, all the halogen is extracted from the soln. ; but if the lead halide be soluble, a state of equilibrium is reached. The state of equilibrium is influenced by the heat of the reaction, so that if heat be absorbed, the proportion of alkali hydroxide increases with rise of temp. and conversely ; the time required to attain equilibrium is smallest with the iodides, and diminishes as the temp. rises. The amount of decomposition is dependent only on the halogen ; the alkali metal in combination with the halogen seems to have very little influence on the result. In illustration, with 0·1N-soln. of the alkali halides, the following percentage amounts of alkali hydroxide are formed :

	KCl	NaCl	KBr	NaBr	KI	NaI
25°	33·60	33·50	80·00	80·10	85·10	85·00
50°	36·80	36·80	79·20	79·30	84·00	83·50
79°	41·62	41·64	77·60	77·75	83·40	83·50
88·5°	56·08	56·20	76·40	76·35	82·90	82·86

E. P. Perman found that potassium iodide acts more slowly on lead oxide than on lead chloride. G. André found that lead oxide is soluble in a boiling soln. of **barium chloride**, forming an oxychloride ; similarly also with **strontium chloride** when $SrCl_2.2PbO.5H_2O$ is formed ; and with **calcium chloride**, $CaO.CaCl_2.2PbO.4H_2O$, is formed. A soln. of **magnesium chloride** readily dissolves lead oxide ; the solubility increases with the temp. and conc. of the soln. A. Voigt said that lead oxychloride, $3PbO.PbCl_2.H_2O$, is deposited as a gelatinous mass ; and H. Hof and B. Rinck showed that with a boiling soln. of magnesium chloride of sp. gr. 1·32, crystals of $Mg_2PbCl_6.13H_2O$ are deposited on cooling. O. Unger found lead oxide to be soluble in a soln. of **zinc chloride** ; and G. André showed that after a long contact of the lead oxide with the zinc chloride soln., needle-like crystals of what appears to be a compound of $3ZnO.ZnCl_2$ and $PbCl_2.PbO$ are formed. F. Roderbourg patented the use of a reaction in which molten zinc chloride reacts with lead oxide, forming lead chloride. A soln. of **manganese chloride** converts lead oxide into lead chloride. G. L. Fowler and J. Grant found that **potassium chlorate** mixed with lead oxide forms lead dioxide and potassium chloride at a temp. below its normal temp. of decomposition ; and W. R. E. Hodgkinson and F. K. S. Lowndes showed that the presence of lead oxide favours the evolution of oxygen from decomposing potassium chlorate, and results in the liberation of some chlorine.

When a mixture of lead oxide and **sulphur** is heated, lead sulphide and sulphur dioxide are formed, but, according to P. Berthier,[5] no sulphate is produced. J. B. Senderens showed that when a mixture of lead oxide, sulphur, and water is heated in a sealed tube, lead sulphide and sulphate are formed with the evolution of 15·8 Cals. of heat per mol of PbO. P. Berthier said that not the slightest trace of lead is produced when a mixture of **selenium** and lead monoxide is heated ; but the two substances react in all proportions, forming products which resemble those obtained by fusing mixtures of **lead selenide** and litharge. The lead oxide may be dissolved out by hydrochloric acid. Hence, sulphur may be separated from selenium by fusion with litharge. P. Berthier said that with **tellurium,** telluric acid is formed, and when the litharge is in excess lead tellurate is produced, but if the litharge be not in excess, most of the telluric acid is volatilized, and lead telluride remains. A. Gautier found that when heated with **carbon disulphide,** crystals of lead sulphide are formed and carbon and sulphur dioxides are evolved,

but no carbonyl sulphide is produced. According to E. Priwoznik, and F. Isambert, with **ammonium hydrosulphide,** lead sulphide and ammonia are produced. P. Richter found that an intimate mixture of **calcium sulphide** and lead oxide, at ordinary temp., becomes grey owing to the formation of lead sulphide ; and when heated, in air, calcium sulphate is produced. In his memoir, *De l'action de la litharge sur différents sulfures métalliques,* P. Berthier showed that when an excess of lead monoxide is fused with an excess of a metal sulphide, some, like barium sulphide, are decomposed with the formation of a sulphate ; and some, like the sulphides of the heavy metals, give off sulphur dioxide. The metal of the sulphide either unites directly with the lead, or is converted into oxide, and fuses along with the lead oxide while lead separates out. Some lead sulphide may be produced as well as the metal. Any undecompoesd sulphide fuses, with the excess of lead oxide and the metal, forming a slag. He examined the effect of lead oxide on the **sulphides of barium, zinc, tin (stannic), manganese, arsenic, antimony, and bismuth.** With **ferrous sulphide,** and an excess of lead oxide, the products are sulphur dioxide, iron oxide, and metallic lead ; and with a smaller proportion of lead oxide, some lead sulphide is produced. A mixture of **lead sulphide** and oxide, in theoretical proportions, at a strong red heat, reacts as symbolized : $PbS+2PbO=3Pb+SO_2$; if the lead oxide be in excess, the reduced lead will be found covered with a layer of fused oxide ; and if lead sulphide be in excess, part will dissolve in the reduced lead, and part will accumulate on top of the metal. H. Rose found that with stannic sulphide, lead and stannic oxide are formed : $6PbO+SnS_2=6Pb+SnO_2 +2SO_2$. According to R. Schenck and co-workers, when lead monoxide is treated with **sulphur dioxide,** lead sulphide and sulphate are formed, or a basic sulphate is produced. The reaction was studied by D. L. Hammick, who showed that when the lead oxide is just below visible redness, a dull red glow passes through the mass of oxide, and lead sulphide and sulphate are produced without sulphur trioxide or sulphur : $4PbO+4SO_2=PbS+3PbSO_4$. The black powder absorbs 8–17 per cent. of sulphur dioxide, and with a more prolonged heating (3 weeks), lead sulphate and some sulphur and sulphur trioxide are produced. It is possible that the secondary reactions : $PbS+PbSO_4=2Pb+2SO_2$, and $4Pb+PbSO_4=PbS +4PbO$, occur ; and that the sulphur and sulphur trioxide are due to the reac'ion indicated by J. Uhl : $Pb+6SO_2=PbS+4SO_3+S$. According to J. A. Wilkinson, the reaction between **sulphur trioxide** and lead oxide is attended by a white luminescence. The solubility of lead oxide in **sulphuric acid** is determined by the solubility of lead sulphate (*q.v.*) in that acid. A. Seyewetz and P. Trawitz found that **ammonium persulphate** converts lead monoxide into the dioxide.

Lead monoxide was found by E. C. Franklin [6] to be soluble in liquid **ammonia.** I. W. Fay and co-workers detected signs of reduction when the oxide is heated in ammonia gas for 6 hrs. at 299°. H. Leroux found that in an oxidizing atm., $6PbO+2Sb_2O_3+O_2 \rightarrow 2Pb+2(PbO)_2Sb_2O_5$; and in a closed vessel, $2PbO+Sb_2O_3 \rightarrow 2Pb+Sb_2O_5$. The oxide is readily soluble in **nitric acid,** forming lead nitrate. E. Müller and H. Barck observed no action with **nitric oxide** occurs up to 650°. F. Ephraim found **sodium amide,** $NaNH_2$, rapidly reduces lead oxide. T. B. W. Welsh and H. J. Broderson found that, at room temp., 100 e.c. of anhydrous **hydrazine** dissolve a gram of the red variety of lead oxide ; and E. Müller and H. Barck, that **nitric oxide** is slightly decomposed at 600°. H. Braconnet attributed the low solubility of lead in conc. **nitric acid** to the formation of a protective film of lead nitrate ; and U. R. Evans saw that conc. nitric acid converts litharge into a basic nitrate which dissolves at once when the acid is diluted. According to A. Oppenheim, a soln. of **phosphorus** in benzene reacts with a soln. of lead monoxide in alkali-lye, and, on heating, a black precipitate containing 98–99 per cent. of lead is formed. The product melts when heated in hydrogen gas without forming phosphine. A. Michaelis said that **phosphorus trichloride** does not react with lead oxide at 160°, but at a higher temp., a vigorous reaction occurs : $2PCl_3+6PbO=Pb(PO_3)_2+3PbCl_2+2Pb$. When lead oxide is

heated with an excess of **phosphoric acid,** T. Fleitmann found that lead tetra-metaphosphate is produced. P. Berthier found that **arsenic** is oxidized to the trioxide when it is heated with lead monoxide, some slag is formed, and if the litharge be not in excess arsenical fumes are also evolved. P. Berthier, and J. Percy reported that under similar circumstances **antimony** is similarly oxidized to the trioxide ; while with **bismuth,** part is oxidized, and unites with the lead oxide so that the latter loses its oxidizing power. According to H. Leroux, the composition of the regulus obtained when different proportions of antimony of 98·6 per cent. purity is heated with lead oxide is as follows :

Antimony .	0·4	0·8	1·6	3·2	5·2	6·4	8·74	12·8 per cent.
Regulus $\begin{cases} Sb \\ Pb \end{cases}$	—	—	—	0·51	2·24	13·02	18·43	21·62
	0·16	0·76	1·60	5·09	9·64	11·14	13·69	18·18

When litharge is heated with **arsenic trioxide,** both P. Berthier, and J. Percy reported that fusible, orange-yellow, glassy masses are produced, and the former concluded that the trioxide is not oxidized to the pentoxide since only a trace of metallic lead was formed. P. Berthier found that when heated with **arsenic pentoxide,** litharge formed very fluid liquids which solidified to crystalline enamels. He also showed that a mixture of lead oxide and **antimony trioxide** (5 : 1) is readily fusible. G. Tammann said that the reactions with arsenic and antimony trioxides begin respectively at 310° and 400°. For the action of arsenic, antimony, and bismuth sulphides, *vide supra.* Lead oxide is soluble in a boiling soln. of **copper nitrate,** with the precipitation of cupric oxide ; it is partially soluble in soln. of **cadmium nitrate,** and of **manganese nitrate** with the precipitation of the corresponding oxides. According to J. Persoz, lead oxide is not acted on by soln. of the **nitrates of silver, cerium, cobalt, nickel,** and **magnesium.** V. Kohl-schütter and A. d'Almendra found that lead monoxide is coated with silver when immersed in a soln. of silver nitrate.

Lead oxide is quickly reduced to the metal when heated to dull redness with **carbon**—charcoal, coal, or coke. According to J. Percy,[7] the temp. of reduction is below that at which carbon dioxide is converted to carbon monoxide by carbon, and hence carbon dioxide is evolved during the reduction. C. R. A. Wright and A. P. Luff gave 435° for the temp. of reduction with dense sugar-carbon, and 415° with a porous form ; and F. O. Doeltz and C. A. Graumann said that no perceptible reduction occurred in 30 mins. at 500° ; at 530°, some reduction occurred in 15 mins. ; and at 600° the reduction was very marked in 30 mins. Observations were also made by F. Kügelgen, R. Lüpke, and C. G. Baert. As shown by K. Stammer, and I. L. Bell, lead monoxide is completely reduced by **carbon monoxide.** G. C. Winkel-blech said that the reaction with lead oxide, made by the action of alkali-lye on a hot soln. of lead acetate, occurs not far above 100° ; C. R. A. Wright and A. P. Luff gave 160°–185° for the temp. of the reaction ; L. Peetz found the reaction very slow at 240°–300° ; F. Glaser said a temp. over 300° is necessary for the reduction of lead oxide by carbon monoxide. F. J. Brislee measured the rate of reduction of lead oxide by carbon monoxide, at 300°, and found a break in the time-reduction curve, corresponding with the formation of lead suboxide :

Time . .	0	3	6	7½	9	12	18	21	30 hrs.
Weight . .	2·000	1·957	1·936	1·919	1·917	1·913	1·901	1·896	1·861 grms.

I. W. Fay and co-workers found signs of reduction when lead oxide is heated in an atm. of carbon monoxide for 6 hrs. at 160°. The subject was studied by W. Fränkel and co-workers. The catalytic effect of lead oxide on the proportion of carbon monoxide obtained during the oxidation of carbon was discussed by E. Berger and L. Delmas. M. Dennstedt and F. Hassler, and O. L. Erdmann found that lead monoxide is not much affected by **carbon dioxide** in the cold, and at 100°, only a trace is absorbed. P. Termier found that in air both the rhombic and tetragonal forms of lead oxide absorb carbon dioxide with equal rapidity.

F. J. Brislee observed no sign of an equilibrium in the reaction: $Pb_2O + CO_2 = 2PbO + CO$; and $2Pb + CO_2 = Pb_2O + CO$. I. W. Fay and co-workers observed signs of reduction when lead oxide is heated in **methane** for 6 hrs. at 210°. H. N. Warren found that **calcium carbide** reduces lead oxide, and the reaction is accompanied by incandescence; a calcium-lead alloy is formed and carbon dioxide is evolved. H. Moissan added that no alloy is produced. J. Percy said that heated lead monoxide is reduced by **cyanogen**; and the oxide is also reduced by fusion with **potassium cyanide**; J. von Liebig, and H. Rose showed that potassium cyanate is formed at the same time. L. Hackspill and R. Grandadam found that with fused alkali cyanides under ordinary atm. conditions, lead and alkali carbimide are formed; but with cyanide in vacuo at 570°–575°, the sodium carbimide seems to decompose into sodium, nitrogen, carbon, and carbon monoxide and dioxide.

P. Sabatier and A. Mailhe [8] found that the vapours of the primary **alcohols** slowly reduce lead oxide above 260°, forming carbon dioxide and aldehyde; the action is more rapid at 325° when some aldehyde. is oxidized to acid. The acid forms a salt which is partially decomposed, forming ketone. H. Franzen and L. Hauck found that combustion occurs when lead monoxide is shaken with an aq. soln. of **formaldehyde.** V. Kohlschütter and H. Rösti found that a dil. soln. of **acetic acid,** or a $0.2N$-soln. of **tartaric acid** in amyl alcohol dissolves the yellow oxide faster than the red one. According to J. Pelouze, dry **glycerol**, or, according to E. Frémy, an aq. soln. of glycerol dissolves lead monoxide. When rubbed up with glycerol, lead monoxide forms a hard cement—say 50 grms. of lead oxide and 5 c.c. of glycerol—discussed by J. Persoz, O. Rost, T. Morawsky, C. H. Hirzel, H. E. Merwin, F. Bayer, etc. With **glycol,** also, T. Goldschmidt obtained a sticky mass which hardened to a cement; and a similar result is obtained with **phenol.** The compound with phenol was investigated by A. Laurent, F. C. Calvert, C. Grabe, and F. F. Runge. Lead oxide forms a sparingly soluble saccharate when treated with a soln. of **sugar.** A. Wohl found that the yellow form of litharge dissolves much more rapidly than the red form; the speed of soln. is fastest at 80° or 90°. J. Babé and W. Witter added that the solubility of the oxide in sugar soln. is much augmented if alkali or alkaline earth hydroxides be present. Lead oxide can be separated from arsenic oxide, etc., in virtue of its solubility in sugar soln. The solubility of lead oxide in sugar was examined by J. Peschier; in **glucose,** by J. Persoz; and in **dextrin,** by M. Lachaud, who found that lead oxide removes dextrin from its aq. soln. Lead oxide saponifies some of the **fatty esters,** forming lead soaps studied by W. Schrauth, and C. de la Harpe and W. A. van Dorp. Lead oxide is used as a drier since it hastens the setting of **linseed oil** by accelerating the absorption of oxygen; the reaction was discussed by W. Lippert, and L. L. Steele. R. Schweitzer found lead oxide to be soluble in **volatile oils**; W. Eidmann, insoluble in **acetone,** and L. Pincussohn, easily soluble in **pyridine** nitrate and hydrochloride. According to E. Seidl, P. I. Bean, C. O. Weber, and D. F. Twiss, lead oxide accelerates the hot vulcanization of **rubber.** Lead oxide was found by J. Aloy and C. Rabaut to inhibit the hydrolysis of benzoylated **cyanohydrins** by acetic acid. L. Kahlenberg and H. W. Hillyer found that when lead oxide is added to a boiling soln. of normal potassium tartrate, it is freely dissolved, and the soln. becomes alkaline owing to liberation of potassium hydroxide. Lead oxide is freely dissolved until the soln. contains lead oxide and potassium tartrate in mol. proportions; beyond this point, soln. takes place with difficulty only, but by long-continued boiling with fairly conc. soln. of the tartrate, about 1·24 mol. proportions of lead oxide can be dissolved in 1 mol. proportion of potassium tartrate. Where the ratio of oxide to tartrate is above unity, only half the potassium in the tartrate is liberated as hydroxide. From a conc. boiling soln. containing excess of lead, a preciptate is formed, on cooling, which is a basic lead tartrate of the formula $(PbO)_2C_4H_4O_6Pb$. From dil. soln., alcohol causes a precipitate which is probably a mixture of a tartrate of the proportion $Pb : K = 1 : 1$ with a more

basic lead tartrate. The normal tartrates of sodium, lithium, rubidium, and ammonium act like potassium tartrate, but thallium tartrate and potassium antimonyl tartrate do not act on lead oxide. When potassium ethyl tartrate is treated with lead oxide, it is saponified, but the resulting white lead salt goes into soln. only on adding an alkali hydroxide. Potassium hydrotartrate acts on lead oxide like ethyl potassium tartrate, only much more slowly ; the action is much accelerated by the addition of a little potassium hydroxide. Potassium malate, citrate, lactate, and glycerate take up but insignificant quantities of lead oxide, whilst potassium succinate, malonate, acetate, and propionate do not act on it. Potassium mucate and potassium saccharate act on lead oxide in a similar way to the tartrate, forming basic salts of the probable formulæ $C_6H_4O_8Pb_3$. The actions take place between two mols of lead oxide and one mol of mucate or saccharate. It is concluded that : (i) In order that its normal potassium salt may react readily with lead oxide, the organic acid must be dibasic, and must contain two, or a multiple of two, alcoholic hydroxyl groups ; (ii) The number of mols of the oxide with which one mol of salt readily reacts is equal to one-half the number of alcoholic hydroxyl groups contained in the acid. J. Béchamp found that water-free **acetic acid** unites directly with lead oxide. W. Kubel, and B. Kosmann found that soln. of **magnesium acetate** dissolve lead oxide in quantities dependent on the conc. and temp. of the soln. Conc. soln. deposit $Mg(C_2H_3O_2)_2.Pb(OH)_2$. Soln. of **lead acetate** dissolve lead oxide but no red-lead basic acetates are formed. The reaction was studied by F. Rochleder, D. Woodman, and W. Kubel. H. Rheinboldt and E. Wedekind studied the adsorption of **organic dyes** by lead oxide. A. J. Carlson and A. Woelfel found lead oxide to be soluble in **gastric juice ;** and J. Aub gave 1·1520 grms. per litre for the solubility of lead oxide in **blood serum.**

H. Moissan [9] found that **boron** reduces lead oxide when heated, and the mass becomes incandescent ; H. Moissan and P. Williams also showed that **calcium boride,** CaB_6, reduces lead oxide at a red heat. When fused with **boric oxide,** lead borate is formed (q.v.). H. N. Warren [10] said that **silicon** reduces lead oxide vigorously ; and a mixture of silicon, aluminium, and lead oxide explodes when heated. L. Kahlenberg and W. J. Trautmann found that lead oxide is rapidly reduced by powdered silicon when heated, $3PbO+Si=PbSiO_3+2Pb$; H. N. Warren's statement that a lead silicide is formed was not confirmed. E. Lay noted that lead oxide is reduced by **silicon hydronitride,** Si_2HN_3. For the action of lead oxide on **silica,** vide lead silicates. Quartz glass was found by F. Damm and F. Krafft to be strongly attacked by the vapour of lead oxide. J. C. J. Cunningham found that **alumina, asbestos,** and **porcelain** are rapidly attacked by fused lead oxide. R. Canaval opened up **silicates** for analysis by melting them with lead oxide. V. Vesely found the fusibility of **glass** is lowered by admixture with lead oxide. T. W. Hogg found that glass is attacked by lead oxide at a temp. below visible redness :

If a polished plate of glass be coated with oxide of lead, and then heated up to a temp. of scarcely visible redness, or even slightly below this, it will be found, after cooling and removing the surplus oxide, that the surface has been distinctly corroded, owing to the oxide having entered into combination with the constituents of the glass. The corroded parts produced by conducting the operation at this temp. possess quite a smooth surface, but if the corrosion be allowed to take place at a decided red heat the parts are rough and not unlike the effect produced by dry hydrofluoric acid. By soaking these corroded plates in a soln. of ammonium sulphide the lead may be converted into sulphide of lead, and the corrosion may be so varied under different conditions that brilliant mirror-like films may be obtained of considerable durability and of sufficient thickness to be quite opaque, or so thin that light of a brownish hue is transmitted. Using lead oxide as a pigment on a glass plate, and if another plate, preferably of some dark blue or ruby tinted glass, be placed immediately over it but prevented from actual contact by suitable means—and the two plates heated for about an hour to a temp. of scarcely visible redness, the upper glass always has its polish so altered that a distinct reverse of the writing appears upon it, more or less sharp according to the distance between the two surfaces.

An aq. soln. of lead oxide was found by M. Pleissner to attack glass at

25°–40°, so strongly that it appeared to have been etched by hydrofluoric acid. E. J. Kohlmeyer discussed the attack of firebricks by lead vapours, and he found the **spinel**, 3MgO.Al$_2$O$_3$, resisted the attack best. P. Berthier obtained an opaque mass by fusing **titanic oxide** with eight times its weight of litharge. G. Tammann found that the reaction with silica, titania, and zirconia begins respectively at 580°, 470°, and 700°.

According to J. L. Gay Lussac and L. J. Thénard,[11] and J. von Liebig, **potassium** or **sodium**, just above its m.p., vigorously reduces lead oxide to the metal ; and M. Rosenfeld found that sodium, reduced to a fine state of subdivision by trituration with a suitable solid, when mixed with lead oxide ignites spontaneously, leaving a residue of metallic lead. J. A. Wilkinson observed no luminescence during the reduction of lead oxide by sodium. F. M. Perkin found that lead oxide is readily reduced by **calcium ;** C. Winkler, by **magnesium ;** and T. Goldschmidt showed that the reduction by **aluminium** is explosively violent. C. E. Wait found that **silver** reacts with lead oxide, forming lead and silver oxide ; E. J. Kohlmeyer showed that molten lead oxide can dissolve 3–6 per cent. of silver which is present as silver oxide ; the f.p. is at the same time depressed—*vide* silver plumbite. K. Williams found that in assaying silver if an excessively high proportion of litharge is present in the flux, low results are obtained owing to the dissolution of silver in the slag. P. Berthier showed that litharge oxidizes many metals and metalloids. Observations on **copper, zinc, tin,** and **iron** were reported by P. Berthier, and J. Percy. Iron, **nickel,** and silver were found by J. C. J. Cunningham to be attacked by heated litharge. E. J. Kohlmeyer, and J. C. J. Cunningham noted that **platinum** is rapidly attacked by lead oxide at 1000°–1175° ; and about 3 per cent. of platinum can dissolve in the molten oxide.

M. Höhnel observed that when lead oxide is stirred into a mixture of **sodium dioxide** and a little water, sodium plumbate, Na$_2$PbO$_3$.4H$_2$O, is formed. J. A. Hedvall and N. von Zweigbergk showed that a higher oxide of lead, not the dioxide, is formed when lead oxide is heated with **barium dioxide,** and at the same time, some barium orthoplumbate is formed over 500°. P. Berthier investigated quantitatively the action of heat or rather the fusibility of mixtures of litharge with **cuprous and cupric oxides, zinc oxide, iron oxides, manganese oxide,** and **stannic oxide**—*vide infra.* plumbites ; and F. de Carli, on **molybdic, tungstic, vanadic, and chromic oxides.** G. Tammann said that the reaction with molybdic oxide begins at 460° ; with tungstic oxide, at 480° ; with zinc sulphate, at 490° ; with magnesium sulphate, at 490° ; with copper sulphate, at 495° ; with silver sulphate at 425° ; and with silver nitrate at 175°. The reaction with zinc sulphide was represented : ZnS+PbO=ZnO+PbS+12·6 Cals. ; with ferric sulphate, 15·2 Cals. are evolved at 460° ; and with ferrous sulphate, 11 Cals. at 540°. The reaction with vanadium pentoxide sets in at 325°. J. Milbauer found that when litharge and **chromic hydroxide** are heated together, lead chromate is formed. J. A. Hedvall observed no sign of combination when a mixture of **cobalt oxide** and litharge is heated to 1100°–1300°. According to G. Tammann, if lead oxide be kept under a soln. of **silver nitrate** or **sulphate,** it is gradually blackened in diffuse light, the action is rapid in sunlight ; and silver oxide is formed.

§ 15. Lead Hydroxides

According to M. Pleissner,[1] normal **lead hydroxide,** $Pb(OH)_2$, separates when a soln. of lead acetate is added to one of ammonium, sodium, or barium hydroxide. This hydroxide may remain in the liquor as the solid phase, but when separated from the soln. it decomposes into **lead dioxydihydroxide,** $Pb_3O_2(OH)_2$, in the cold, and into lead monoxide, PbO, if heated. At 100°, only lead monoxide is stable in the binary system : $PbO-H_2O$. The passage of the dioxydihydroxide to the monoxide can be effected at a low temp. by light, and by saturating the liquid with oxygen. According to A. Ditte—*vide supra*—while the normal hydroxide is first precipitated at 25°, by adding an aq. soln. of potash-lye to a soln. of a lead salt, the potassium hydroxide transforms the normal hydroxide into the dioxydihydroxide. The preparation of the normal hydroxide has been reported by A. Payen, V. Kohlschütter and co-workers, and E. Müller. Besides lead dioxydihydroxide, another basic hydroxide, namely, *lead oxydihydroxide,* $2PbO.H_2O$, or $Pb_2O(OH)_2$, has been reported by L. Schaffner, A. Ogata and T. Kai'un, and C. Lüdeking.

M. Traube-Mengarini and A. Scala found that distilled water acts on lead in vacuo, and **colloidal lead hydroxide** is formed. The clear sol becomes turbid when exposed to air. V. Kohlschütter and H. Roesti made it by pouring a soln. of lead acetate into one of ammonia. N. G. Charterji and N. Dhar said that when lead hydroxide dissolves in alkali hydroxide a large proportion of colloidal lead hydroxide is formed. M. Kimura found that when lead at a red heat is poured into cold water, some colloidal hydroxide is formed. V. Kohlschütter, and A. Scala said that filter-paper adsorbs the hydroxide from the sol. B. Szilard found that lead hydroxide is peptonized by thorium nitrate, forming a colloidal sol. N. R. Dhar and S. Ghosh found that the hydroxide is peptized by alkali-lye with sugar, starch, or glycerol.

Most of the reported methods of preparing lead hydroxide, refer to the dioxydihydroxide. Thus, according to P. A. von Bonsdorff, when lead is exposed to the action of water, and of air freed from carbon dioxide, white flakes of lead hydroxide are formed. J. Tünnermann made it by dropping a soln. of lead acetate into an excess of ammonia until a permanent precipitate is formed ; and drying the washed product at a gentle heat. A. Payen saw that the precipitate should be washed out of contact with air, and dried at 15°. He also obtained crystals of the anhydrous oxide and of hydroxide by mixing 4 vols. of water sat. at 30° with lead acetate, 400 vols. of boiling water, and 4 vols. of aq. ammonia. The two compounds were separated by levigation. He also mixed 100 vols. of water sat. at 25° with lead acetate, 60 vols. of cold water freed from air by boiling, and 4 vols. of aq. ammonia diluted with 60 vols. of air-free water. The mixture was kept at 30° for 24 hrs. E. Mitscherlich precipitated the soln. of a lead salt with potassium or sodium hydroxide ; G. J. Mulder poured off the mother-liquor, boiled the precipitate with potash-lye for some time, and dried the washed product at 100°. G. C. Winkelblech added that if potassium hydroxide be added to lead nitrate or acetate, even in excess and aided by heat, a basic salt, not the hydroxide, is precipitated. According to W. Böttger, the hydroxide formed by the action of aq. ammonia on a soln. of lead acetate, or of baryta-water on one of lead nitrate, has a variable composition ; S. Glasstone said that the product is a basic salt ; and E. Euston found that lead hydroxide forms adsorption complexes with barium sulphate or carbonate, calcium or lead carbonate, and zinc dihydroxycarbonate. H. T. S. Britton showed that lead hydroxide is precipitate by alkali hydroxide when the H-ion conc. is about 10^{-8}.

R. F. Jackson studied the ternary system : lead acetate, lead oxide, and water at 25°, and found that lead hydroxide, $Pb(OH)_2$, is the only solid phase in equilibrium with soln. containing less than 4·8 per cent. of lead acetate. W. Herz found that when lead oxide is shaken with an aq. soln. of alkali halide and water, a pasty mass

is formed; but when the equilibrium is approached from the other side : $PbCl_2$ $+2KOH \rightleftharpoons 2KCl+Pb(OH)_2$, the constant $[PbCl_2][KOH]^2/[KCl]^2=0\cdot0073$; for the corresponding reaction with aq. ammonia, $0\cdot00082$; and with methylamine, $0\cdot00066$. M. Pleissner obtained lead oxide by the action of baryta-water on a soln. of lead acetate ; and basic nitrate and basic chloride respectively with soln. of lead nitrate and chloride. W. B. Priest heated a suspension of lead sulphate in lime-water, until the liquid had a neutral reaction, and removed the resulting calcium sulphate by levigation. A. Ditte obtained crystals of this hydroxide by saturating with precipitated lead hydroxide a soln. containing 100–300 grms. of K_2O in a litre of water, and on raising the temp., this hydroxide was precipitated. S. Hughes obtained lead hydroxide by grinding lead fume with a soln. of sodium hydroxide. A. Ditte treated hydrated lead dioxide with a soln. of potassium iodide, and obtained lead hydroxide. R. Lorenz prepared this hydroxide by electrolyzing an aq. soln. of alkali chloride or nitrate using a platinum plate as cathode, and a plate of lead as anode. The electrolyte was continually stirred during the electrolysis. Modifications of the process were made by W. Hartmann, H. Sjögren, and T. G. Timby. Analyses by J. Tünnermann, A. Payen, E. Mitscherlich, and G. J. Mulder correspond with $3PbO.H_2O$, i.e. lead dioxyhydroxide, $Pb_3O_2(OH)_2$, or, as S. Glasstone expresses it, $Pb(HPbO_2)_2$—**lead hydroplumbite**. A. Ogata and T. Kai'un do not recommend lead nitrate for the preparation of lead hydroxide, but with lead acetate a product $2PbO.H_2O$ is formed.

M. F. Heddle described minute crystalline scales of a mineral which he named *hydroplumbite*, and which was found with cerussite and pyromorphite on galena from Leadhills. The composition was reported as $3PbO.H_2O$; but the evidence is unsatisfactory. An approximation to this product was said to be formed in rhombic crystals by allowing the precipitate, produced by adding ammonia to a soln. of lead acetate, to stand under water for a long time.

S. Glasstone found that no known method of preparation yields a substance which has definitely the composition $Pb(OH)_2$, $3PbO.H_2O$, or $2PbO.H_2O$. The products he obtained were either individuals with the composition $5PbO.2H_2O$, or $8PbO.3H_2O$, or solid soln. of two or more simple hydrates. The composition depends on the temp. and conc. of the precipitants, for these determine the amount of adsorbed water. He explains the chemical and physical properties of the so-called hydrated oxide by assuming that it is a *lead plumbite*, $Pb(HPbO_2)_2$, where the *plumboformic acid*, $H.PbO.OH$, is analogous to formic acid, $H.CO.OH$. The appearance of lead dioxydihydroxide varies with its mode of preparation. Usually, it appears as a white powder, which, under the microscope, consists of crystals which A. Payen regarded as strongly refracting octahedra, and A. Ditte, as transparent hexagonal prisms. According to R. S. Owens, crystals of lead hydroxide can be precipitated by adding a soln. of sodium hydroxide to an equal vol. of one of lead acetate at a given temp. The size of the crystals can be varied within rather wide limits by varying the temp. and conc. of the soln. Thus, at 20° :

Conc. of soln.	N-	$\frac{1}{2}N$-	$\frac{1}{4}N$-	$\frac{1}{8}N$-	$\frac{1}{16}N$-	$\frac{1}{32}N$-
Diam. crystals, mm. $\times 10^3$	1·0	1·5	7·5	25·0	37·5	white p.p.

By varying the temp. of, say, the $\frac{1}{8}N$-soln., at 20° the diam. was 25 mm. ; at 33°, 30 mm. ; at 47°, 50 mm. long and 7·5 mm. wide ; at 66°, 17·5 mm. for the crosses, and 12·5 mm. for the cubes. A. Ditte gave 7·592 at 0° for the sp. gr. of the crystals. M. Pleissner found that when confined with water in a sealed tube and exposed to sunlight, or heated for 3 hrs. at 100°, the crystals pass into orange-yellow flakes of lead monoxide. A. Ditte also noted the change which occurs in sunlight. E. Mitscherlich thought that the compound retains its water and colour at 100°, and A. Payen said that water begins to come off at 130°, and is all expelled at 145°. S. Glasstone found no loss in weight occurs in vacuo at ordinary temp.; and he calculated the free energy of the reversible reaction, $PbO.nH_2O \rightleftharpoons PbO+nH_2O$, to be 965·4 joules per mol of lead monoxide at 20°. He observed no appreciable vap.

press. for the partly decomposed hydrated oxide at room temp., and this is in agreement with the fact that the hydrated oxide does not lose weight in a vacuum desiccator. If the vap. press. of N-NaOH is 15 mm., and that of the hydrated oxide is p mm., then, on the assumption that the reaction is reversible, $\log p = 0.17241 \, x + \log 15$; for $Pb(OH)_2$, $x=1$ and $p=22$ mm.; for $2PbO.H_2O$, $x=4\frac{1}{3}$, and $p=33$ mm.; for $3PbO.H_2O$, $x=\frac{2}{3}$, and $p=49$ mm. M. Pleissner noted that if heated with water in a sealed tube at 100°, it gives orange-red crystals of lead oxide, and, added V. Kohlschütter and H. Roesti, the crystals are pseudomorphs after $3PbO.H_2O$. J. J. Berzelius noted that the compound reacts alkaline to litmus, and M. Pleissner, to phenolphthalein, and to iodeosin. J. Sehnal said that the compound dissolves in hot and cold water, and he gave 138·5 mgrms. Pb per litre for the solubility at 20°; F. Kohlrausch gave 0·4 millimol per litre at 18°; M. Pleissner, 0·45 millimol, or 100·5 mgrms. PbO, per litre at 18° when the solid phase is $Pb_3O_2(OH)_2$; W. Herz, 0·93 $\times 10^{-4}$ mol per litre at 25°; W. Böttger, 0·092 millimol, or 20·6 mgrms. per litre at 20°. The values of F. Kohlrausch, W. Herz, and W. Böttger calculated from the electrical conductivity are based on assumption as to the nature of the ionization. M. Pleissner's values for the mol. conductivity, μ, the percentage degree of ionization, a, and the ionization constant, K, are:

Pb-mgrms. per litre	.	.	.	93·3	106·0	111·4	124·4	131·4
μ .	.	.	.	60·5	60·3	59·1	57·6	57·6
a $\begin{cases} Pb(OH)^2 \rightleftharpoons Pb(OH)^\cdot + OH' \\ Pb(OH)^\cdot \rightleftharpoons Pb^{\cdot\cdot} + OH' \end{cases}$		.	.	27·0	26·9	26·4	25·7	25·7
		.	.	12·9	12·8	12·5	12·2	12·2
K $\begin{cases} Pb(OH)^2 \rightleftharpoons Pb(OH)^\cdot + OH' \\ Pb(OH)^\cdot \rightleftharpoons Pb^{\cdot\cdot} + OH' \end{cases}$		.	.	4·50	5·07	5·10	5·35	5·62
		.	.	20·0	25·2	25·3	29·9	33·4

E. Berl and G. Austerweil estimated that the ionization in a soln. with 0·262 millimol of lead hydroxide per litre is complete. As previously indicated, M. P. Applebey and R. D. Reid estimated the ionization constant of H_2PbO_2 regarded as an acid— to be 0.33×10^{-11} to 0.39×10^{-11}, and S. Glasstone gave 1.35×10^{-12} at 25°; and for the solubility product, the latter gave 0.82×10^{-15}, and the former 0.47×10^{-15} to 0.91×10^{-5}. W. R. Cooper discussed the *lead hydroxide accumulator* in which more conc. sulphuric acid is employed as electrolyte than is the case with the ordinary lead dioxide accumulator. There is a greater output from the former cell, but the variation in voltage over the discharge is greater.

Lead hydroxide is amphoteric, behaving both as a weak acid and as a weak base. W. Biltz and F. Zimmermann said that lead hydroxide is a feebler base than magnesium hydroxide, and, according to J. K. Wood, lead hydroxide is more basic than zinc and beryllium hydroxides, since, for the weaker hydroxyl-ion, the ionization constant for beryllium hydroxide is 5.2×10^{-11}; for zinc hydroxide, 145.0×10^{-11}; and for lead hydroxide, 3090.0×10^{-11}. The soln. of lead hydroxide in aq. soln. of the hydroxides of the alkalies and alkaline earths furnishes **plumbites**, M_2PbO_2, or $Pb(OK)_2$—*vide infra*. At ordinary temp., V. Kohlschütter and H. Roesti observed only a partial transformation to plumbite with $2N$- to $10N$-NaOH; $10N$-NaOH reddens the hydroxide; $2N$- to $12N$-soln. of ammonia does not change the product. W. Herz added that the solubility of lead hydroxide in sat. soln. of the alkali hydroxides, is not altered by desiccation at 60°–70°; and that it is completely dissolved when the soln. has 8·5–8·8 mols of hydroxyl groups for one gram-atom of lead. G. Carrara and G. B. Vespignani found that if the potash-lye be not in too great excess, $Pb(OH)(OK)$, is formed—*vide infra*. R. C. Wells found that lead hydroxide is more soluble than the hydroxides of copper, zinc, aluminium, and iron (ic), and less soluble than those of silver, calcium, magnesium, manganese, iron (ous), and nickel.

Ordinary lead salts, in which the lead oxide acts as a base, are produced by the action of acids on lead hydroxides. A. Jäger showed that dil. hydrofluoric acid alone can dissolve a little lead hydroxide. M. Pleissner found that iodine is adsorbed. and potassium iodide decomposed, by lead hydroxide. J. Kersten found that alkali chlorides in soln. are quantitatively converted into the oxychloride, $5Pb(OH)_2.PbCl_2$,

and alkali hydroxide ; G. André found that with chlorides of the alkaline earths, complex oxychlorides are formed.   H. Böttger found that with sodium polysulphide, lead sulphide, alkali thiosulphate, as well as some free alkali hydroxide, are formed. A. Geuther considers the thiosulphate to be produced by a secondary reaction between sulphur and alkali hydroxide.   D. Strömholm showed that soln. of ammonium or potassium fluoride or chlorate give no basic salts ; 0·05N-soln. of potassium chloride, bromide, or iodide produce basic salts ; soln. of borax do not attack the hydroxide ; and a soln. of potassium cyanide dissolves a little hydroxide. According to W. Biltz and F. Zimmermann, lead hydroxide becomes violet-brown when immersed in $\frac{1}{10}N$-AgNO$_3$ owing to the precipitation of a little silver hydroxide ; with $\frac{1}{10}N$-Hg(NO$_3$)$_2$, a yellowish-red coloration is acquired owing to the formation of a little mercuric hydroxide.   L. Kahlenberg found that hydroxylic organic substances—like tartaric, malic, or lactic acids, glycerol, or sugar—form complexes. The action on glycerol was investigated by T. Morawsky, and E. Fischer and V. Tafel ; and the action of formaldehyde, by H. Franzen and L. Hauck.   D. Strömholm found that soln. of ammonium oxalate, or potassium picrate, produce basic salts ; alkali acetate, methylethyl-sulphonate, benzosulphonate and naphthosulphonate have very little action ; while the alkali succinate, camphorate, and phthalate also have very little action.   R. Haller showed that the hydroxide readily adsorbs dye-stuffs.   M. Pleissner said that glass is strongly attacked when treated with an aq. soln. of lead hydroxide.

L. Schaffner reported the hydrated oxide, 2PbO.H$_2$O, or **lead oxydihydroxide,** Pb$_2$O(OH)$_2$, to be formed when a soln. of lead acetate is treated with potash-lye. S. Glasstone regards this compound as a basic lead plumbite, **lead hydroxhydroplumbite,** Pb(OH)HPbO$_2$.   C. Lüdeking prepared it in large crystals by boiling lead oxide with a conc. soln. of potassium hydroxide, and allowing the cold soln. to absorb carbon dioxide slowly from the air.   J. Löwe said the alkali should be in excess.   As the potassium hydroxide becomes converted into carbonate, short, thick, well-developed, colourless, transparent, tetragonal crystals are deposited ; the axial ratios are $a : b : c = 1 : 1 : 0·824$.   The crystals are highly refractive.   The oxydihydroxide has an alkaline reaction, and becomes opaque when exposed to the air owing to the formation of carbonate ; it becomes yellow when heated, and retains its original crystalline form.

R. Weinland and F. Paul[2] referred the various basic salts of lead to those having the bivalent groups, [Pb(OH)$_2$Pb]$^{··}$;   [Pb{(OH)$_2$Pb}$_2$]$^{··}$;   or [PbO.Pb(OH)$_2$Pb]$^{··}$; and to the tervalent groups, [Pb$_4$(OH)$_5$]$^{···}$, and [Pb$_6$(OH)$_9$]$^{···}$.

§ 16. The Plumbites

E. Aston [1] was unable to isolate **sodium plumbite, or potassium plumbite,** and the evidence for the existence of these salts is determined by the behaviour of soln. of lead oxide in alkali-lye. C. W. G. Karsten found that lead monoxide dissolves in a soln. of alkali hydroxide or carbonate, forming a yellow liquid, which does not crystallize. G. Grube said that freshly precipitated lead dioxydihydroxide gives with $8N$- to $12N$-KOH a soln. with 0.1–0.2 mol K_2PbO_2. J. Milbauer found red-lead, dissolved in alkali-lye, gives a mixed soln. of plumbite and plumbate. O. Seidel, and S. Meunier found that lead oxide likewise dissolves in molten potassium hydroxide—some alkali plumbate is formed at the same time. M. H. Klaproth found that on cooling the colourless soln. of white-lead in boiling alkali-lye, small silvery-white scales are deposited, and they acquire a grey colour on exposure to air. The mother-liquor yields a brownish-red scaly mass which redissolves in water with the exception of a few scarlet scales.

There is evidence of the existence of compounds in which lead monoxide acts as an acid anhydride, forming a series of salts called **plumbites,** M_2PbO_2, where M represents a monad radicle. In his memoir: *Sur la combinaison des oxides métalliques avec les alkalies et le chaux*, C. L. Berthollet showed that certain metal oxides exercise the functions of an alkali towards the acids, and they can act as acids with the alkalies. T. Bergman found that alkali-lye dissolves lead oxide; and C. L. Berthollet, that lime-water dissolves lead oxide, and when the soln. is conc., it yields a crystalline solid. A. Hantzsch said that the conductivity of alkaline soln. of the metal hydroxide, and the rate at which this soln. saponifies ethyl acetate give no grounds for G. Grube's, and C. Liebenoff's assumption that PbO_2''-ions exist in soln.; the plumbites all appear to be salts of a monobasic acid analogous with the corresponding stannites and germanites. Lead hydroxide as a base is stronger than beryllium hydroxide, and it might be anticipated that the acid would be weaker. This is not the case, and he said that this is explained by assuming that there is an internal constitutive change by which the lead becomes quadrivalent and the acid character becomes strengthened. He therefore regards the plumbites as salts of a kind of *plumboformic acid*, H.PbO.OH, analogous with formic acid H.CO.OH, and not as salts of *plumbous acid*, H_2PbO_2.

$$O=Pb{<}^{H}_{OH} \qquad\qquad\qquad Pb{<}^{OH}_{OH}$$
Plumboformic acid, H.PbO.OH. $\qquad\qquad$ Plumbous acid, H_2PbO_2.

W. Herz found that equilibrium is but slowly attained when dried lead hydroxide is employed. J. Raubenbauer found that the quantity of lead hydroxide dissolved by sodium hydroxide soln. varies with the conc., and there is a maximum value for the solubility when the at. ratio Pb : Na is 1 : 14. The existence of the maximum

is attributed to two independent factors : (i) the hydrolysis decreasing as the soln. becomes more conc. ; and (ii) the dehydration of the hydroxide by the conc. alkali-lye producing a less soluble monoxide. S. Glasstone obtained for conc. in mols per litre at 25° :

Conc. NaOH	Conc. PbO.nH$_2$O	Conc. KOH	Conc. PbO.nH$_2$O	Ratio NaOH : PbO.nH$_2$O	Ratio KOH : PbO.nH$_2$O
0·9985	0·0620	0·9985	0·0631	16·1	15·8
0·1177	0·00881	0·1177	0·00892	13·4	13·2

According to E. Bert and G. Austerweil, the solubility of lead oxide, in mol per litre, in soln. of sodium hydroxide, is :

N-NaOH	.	0·0510	0·1024	0·2035	0·4794	1·0045	1·9872	4·9705
Mol PbO (18°) .		0·0041	0·0067	0·0123	0·0273	0·0560	0·1008	0·2316
Mol PbO (74°) .		0·0034	0·0067	0·0180	0·0362	0·0807	0·1430	—

They infer that in soln. containing less than a mol of NaOH per litre, the lead oxide dissolves as **sodium hydroplumbite,** NaHPbO$_2$, and in more conc. soln. some normal plumbite, Na$_2$PbO$_2$, is formed. They calculate the ionization constant of the monobasic acid H$_2$PbO$_2$ to be $1·1 \times 10^{-12}$ at 18° ; S. Glasstone gave $1·3 \times 10^{-12}$ at 20° ; and M. P. Appleby and R. D. Reid gave $0·33 \times 10^{-11}$ for the red form of lead oxide at 20°, and $0·39 \times 10^{-11}$ for the yellow form. According to J. K. Wood, with different soln. of sodium hydroxide, the proportion of lead hydroxide dissolved is nearly in the at. ratio Pb : Na=1 : 15 for soln. of different conc., and that the hydrolysis constant is 0·0035, so that 0·1N-Pb(OH)(ONa) is 17 per cent. hydrolyzed.
FIG. 64.—Equilibrium Diagram for the System PbO–H$_2$O–NaOH.

E. Müller and co-workers' equilibrium diagram for the system lead hydroxide and oxide, and alkali plumbite and hydroxide, is shown in Fig. 64. The curves AC and BD refer to the yellow and red oxides and the points of intersection of these lines with FG, represent the transformation of the yellow and red oxides into the alkali plumbite. The curve HI represents the solubility of lead hydroxide in alkali-lye of different conc. ; and FG, of alkali plumbite. To the right of HI, the hydroxide passes into oxide, and to the left, the oxide passes into hydroxide. N. G. Chatterji and N. R. Dhar found that the peptization of lead hydroxide by alkali-lye is a case of true peptization and not of chemical combination.

A. C. Cumming measured the potential of lead against a soln. of 0·0576 mol of lead oxide in a litre of N-NaOH and found 0·539 volt referred to the normal hydrogen electrode, while for 0·0089 mol in a litre of 0·1N-NaOH, he obtained 0·484 volt. He considered that the soln. contained NaPb(OH)$_2$. For S. Glasstone's, and M. P. Appleby and R. D. Reid's observations, *vide* lead oxide. G. Carrara and G. B. Vespignani measured the mol. conductivity, μ, of soln. with a mol of potassium hydroxide, in v litres, and of soln. with 0·5621 grm. of lead oxide per litre, at 25° :

v . . .	5	10	20	40	80	160	320	640	1280
μ {KOH . .	217·71	221·48	225·30	229·38	231·18	232·75	232·5	—	—
{KOH+PbO	184·07	193·42	195·38	200·12	201·88	202·40	206·40	204·16	199·68

and they inferred that the soln. probably contains **potassium hydroplumbite,** Pb(OH)(OK). G. Grube found the normal potential of lead against K_2PbO_2 in $8\cdot42N$-KOH, at $18°$, is $-0\cdot613$ volt; and in a molar soln., there is $2\cdot05\times10^{-17}$ gram-ion per litre. S. Glasstone found the potential of the electrode $Pb \mid PbO.nH_2O$, N-NaOH against the $Hg \mid HgO$, N-NaOH electrode to be $0\cdot554$ volt at $20°$, where the corresponding value for lead monoxide is $-0\cdot559$ volt at $20°$. The nature of the oxidation product is determined by the character of the electrode material. Under the same conditions, yellow, flocculent lead sesquioxide is formed with palladium electrodes, while with nickel or iron electrodes the product is of a darker colour and is powdery. Secondary and side reactions take place with electrodes of zinc, tin, aluminium, chromium, and manganese. Oxidation does not always take place, for, according to conditions, simple reduction or alternate oxidation and reduction may occur.

G. Grube found that air passed into an alkaline soln. of a plumbite, in which was dipped a platinum plate, does not form plumbate. G. Grube electrolyzed a soln. of potassium plumbate and obtained a deposit of lead dioxide. According to F. Jirsa, the electrolysis of a N-soln. of potassium hydroxide between lead electrodes by means of an alternating current of 49 periods brings about the formation of potassium plumbite as the only product. The plumbite may be electrolytically oxidized to plumbate if electrodes of copper, silver, gold, cadmium, magnesium, mercury, nickel, iron, platinum, and palladium are used, but no oxidation occurs when lead, bismuth, cobalt, thallium, or carbon is used. V. Zotier found that when a soln. of lead oxide in sodium hydroxide is treated with hydrogen dioxide, lead dioxide is first formed, which then reacts with some hydrogen dioxide, giving rise to oxygen and some lead oxide, so that the precipitate produced usually consists of both oxides. With increasing quantities of hydrogen dioxide, the quantity of lead dioxide rises to a maximum, and then remains constant. For the quantity of hydrogen dioxide necessary to produce this maximum quantity of lead dioxide, the reaction is expressed by this equation, $10PbO+10H_2O_2=10H_2O+4PbO_2+6PbO+3O_2$. The amount of lead dioxide formed diminishes with rise of temp., slightly up to $30°$, considerably from $30°$ to $60°$, and very rapidly above $60°$. At about $90°$–$95°$ lead dioxide is formed, but disappears immediately, due to the second phase of the reaction. Water has but little influence on the reaction, and considerable quantities must be introduced before differences greater than those due to experimental error are noticeable. The quantity of lead dioxide formed diminishes as the ratio NaOH : PbO increases, and with sufficient sodium hydroxide the lead dioxide formed is immediately decomposed. R. F. Weinland and A. Gutmann found that sodium thiosulphate, at ordinary temp. or when heated, does not act on sodium or potassium plumbite. M. H. Klaproth found that metallic lead is precipitated from the soln. by phosphorus and zinc, but not by iron; and N. W. Fischer showed that tin precipitates all the lead from a soln. of potassium plumbite. H. Erdmann and P. Köthner said that acetylene gives no precipitate with a soln. of potassium plumbite; an alkaline soln. of chromic oxide was found by G. Chancel to give a precipitate; and A. Streng obtained precipitates with similar soln. of stannous or stannic oxide, arsenious oxide, and antimonous oxide. T. Rondelli found that iron and steel are superficially oxidized by a soln. of sodium plumbite. J. G. F. Druce could not obtain a *methyl plumbite* by treating potassium plumbite with methyl iodide; only potassium and lead iodides, and methyl alcohol were formed. According to A. Bonnet, when cotton is mordanted with an alkali plumbite and then washed with a large quantity of water, dissociation takes place, and the fibre becomes charged with lead dioxide, which partially oxidizes and destroys it. A similar change takes place with plumbates, except that the fibre is not oxidized, lead monoxide being deposited.

According to C. W. G. Karsten,[2] lead oxide dissolves in aq. ammonia or ammonium carbonate, forming a dark yellow liquid which decomposes on evaporation. G. C. Wittstein said that the soln. is turbid. There is no

evidence of an *ammonium plumbite* or of *lead amminoxide*, although F. C. Calvert reported such.

According to C. W. G. Karsten,[3] lead oxide unites with cuprous oxide when the two compounds are fused ; and a similar product, *cuprous plumbite*, is said to be formed by fusing cupric oxide with a proportionate quantity of lead ; if the lead is in excess, some copper is also formed. A similar product is obtained by fusing copper with lead oxide. An alloy of copper and lead is formed at the same time, and part of the lead remains unreduced even when the copper is in large excess. The dark-coloured, fused mass formed in the cupellation of cupriferous silver with lead is said to contain *cupric plumbite*. S. Glasstone failed to make copper plumbite. P. Berthier examined the fusibility of mixtures of lead oxide with cuprous and cupric oxides. J. C. J. Cunningham melted mixtures of lead oxide (m.p. 875°)
FIG. 65.—Freezing-point Curve of Mixtures of Lead and Cupric Oxides.

and cupric oxide and found a eutectic of 698° and about 30 per cent. of cupric oxide. The ascending branch on the cupric oxide side could not be determined—Fig. 65. No evidence of chemical combination appeared. F. Wöhler described a compound of silver and lead oxides with the composition of a *silver plumbite*, $Ag_2O.2PbO$, which he obtained by adding potassium hydroxide and silver nitrate to a soln. of potassium plumbite, or potassium hydroxide to a mixed soln. of silver and lead salts. The yellow precipitate is freed from free lead oxide by the solvent action of an excess of the precipitant. The product readily dissolves in nitric acid ; it blackens in light ; decomposes into lead oxide and metallic silver at a red heat, and is reduced to an alloy of silver and lead when heated in a current of hydrogen.

J. Krutwig's product, using sodium hydroxide as precipitant, has a composition $Ag_2O.PbO.2H_2O$. H. Rose, and E. Aston found the precipitate to have a variable composition ; and H. Rose also obtained a product of variable composition by the action of moist silver oxide on a soln. of lead nitrate or acetate. According to F. Bullnheimer, **silver plumbite,** $Pb(OAg)_2$, is produced by adding excess of a soln. of lead nitrate in aq. potash-lye to a soln. of silver nitrate in aq. potash-lye, with just so much ammonia that no precipitate forms at once when this soln. is mixed with the lead soln., about 2 grms. of lead nitrate being added for every gram of silver nitrate. The mixture is warmed gently on the water-bath, when a crust of small needles with the above composition is deposited. P. Groth gave for the axial ratios of the rhombic crystals $a : b : c = 0.73 : 1 : 0.79$. F. Bullnheimer found the sp. gr. to be 8·6 ; the crystals are stable towards light, but when heated to 140°–150, they become greyish-black and only lose a little in weight at 400°. Decomposition into silver, lead oxide, and oxygen occurs on melting. The plumbite is insoluble in water, aq. ammonia, or potash-lye ; it is precipitated by potassium hydroxide as a yellow powder from its soln. in acetic acid. It is readily soluble in dil. nitric acid, conc. sulphuric, hydrofluoric, or hydriodic acid ; it is very stable towards dil. sulphuric or hydrochloric acid. When triturated, it gives an olive-green powder.

According to C. W. G. Karsten,[4] and C. L. Berthollet, lead oxide dissolves in a hot soln. of lime-water, forming a yellow liquid, which, on evaporation, furnishes small spiculæ, once thought to be *calcium plumbite*. They have a caustic taste, and are slightly soluble in water, forming a soln. which blackens wool, nails, and horn. C. W. G. Karsten also found that baryta-water forms with lead oxide a deep yellow soln. of *barium plumbite*, which decomposes into its constituent oxides on evaporation. E. Aston was not able to prepare *strontium plumbite* or the plumbites of the other alkaline earths by adding a conc. boiling soln. of the hydroxide to a lead salt. Crystalline scales of lead oxide were deposited in every case.

G. Grube obtained a mixture, $2MgO.PbO.3H_2O$, or *magnesium plumbite*, by the oxidation of magnesium hemiplumbide in the presence of moisture. P. Berthier heated mixtures of lead and zinc oxides, but no *zinc plumbite* was isolated. S. Glasstone attempted to make *mercury plumbite*, and *tin plumbite*, but without success. He considered the ordinary hydrated monoxide to be *lead plumbite—vide supra*. P. Berthier failed to make *manganese plumbite*, and *iron plumbite*; nor was J. A. Hedvall able to make *cobalt plumbite*. J. J. Berzelius added ammonia to a mixed soln. of nickel and lead salts; and excess of ammonia does not extract the nickel oxide from the precipitate which was thought to be *nickel plumbite*.

§ 17. The Higher Oxides of Lead

A number of higher oxides of lead have been reported—Pb_4O_5, Pb_3O_4, Pb_5O_6, Pb_5O_7, Pb_2O_3, Pb_5O_8, and PbO_2. For Pb_3O_4 and PbO_2, *vide infra*, but the evidence of the chemical individuality of many of the other oxides is not satisfactory. W. Reinders and L. Hamburger [1] consider that lead monoxide and lead dioxide are end-members of a series of solid soln., and that the intermediate oxides with $Pb : O = 4 : 5$, $5 : 7$, $2 : 3$, and $5 : 8$ are arbitrary steps in the series.

G. J. Mulder, J. Löwe, and J. J. Houton-Labillardière found that many samples of commercial red-lead approximated in composition to *lead tetritapentoxide*, Pb_4O_5; and A. P. West considered that commercial red-lead contains PbO, Pb_3O_4, and Pb_4O_5. G. Kassner went so far as to make assumptions on the constitution of this product on the assumption that it is a true compound, and not imperfectly oxidized red-lead.

C. R. A. Wright and A. P. Luff [2] found that a commercial sample of red-lead had the composition Pb_5O_6, and when heated in an atm. of carbon dioxide for 4 hrs. at 200°, no

carbonate was formed. It was therefore concluded that the material was a definite compound—*lead pentitahexoxide*—because had it been a mixture of Pb_3O_4 and $2PbO$, some carbonate would have been formed. The experiment is not an adequate proof of the conclusion. R. Brauner reported *lead pentitaheptoxide*, $3PbO.2PbO_2.3H_2O$, or $Pb_5O_7.3H_2O$, or $Pb_5(OH)_6O_4$, to be formed by treating a soln. of lead nitrate with an excess of hydrogen dioxide, and after filtration treating the liquid with dil. potassium hydroxide. The same compound was reported by J. Milbauer; and F. Fischer and H. Plötze obtained a similar product by the action of oxygen at 375° and 100 atm. press. on a mixture of equal vol. of lead oxide and potassium hydroxide. The product is orange-yellow; and, according to W. Reinders and L. Hamburger, it is not stable above 440°. B. Brauner said that it is not changed by a cold soln. of potassium hydroxide, but dissolves in the hot soln. It reacts with various reagents more quickly than lead sesquioxide or red-lead.

F. Fischer and H. Plötze heated lead carbonate to 400°–450° in oxygen under a 100 atm. press. The dark brown product has a composition corresponding with *lead pentitoctoxide*, Pb_5O_8. Lead hydroxide, or dioxide, can be used in place of the carbonate, but not red-lead. Alkali hydroxides, carbonates, or borates act as catalytic agents. At 500°, it forms red-lead. They regard the Pb_5O_8 oxide as *lead pyroplumbate*, $Pb_2(Pb_3O_8)$; but W. Reinders and L. Hamburger consider the product to be a chance member of a series of solid soln. G. Kassner said that lead pyroplumbate:

$$Pb<^O_O>Pb<^O_O>Pb<^O_O>Pb<^O_O>Pb$$
serves to bring lead into line with silicon in the production of poly-acids. The only known poly-acid of tin is $H_2Sn_5O_{11}$. While the polysilicates are decomposed when heated with water under press., the polyplumbates are produced by the hydrothermal treatment of the orthoplumbates.

G. C. Winkelblech[3] found that sodium hypochlorite first precipitates from soln. of lead salts a reddish-yellow mixture of lead chloride and **lead sesquioxide,** or **lead hemitrioxide,** Pb_2O_3, and if the warm mixture is allowed to stand for some time it furnishes lead dioxide. To obtain the sesquioxide free from chloride, lead nitrate or acetate is treated with a sufficient excess of potassium hydroxide to redissolve the precipitate, and the soln. treated with sodium chloride. The yellow precipitate is then washed and dried. J. F. L. Hausmann employed a similar method of preparation, and he found that the product is not completely dehydrated at 140°–150°. F. Jirsa electrolyzed a soln. of 40 grms. of potassium hydroxide and 4·5 grms. of lead monoxide per litre, with palladium electrodes, using an alternating current. Yellow lead sesquioxide was deposited, and a soln. of lead metaplumbate was formed—*vide* lead plumbite. F. Fischer and H. Plötze regard this oxide as *lead metaplumbate*, $Pb(PbO_3)$.

M. Höhnel obtained the sesquioxide by the action of a soln. of lead acetate on calcium plumbate; H. Bollenbach, by the action of potassium permanganate on a soln. of sodium plumbite; V. A. Jacquelain, by pouring a soln. of red-lead in acetic acid into a dil. soln. of ammonia, washing the product with hot water and a little very dil. acetic acid, and drying at 100°; and L. Marino, by the action of 3 per cent. nitric acid on a soln. of lead pyroselenate in sodium hydroxide. H. Debray obtained it by heating lead dioxide at 350°; T. Carnelley and J. Walker worked at 280°–290°; and F. Fischer and H. Plötze by the action of oxygen at 100 atm. press., on lead monoxide at 410°–480°, but not on lead dioxide or red-lead at that temp.

According to E. Frémy, and O. Seidel, when alkaline soln. of potassium plumbate and plumbite are mixed, the precipitate, after washing and drying over sulphuric acid, has the composition of *lead trihydroxide*, $Pb_2O_3.3H_2O$, or $Pb(OH)_3$. E. Frémy regarded it as a hydrated form of red-lead. G. Grube, O. Seidel, S. Glasstone, and L. Bellucci and N. Parravano obtained this substance by a somewhat analogous process. The colour is variously described as yellowish-brown, and orange-yellow. E. Zintl and A. Raach tested the theory that the colour of compounds is due to the vibration of atoms or the oscillatory change in valency within the molecule of lead hemitrioxide by means of radioactive indicators. If such oscillations occur in a compound containing inactive quadrivalent lead and induced active bivalent lead, a regular distribution of the radioactive isotopes over all the

lead atoms is to be expected. A preparation of lead hemitrioxide with incited bivalent lead yields, after treatment with nitric acid, bi- and quadri-valent lead of equal activity, but the experiment is regarded as inconclusive since atomic exchange during the production or decomposition of the hemitrioxide is not improbable. If, however, lead hemitrioxide is obtained by the precipitation of a $3N$-alkaline soln. of inactive plumbate with a $3N$-alkaline soln. of radioactively incited plumbite and the precipitate, after being illuminated during 3 hrs., is dissolved in $12N$-alkali hydroxide, a soln. is obtained from which barium hydroxide precipitates barium plumbate of such small activity that it can be attributed only to co-precipitated barium plumbite. An oscillatory exchange in the mol., $Pb_2O_3.3H_2O$, is therefore considered not to occur under the influence of light.

According to S. Glasstone, the different methods of preparation of lead sesquioxide involve the oxidation of alkali plumbite to plumbate—by chlorine, bromine, iodine, hydrogen dioxide, potassium persulphate, etc.—or the reduction of alkali plumbate to plumbite—by nascent hydrogen from zinc dust or aluminium powder, or from sodium stannite or sulphite. He found the most satisfactory mode of preparing the hydrated sesquioxide to be as follows :

Sodium hydroxide soln. (250 c.c. of 12 per cent.) sat. with lead monoxide was dil. to 500 c.c., and 500 c.c. of sat. bromine water were added. The mixture was kept over-night and then washed by decantation with water containing a little acetic acid to remove the excess of hypobromite and alkali. A paste of the precipitate and water was stirred into a soln. of 60 grms. of sodium hydroxide in 300 c.c. of water, warmed at 50°. The liquid was filtered, 40 grms. of acetic acid diluted with 150 c.c. of water were slowly added to the cold filtrate with continual stirring, and the gelatinous, yellowish-brown precipitate obtained was washed by decantation and filtered by the aid of the pump. Before drying, a small portion of the precipitate was analyzed in order to determine the ratio of dioxide to monoxide. If the precipitate still contained excess of monoxide, it was redissolved in alkali and again precipitated with acid. On drying in a desiccator, the sesquioxide darkened in colour and shrunk into small lumps, which gave a brown powder by gentle grinding ; with fine grinding the colour became somewhat lighter.

S. Glasstone's analysis agreed with $Pb_2O_3.3H_2O$. A. Hutchinson and W. Pollard regarded lead sesquioxide as *plumbous metaplumbate*, $Pb(PbO_3)$; or, as L. Bellucci and N. Parravano expressed it, the hydrated sesquioxide is plumbous metaplumbate, $Pb[Pb(OH)_6]$. L. Marino considered the sesquioxide to be an oxide of quadrivalent lead ; and, with less probability, it can be regarded as an oxide of bivalent lead :

$$Pb{<}{^O_O}{>}Pb{=}O \qquad O{<}{^{Pb=O}_{Pb=O}} \qquad O{<}{^{Pb-O}_{Pb-O}}$$
G. C. Winkelblech said that lead sesquioxide is a non-crystalline reddish-yellow powder which holds hygroscopic water so very tenaciously that it is removed only slowly by heating the product in vacuo. O. Seidel said that the hydrated oxide does not change perceptibly in air, and at 160°–190° it becomes brown, and loses a mol of water. L. Bellucci and N. Parravano found it lost a mol of water at 170°, and the whole of the water is given off at a higher temp. and at the same time some oxygen is lost and lead monoxide formed. As indicated above, the dehydration of the sesquioxide is probably attended by its decomposition into a mixture of monoxide and dioxide. The colour is not changed at 100°, and V. A. Jacquelain found that it darkened without giving off oxygen at 150°. T. Carnelley and J. Walker observed no loss of oxygen below 360°, but at 360°–415°, it forms red-lead ; and G. C. Winkelblech observed that at a red-heat it furnishes lead monoxide and oxygen. H. Debray said that the greenish-brown sesquioxide passes slowly into red-lead at 350°, and rapidly at 440°. J. F. L. Hausmann showed that the oxide absorbs carbon dioxide from the air without changing colour; and G. C. Winkelblech showed that it is reduced to the monoxide by oxalic or formic acid ; and that when heated with nitric, sulphuric, hydrofluosilicic, or acetic acid it forms a yellow liquid from which it is precipitated by alkalies ; on standing a few minutes, however, the liquid decomposes—*e.g.* with hydrochloric acid into

free chlorine and lead chloride. O. Seidel obtained similar results. H. Schulze found that sodium sulphite changes the sesquioxide lemon-yellow, and then white, forming a mixture of lead sulphite and sulphate. E. Müller and H. Barck said that at 200° the sesquioxide is decomposed by nitric oxide.

O. Seidel found that a boiling aq. soln. of potassium hydroxide first dissolves some lead monoxide and afterwards some lead dioxide. S. Glasstone said that the sesquioxide is soluble in the alkali-lye, but not so soluble as the monoxide, while the dioxide is almost insoluble. The boiling soln. in alkali-lye precipitates lead aioxide, and alkali plumbate remains in soln. The soln. of the sesquioxide in dlkali-lye contains plumbite and plumbate, for, on boiling such a mixture, similar results are obtained. Hence, the dissolution of the sesquioxide in an alkali may be represented as a balanced reaction, $Pb_2O_3.3H_2O_{solid}+3OH'\rightleftharpoons HPbO'_2+Pb(OH)_6\cdot\cdot$ $+H_2O$. Hence, $[HPbO'_2][Pb(OH)_6'']=K[OH']^3$, where K is constant. The solubility of the sesquioxide in alkaline soln. of varying conc., expressed in mols per litre, shows that:

NaOH	Plumbite	Plumbate	$K\times10^6$
1·20	0·00875	0·000412	2·09
1·26	0·01212	0·000350	2·08
1·79	0·00160	0·011500	3·20
2·41	0·02000	0·001200	1·72
2·63	0·02150	0·002650	3·12

The electrode potential of mixtures of alkali plumbite and plumbate is of the order 0·30 volt, with the hydrogen electrode, at 17°; and the potential of the electrode $Pt\,|\,Pb_2O_3.H_2O,\,PbO_2\,|\,N\text{-}NaOH$, with the hydrogen electrode, is 0·302 volt at 17°. S. Glasstone hence computed the free energy of the reaction: $2PbO_2+H_2=Pb_2O_3$ $+H_2O$ to be $2\cdot224\times96540$ joules; and for $PbO_2+PbO\rightarrow Pb_2O_3, 0\cdot068\times96540$ joules; for $Pb_2O_3+PbO\rightarrow Pb_3O_4$, $0\cdot160\times96540$ joules; and for $PbO_2+2PbO\rightarrow Pb_3O_4$, $0\cdot228\times96540$ joules.

§ 18. Red-lead, or Minium

The preparation of **red-lead**, Pb_3O_4, is described by Vitruvius in his De architectura (7. 12, c. 15 B.C.). He called it sandaraca, and stated that it was accidentally discovered, for some jars of ceruse or white-lead, for use as a cosmetic, were converted into red-lead during a fire; and it was afterwards made by roasting ceruse

—cerussa si coquatur rusescit. Dioscorides, in his *De materia medica* (**5**. 103, *c*. A.D. 75), also said that it is made by heating white-lead in the following manner:

> Put a new earthen vessel, preferably an Attic one, over coals ; sprinkle it with powdered ceruse, stir constantly, and when it has acquired the colour of ashes, remove and cool it for use. If you desire to burn it, place the powdered product in a hollow platter, and having set this on coals, stir with an iron rod until the product has acquired the colour of sandarach. Then remove it from the fire, and use the product.

Pliny, in his *Historia naturalis* (**34**. 54 ; **35**. 20, *c*. A.D. 77), repeated much of what had been said by Vitruvius and Dioscorides. He confused red-lead, or *cerussa usta*, as he called it, with many other red substances—*purpurea rubica* (iron oxide), *cinnabaris* (the resin of the *dracœna cinnabari*), *sil marmoreum crematum* (calcined ochre), *minium* (cinnabar), and *sandaraca* (red orpiment, or arsenic sulphide). Dioscorides pointed out that *minium* and *cinnabaris* can be distinguished by heating, when the former gives off a suffocating vapour from which the operator should be protected by covering his face with a bladder. Minium (mercuric sulphide), we are told, was adulterated with red-lead, and in time the adulterant alone received the name *minium*—the term minium being now applied to red-lead, and not to cinnabar, vermilion, or mercuric sulphide. Pliny said that about 320 B.C. a painter called Nicias first used red-lead as a pigment. The term *miniature* has now lost all trace of its association with red-lead used in painting. It is not known who found that red-lead could be prepared from litharge or from metallic lead ; as previously indicated, the fact is mentioned in the Latin, twelfth-century, translations of Geber's *Summa perfectionis magisterii ;* in Albertus Magnus' *Compositum de compositis ;* and in works by subsequent writers.

G. Agricola's [1] *minium nativum* was cinnabar. The occurrence of red-lead or minium in nature has been indicated in connection with litharge. [2] It has been reported from the Isle of Anglesey, Wales ; from Grassington Moor, and Weardale, England ; Leadhills, Scotland ; Bleialf, Eifel ; Badenweiler, Baden ; Brillon, Westphalia ; Zmeinogorsk, Siberia ; Zimapan, Mexico ; Wythe Co., Virginia ; Alturas Co., Idaho ; Leadville, Colorado ; etc.

Red-lead is formed when lead monoxide at a dull red heat is exposed for a considerable time to air. According to P. A. von Bonsdorff,[3] when lead-shavings in contact with water, and protected from dust, are exposed to the air for some months, the red-lead appears on those surfaces which are directly exposed to the air. Drawings made on paper with metallic lead are stated by P. A. von Bonsdorff to have acquired a red colour owing to the oxidation of the film of lead. J. J. Nöggerath, and A. Levol made confirmatory observations. According to J. Milbauer, the air of towns forms only a basic carbonate ; but sea-air oxidizes the lead further ; and the presence of ozone is particularly favourable to the production of red-lead ; and according to J. B. Huffard and P. E. Haynes, compressed oxygen accelerates the reaction. E. J. Kohlmeyer observed some red-lead to be formed on lead which had been embedded in cement. C. F. Schönbein found that lead precipitated by zinc and washed, when exposed to the vapour from aq. ammonia and air, becomes covered with a film of red-lead, and lead carbonate. O. W. Brown and A. R. Nees found that when spongy lead obtained by electrodeposition, ordinary lead, and atomized lead are oxidized in a rotating furnace at different temp. up to 500°, the finer particles are converted into red-lead, while the larger ones are merely coated with oxide ; the product was ground, the finer particles were separated by levigation, and the residue was roasted again. The product was again ground and levigated. The finer portions, reddish-brown in colour, were roasted for 3–4 hrs. at 430°–450°, when they yielded brilliant, amorphous red-lead. J. A. Wilkinson found that sodium dioxide quickly converts molten lead into red-lead.

G. Kassner showed that when lead monoxide is exposed to the action of light and moist oxygen at ordinary temp., red-lead is formed. J. Milbauer found that

ozonized air converts lead hydroxide or carbonate, moistened with sodium or potassium hydroxide, first to a honey-yellow oxide and then to red-lead. According to J. B. A. Dumas, when finely divided massicot is heated for 24 hrs. or more either on the flat hearth of a reverberatory furnace, or in vessels with wide mouths projecting from the side of the furnace, and the mass frequently stirred, red-lead is formed provided the temp. does not rise above dull redness. Ordinary litharge is so dense that it oxidizes much more slowly than massicot ; and massicot in turn oxidizes more slowly than the softer oxide obtained by heating white-lead. Thus, after three firings, each of 24 hrs.' duration, the red-lead from massicot contained 58 per cent. of Pb_3O_4, while that obtained under similar conditions from white-lead contained 95·3 per cent. H. Hocking worked with air under pressure. On a manufacturing scale, lead is first drossed into massicot at about 340°, and afterwards oxidized; and then heated at a higher temp.—near 500°—until a sample, on cooling, has the required tint. The red-lead is then withdrawn, sieved, and levigated. A small proportion of white-lead from the stack process, which is rejected because of stains, is worked for red-lead either alone or mixed with the ordinary materials.

V. A. Jacquelain showed that lead oxide at 450° in air is slowly converted into red-lead. M. Liebig said that the temp. should not exceed 350°. H. le Chatelier found the dissociation press. of red-lead to be 5 mm. at 455° ; 60 mm. at 500° ; 183 mm. at 555° ; and 763 mm. at 636°. The partial press. of the oxygen in air is about 150 mm., so that red-lead cannot be formed in air above 550°, and oxidation of litharge occurs most rapidly at about 500°. When red-lead is heated, T. Carnelley and J. Walker found that it becomes redder, then violet and black, and on cooling again it resumes its scarlet-red colour ; it is stable at 530°. O. W. Brown and A. R. Nees found lead monoxide is converted into red-lead rapidly and completely when heated in air at 525°–530°. J. Milbauer said that in the presence of oxygen, decomposition begins at 470°, and a state of equilibrium occurs in about 3 hrs. : $Pb_3O_4 \rightleftharpoons 3PbO + \frac{1}{2}O_2$; in vacuo, the oxide is completely decomposed at 530° ; and in 2 hrs. at 550°. Red-lead cannot exist in oxygen at 600° ; in air at 565° ; and in carbon dioxide at 550°. No red-lead is obtained from litharge at 450°, the product is always brown ; and between 450° and 550°, the product is red. The optimum temp. is 470°. Small amounts of impurities in the litharge have a marked effect on the rate of oxidation. Nitric acid and ammonia reduce the rate of oxidation one-third and one-seventh respectively; small amounts of sodium nitrate slightly accelerate the reaction ; 0·1 per cent. of lead nitrate produces a fine pink colour ; and 0·1 per cent. of sodium hydroxide gives an intense red. J. Milbauer also found that silver facilitates the oxidation at 300°, but has no appreciable effect at higher temp. ; zinc, and antimony act unfavourably ; while bismuth was said to be inert— O. Herting, on the contrary, said bismuth interferes with the reaction. He said that red-lead made from lead carbonate is reduced at 475°, but O. W. Brown and A. R. Nees could not confirm this. They found that yellow litharge oxidized more slowly than the red variety, and if litharge be treated with water, dil. tannic acid, or a dil. soln. of glue, the rate of oxidation is much decreased. J. Milbauer found that an increase of 10° in the temp. multiplied the rate of reaction by about 1·05. The slopes of the curves in Fig. 66, by O. W. Brown and A. R. Nees,

FIG. 66.—Speeds of Oxidation of Lead Monoxide (as PbO_2) at Different Temperatures.

represent the speed of the reaction, dx/dt, at the temp. named, where red-lead is regarded as a compound of PbO and PbO_2, so that the higher the proportion of lead dioxide, x, in the product, the greater the proportion of red-

lead formed. The most favourable temp. is clearly 425°. W. Reinders and L. Hamburger found the dissociation press., p mm., $Pb_3O_4 \rightleftharpoons 3PbO_{yellow} + \frac{1}{2}O_2$, at different temp. to be:

	444·8°	484·4°	511·2°	537·6°	558·3°	588·1°	600·7°	607°
p . . .	8·4	30·4	76·0	155	270	589	859	1045

The results were represented by $\log_{10} p = -7\cdot8595T^{-1} + 11\cdot8976$; or $\log_{10} p = -7\cdot0895T^{-1} + 1\cdot751 \log T + 0\cdot000216T + 2\cdot8$. The dissociation press. curve is smooth, and gives no evidence of solid soln. or of intermediate oxides. F. A. Henglein gave for the partial press., p, of oxygen for $2Pb_3O_4 \rightarrow 6PbO + O_2$, $\log p = -1373281T^{-1\cdot8611} + 4\cdot6222$ mm.

C. Zenghelis said that at ordinary temp. red-lead is more volatile than lead monoxide. The dissociation press. at 17° is $6\cdot6 \times 10^{-19}$ atm., S. Glasstone calculated $3\cdot3 \times 10^{-19}$ atm. from the data for the e.m.f. of cells with Pb_3O_4 electrodes. He also gave for the dissociation press. at 0·21 atm. (the partial press. of oxygen in air), 570°–573°; W. Reinders and L. Hamburger's value is 539°. C. Schubert, and W. Stahl gave 510°–640° for the temp. at which red-lead forms oxygen and lead oxide. A. Bouzat gave 300 mm. for the dissociation press. at 585°, and 700 mm. at 632°. F. Fischer and H. Plötze showed that at 530° under a press. of 100 atm. of oxygen, red-lead is not changed between 280° and 410°, and at 530°, lead monoxide is rapidly converted into red-lead. With the time constant, 2 hrs., the proportion of red-lead present at different temp. when litharge is heated in air is shown in Fig. 67, by O. W. Brown and A. R. Nees. This again shows that the most favourable temp. for the oxidation of lead monoxide is 425°.

O. W. Brown and A. R. Nees found that red-lead is best obtained from lead dioxyhydroxide in the vicinity of 450°. J. Milbauer, O. W. Brown and A. R. Nees, L. Michel, and G. Jansen found lead carbonates to be suitable for the preparation of red-lead at 425°–430° because of the fine state of

FIG. 67.—Proportion of Red-lead (as PbO_2) formed from Lead Monoxide at Different Temperatures.

subdivision and the flocculent nature of the resulting monoxide formed before it is converted to red-lead. M. Alsburg prepared red-lead by heating lead oxide mixed with lead nitrate; A. Levol, by heating a mixture of 4 parts of litharge (derived from white-lead), one of potassium chlorate, and 8 parts of potassium nitrate—brown lead dioxide is first produced, and by further heating to dull redness, red-lead is formed. The cold mass was well-boiled with distilled water. C. L. P. Burton used a modification of the process. A small amount of red-lead is manufactured as a by-product in the preparation of sodium nitrite by fusing sodium nitrate with lead or litharge. J. Milbauer found potassium chlorate or bromate converts litharge into red-lead at 470°, but not so potassium iodate.

W. Reinders and L. Hamburger found that the higher oxides of lead are converted into red-lead by heating them to 420°. B. Brauner found that a hot soln. of the Pb_5O_7 oxide in not too much potash-lye furnishes red-lead on cooling. The reaction was studied by W. Reinders and L. Hamburger, and J. Milbauer. The preparation of red-lead by heating mixtures of lead dioxide and monoxide, or lead dioxide alone, was studied by V. A. Jacquelain, and J. E. Mackenzie. J. Milbauer heated a mixture of 3 eq. lead monoxide, 2 eq. lead dioxide, with a soln. containing 200 grms. of potassium hydroxide per 100 c.c. of water. He also heated lead dioxide with potassium nitrate at 470°, and extracted the soluble matters with water. A. Levol boiled a soln. of potassium plumbite for 1–2 hrs. with lead dioxide, removed the excess of lead dioxide with cold oxalic acid, and the oxalic acid with alkali-lye. The process was examined by J. Milbauer, who found that oxalic acid

attacks red-lead in the cold. E. Frémy boiled a soln. of lead oxide in alkali plumbate soln., and J. Milbauer represented the reaction : $K_4PbO_4+2K_2PbO_2 +4H_2O=Pb_3O_4+8KOH$. G. Grube allowed a mixture of soln. of two mols of potassium plumbite and one mol of potassium plumbate to stand in contact with 6·9–12·5N-KOH, and after decantation, and suction, washed the precipitate with absolute alcohol, and dried it over potassium hydroxide in vacuo. S. Glasstone allowed lead dioxide to stand in contact with spongy lead in a 15 per cent. soln. of sodium hydroxide for some months ; also a mixture of lead dioxide and monoxide in N-NaOH.

The production of the deepest and most prized shades of red-lead is considered to be a trade secret. According to J. B. A. Dumas, commercial red-lead can be freed from the associated yellow oxide by rapidly digesting it with a soln. of lead acetate ; and J. Milbauer recommended two one-hour digestions with a 20 per cent. soln. J. J. Berzelius, and J. Dalton recommended cold, very dil. acetic acid ; while R. Phillips said that if the acetic acid be too conc., some brown lead dioxide is produced, and J. B. A. Dumas said that the brown dioxide always appears before all the monoxide has been removed. J. Milbauer said that dil. nitric acid is not satisfactory because of the formation of the dioxide, nor does a soln. of lead nitrate, as recommended by J. Löwe, offer any advantages over one of lead acetate. A. Levol recommended boiling the product with very dil. potash-lye, and J. Milbauer said that this process is more rapid than is the case with lead acetate, and it removes at the same time lead sulphate and carbonate, but not calcium carbonate. A 10 per cent. soln. of sodium acetate acts slowly ; while a 10 per cent. hot soln. of ammonium oxalate decomposes red-lead. The adulteration of red-lead with brick-dust, bole, or iron oxide, was formerly more common than it is to-day. Most commercial red-lead is fairly pure. There are combination red-leads on the market which have their tints brightened by an organic dye precipitated on an inert base like barytes. The adulteration of red-lead has been discussed by W. F. Edwards, D. B. Dott, and V. Frehse. Red-lead for use in the manufacture of vermilion is evaluated on its purity of tone, etc. ; glassmaker's red-lead should be free from metallic lead, lead sulphate, antimony, iron, and copper ; while red-lead for match-making is evaluated on its peroxide content which may vary from 28 to 33 per cent. Red-lead for accumulator plates is preferred with less than 0·005 per cent. of iron. The so-called orange-lead approximates 33 per cent. PbO_2, rather more than is the case with ordinary red-lead. C. A. Klein gave for the composition of a good commercial red-lead : 26·5 per cent. PbO_2 ; 0·0008, Ag ; 0·006, CuO ; 0·0004, Sb_2O_4 ; 0·009, Fe_2O_3 ; 0·032, Al_2O_3 ; and 0·075, insoluble in nitric acid. Cadmium, arsenic, and zinc were absent. C. R. A. Wright and A. P. Luff noted that commercial red-lead gave off a little carbon-doxide at 360°, owing to its contamination with a little organic matter. The composition of red-lead has been discussed by M. Longchamp, J. Milbauer, J. J. Houton-Labillardière, J. Löwenthal, J. B. A. Dumas, C. L. Vlaanderen, V. A. Jacquelain, M. Liebig, W. Reinders and L. Hamburger, C. Marchese, E. Szterkhers, W. F. Edwards, D. Woodman, A. P. West, and E. E. Dunlap. Although the composition is somewhat variable, depending on what L. N. Vauquelain called the *suroxigenation*, analyses by J. J. Berzelius, J. B. A. Dumas, and L. N. Vauquelin showed that in the limiting case, the composition is summarized by the formula Pb_3O_4. There has been some discussion as to the constitution of the oxide. J. B. A. Dumas regarded red-lead as *un oxide salin, un plombate de plombe, dont lequel la bas renferme la même quantité d'oxygène que l'acide, sa formule étant* $2PbO.PbO_2$. S. Glasstone's observations on the electrochemical behaviours of the oxide agree with J. B. A. Dumas' hypotheses. It is assumed that lead dioxide is first produced during the oxidation of litharge, and that the dioxide acts as an acid anhydride uniting with the remaining lead monoxide to form **plumbic plumbite**, $Pb(PbO_2)_2$, a salt of hydroplumbic acid, H_2PbO_2 ; or, as A. Hutchinson and W. Pollard express it, red-lead is **plumbous orthoplumbate**, Pb_2PbO_4, a salt of orthoplumbic acid,

H_4PbO_4. G. Grube had a similar opinion. G. Kassner's, A. Hutchinson and W. Pollard's, and L. Marino's formulæ are respectively :

$$Pb{<}{_O^O}{>}Pb{<}{_O^O}{>}Pb \qquad Pb{<}{_O^O}{>}Pb{<}{_O^O}{>}Pb \qquad Pb{<}{_{O-Pb\equiv O}^{O-Pb\equiv O}}$$
Plumbic plumbite, $Pb(PbO_2)_2$.   Plumbous orthoplumbate, Pb_2PbO_4.   Plumbous plumbate, $Pb(PbO_2)_2$.
F. Fischer and H. Ploetze also represented red-lead as lead orthoplumbate. D. I. Mendeléef, and A. Geuther assumed that litharge (q.v.) is a polymerized oxide, say, $Pb_{12}O_{12}$; and E. J. Wade, accepting this, stated that when lead monoxide is oxidized it passes successively along the stages $Pb_{12}O_{13}$, $Pb_{12}O_{14}$, $Pb_{12}O_{15}$, and when the stage $Pb_{12}O_{16}$ is reached, the product is red-lead, $(Pb_3O_4)_4$. This hypothesis is, of course, a leap in the dark. Another view of the nature of red-lead assumes that it is a mixture or solid soln. of lead monoxide and dioxide as indicated by C. A. Klein. From the effect of temp. on the speed of the reaction, J. Milbauer also considered that the oxidation of litharge is rather a physical than a chemical change, and is to be explained by the theory of solid soln. advanced by A. Horstmann ; but in their study of the dissociation press., W. Reinders and L. Hamburger observed no signs of the formation of solid soln. or of compounds other than those indicated in the equation $Pb_3O_4 \rightleftharpoons 3PbO + \frac{1}{2}O_2$. S. S. Bhatnagar, M. Prasad, and D. C. Bahl obtained **colloidal red-lead** by using soap as protective agent.

The physical properties of red-lead.—Red-lead is a scarlet-red, or brownish-red powder ; which, according to O. W. Brown and A. R. Nees,[4] is usually made up of crystals mixed with a small proportion of amorphous material, but samples can be obtained wholly amorphous or wholly crystalline. J. Milbauer observed that red-lead obtained from a hot conc. soln. of potassium hydroxide is in reddish-brown microscopic crystals ; while L. Michel found that the oxide obtained from fused alkali nitrate consists of orange-yellow prisms. When red-lead is heated the colour darkens and becomes quite black, but the original colour is restored on cooling. M. Bamberger and R. Grengg found that natural red-lead lost its colour when cooled to $-190°$. P. von Muschenbrock gave 8·94 for the sp. gr. of red-lead ; W. Herapath, 9·096 at 15° ; P. F. G. Boullay, 9·190 ; C. J. B. Karsten, 8·62. G. Hauser found the sp. gr. of red-lead and orange red-lead varied with the mode of preparation ; and O. W. Brown and A. R. Nees found the sp. gr. of 52 samples of red-lead varied between comparatively wide limits, from 8·32 to 9·16 ; they observed no relation between the crystalline form of the powder and the sp. gr. Amorphous samples have a sp. gr. from 8·66 to 8·90, and crystalline samples usually have a higher sp. gr., and as a rule the sp. gr. increases slightly with the time of heating ; and, in general, the higher the temp. at which oxidation occurs, the higher the sp. gr. The more nearly the composition of the powder approaches Pb_3O_4, the lower the sp. gr. The sp. gr. also depends on the physical nature of the starting material. O. W. Brown and co-workers found that the apparent sp. gr. or the weight of powder occupying 1 c.c. decreases by fine grinding and afterwards increases to a maximum. Thus, with finer grinding, the weight of red-lead occupying 1·484 grms. per c.c. fell to 1·226 grms. per c.c., and then rose to 1·932 grms. per c.c. F. B. Hofmann obtained a fine durable emulsion by shaking red-lead with a mixture of chloroform and water. W. Spring found that when the moist powder is compressed at 3000 atm., a little of it appeared glassy as if it had fused. The action of heat on red-lead has been previously discussed. G. Tammann noticed that mercury does not sink through powdered red-lead at temp. up to 300°.

S. Glasstone found that the $Pt | (Pb_3O_4, PbO), N\text{-NaOH}$ electrode did not behave reversibly and the values were erratic ; the electrode potential of $Pt | (Pb_3O_4), PbO_2), N\text{-NaOH}$ was 0·325 volt on the hydrogen scale at 17° ; the potential of the $Pb | Pb_3O_4, N\text{-NaOH}$ electrode was $-0·610$ volt at room temp. The plumbous ion concentration of red-lead in $N\text{-NaOH}$ for complete ionization : $Pb_3O_4 \rightleftharpoons 2Pb^{\cdot\cdot} + PbO_4''''$, is $2·2 \times 10^{-17}$; the solubility of red-lead in $N\text{-NaOH}$ is $1·1 \times 10^{-17}$ mol per litre at 17° ; and the solubility in water is probably

of the same order of magnitude; the solubility-product of red-lead is $[Pb^{..}][PbO_4'''']=5\cdot32\times10^{-51}$. S. Glasstone found the e.m.f. of the cell $Pt\,|\,(PbO,PbO_2),N\text{-}NaOH,H_2(atm.)\,|\,Pt$ to be $1\cdot078$ volts at $17°$, and hence the free energy of the reaction $PbO_2+H_2=PbO+H_2O$ to be $2\cdot156\times96540$ joules; for the cell $Pt\,|\,(Pb_3O_4,PbO_2),N\text{-}NaOH,H_2(atm.)\,|\,Pt$ he found $1\cdot135$ volts at $17°$, and hence the free energy of the reaction: $3PbO_2+2H_2=Pb_3O_4+2H_2O$, is $4\cdot540\times96540$ joules. Consequently also for $Pb_3O_4+H_2=3PbO+H_2O$ the free energy is $1\cdot928\times96540$ joules. If the cell $Pt\,|\,(Pb_3O_4,PbO),N\text{-}NaOH,H_2(atm.)\,|\,Pt$ were reversible its e.m.f. would be $0\cdot964$ volt. S. Glasstone calculated the free energy of the reaction $3PbO+\frac{1}{2}O_2=Pb_3O_4$ to be 12,350 cals. or $0\cdot536\times96540$ joules at $17°$, when the total energy of the reaction is 16,750 cals. W. Schmidt found the dielectric constant to be $17\cdot8$ for $\lambda=75$ cms. S. Meyer found the magnetic susceptibility to be $-0\cdot478\times10^{-6}$, and the mol. magnetization, $-0\cdot114\times10^{-6}$.

The chemical properties of red-lead.—Red-lead is converted into lead monoxide by numerous reducing agents. H. Mennicke [5] showed that **hydrogen**, *in statu nascendi*, say from zinc and hydrochloric acid in the presence of platinum, reduces red-lead rapidly and quantitatively; and F. Peters found that at ordinary temp., electrolytic hydrogen reduces red-lead to the metal. According to C. R. A. Wright and A. P. Luff, reduction by hydrogen begins at $230°$; I. W. Fay and co-workers found that reduction can be detected after heating red-lead in hydrogen for 6 hrs. at $170°$. P. Sabatier and L. Espil inferred that at $250°$ red-lead is reduced by hydrogen to lead hemioxide without the intermediate formation of the monoxide, and subsequently to the metal. W. Müller found that red-lead is reduced by hydrogen to the metal at $310°$–$315°$. For the free energy of the reaction, *vide supra*. O. Brunck found that **ozone**—*i.e.* ozonized oxygen—has very little action, and it possibly forms a little lead dioxide. C. P. van Hoek examined the hygroscopicity; for the solubility of red-lead in **water**, and **alkali hydroxide** soln., *vide supra*. O. Seidel said that a boiling soln. of the alkali-lye first dissolves lead monoxide, and then slowly takes up the lead dioxide. P. Beck found that in the presence of nitric acid, **hydrogen dioxide** is reduced by red-lead. According to H. Moissan, **fluorine** has no action on red-lead in the cold, but when warmed, lead fluoride is formed. F. Fischer and K. Thiele found red-lead to be sparingly soluble in **hydrofluoric acid**, forming hydrofluoplumbic acid. R. Weber showed that when heated in dry **chlorine**, red-lead is readily converted into lead chloride; A. Classen and B. Zahorsky found that liquid chlorine acts only in the presence of hydrochloric acid. C. Löwig observed that with chlorine-water, lead chloride and dioxide are formed, while **bromine** water acts in an analogous manner. A. Vogel showed that with a small proportion of **hydrochloric acid**, lead chloride, dioxide, and water are formed; but with more acid, lead chloride, chlorine, and water are produced. L. L. de Koninck said that with conc. hydrochloric acid, lead trichloride, not tetrachloride, is formed (*q.v.*).

An aq. soln. of **sulphur dioxide** was found by A. Vogel to transform red-lead into lead sulphate at ordinary temp.; with conc. **sulphuric acid**, red-lead furnishes lead sulphate and oxygen; and with dil. sulphuric acid, lead sulphate and lead dioxide. H. B. North and A. M. Hageman observed that with an excess of **thionyl chloride**, at $150°$, lead chloride and sulphate, sulphuryl chloride, and sulphur dioxide are formed. I. W. Fay and co-workers detected a reduction of red-lead after heating it in an atm. of **ammonia** for 6 hrs. above $300°$. T. W. B. Welsh and H. J. Broderson found that anhydrous hydrazine dissolves $0\cdot01$ grm. of red-lead per c.c.; C. Finzi and E. Rapuzzi, an acetic acid soln. of **hydrazine** forms lead acetate with the evolution of nitrogen; and E. Puxeddu, that **phenyl-hydrazine** has no action at ordinary temp., but when warmed, lead hemioxide is formed. E. Müller and H. Barck showed that **nitric oxide** does not react with red-lead at room-temp., but at $200°$, lead nitrite is quantitatively produced; and J. Milbauer, that **nitrogen peroxide** forms lead nitrate; and A. Vogel found that with **nitric acid**, lead nitrate and dioxide are formed; with boiling acid, the red-lead gradually dissolves, and on

adding water a colourless soln. of lead nitrate is formed. The complete dissolution of red-lead in dil. nitric acid, or dil. acetic acid proceeds very quickly in the presence of hydrogen dioxide; R. Fresenius recommended **cane sugar** or **oxalic acid** for this purpose; A. Partheil, **lactic acid ;** A. Reinsch, J. Milbauer, E. Pieszczek, F. P. Dunnington, L. Opificius, and H. Schlossberg, **methyl alcohol, glycerol, ammonium tartrate, phenol, formaldehyde, phenylhydrazine,** and **hydroxylamine hydrochloride.** According to C. R. A. Wright and A. P. Luff, **carbon** begins to reduce the oxide at 330°; and **carbon monoxide** at 200°, for in a sealed tube containing carbon monoxide, red-lead forms lead carbonate. I. W. Fay and co-workers detected a reduction of red-lead after heating it in an atm. of **carbon monoxide** for 6 hrs. at 150°, and in an atm. of **methane** at 158°. Under similar conditions, **carbon dioxide** has no action. W. Eidmann found that red-lead is insoluble in **acetone.** J. Milbauer found that red-lead is slowly transformed by dil. **acetic acid** into lead acetate, and H. Forestier said that 10 c.c. of acetic acid and 20 c.c. of water suffice for the dissolution of a gram of red-lead in 30 mins. on a water-bath. C. Marchese, and J. J. Berzelius made some observations on this subject. L. Kahlenberg and W. J. Trautmann observed that red-lead is quickly reduced by powdered silicon when the temp. is raised. A. Colson said that about one-third of the red-lead produces lead tetracetate, $Pb(C_2H_3O_2)_4$, and the remainder the normal acetate, $Pb(C_2H_3O_2)_2$. The soln. prepared at 40° was found by V. A. Jacquelain not to be decomposed by **alcohol** or **ether ;** and C. F. Schönbein noted that lead dioxide separated from the soln., slowly at ordinary temp., rapidly when heated. A. Chwala and H. Colle found that a soln. of **sodium acetate** removes a little lead dioxide from red-lead, forming sodium plumbate. D. Woodman said that, unlike lead monoxide, red-lead is insoluble in a soln. of **lead acetate ;** L. Kahlenberg and H. W. Hillyer also found that, unlike lead monoxide, red-lead is insoluble in a boiling soln. of **potassium tartrate,** and F. C. Krauskopf observed no evolution of oxygen during the action. A. Levol said that red-lead does not react with oxalic acid alone. *Orange-lead* is used for the production of paints, colours, printing inks, and enamels ; it resembles red-lead in composition, and usually has a high proportion of lead dioxide as indicated above. It differs from red-lead in colour, bulkiness, grain-size, and in its behaviour towards **linseed oil** or **varnish.** While a mixture of linseed oil or varnish and orange-lead remains soft on keeping, red-lead soon becomes stiff with these media, and the product cannot be thinned again. Hence, when red-lead is used as a paint, it is usual to mix it shortly before use. The poorer grades of red-lead—with their free lead monoxide—quickly stiffen linseed oil.

L. Moser showed that **titanium trichloride** is oxidized by red-lead; E. Lay also noted that with **siliconhydrotrinitride,** Si_2HN_3, red-lead is reduced with incandescence partly to lead and partly to lead monoxide. A. Vogel reported that with a soln. of **stannous chloride,** a white mixture of lead chloride and stannic oxide is formed ; and C. Russo and G. Sensi found **ferrous sulphate** is quantitatively oxidized by red-lead. A. Levol observed no reaction between red-lead and a soln of **mercurous nitrate.**

§ 19. Lead Dioxide

The oxide of lead, known as **lead dioxide,** PbO_2, *lead peroxide,* or *pure oxide of lead,* was first prepared by C. W. Scheele [1] in 1774 by the action of chlorine on red-lead, and it was described in his essay : *Om Brunsten eller Magnesia,* as a dark brown calx of lead containing little or no phlogiston, and therefore having a strong tendency to unite with it again. Soon afterwards J. Priestley also made the same substance by the action of nitric acid on red-lead.

A. Breithaupt [2] described a mineral from Leadhills, Scotland, which he called *Schwerbleierz* or *diplasites plumbicus—διπλάσιος,* double—because the metal is twice as strongly oxidized as is the case with litharge ; J. F. L. Hausmann called it *brown lead oxide ;* and W. Haidinger proposed its name **plattnerite**—after C. F. Plattner. Specimens from Dumfriesshire, Scotland, and Mullan, Idaho, have been described or analyzed by E. Kinch, M. F. Heddle, H. A. Wheeler, J. D. and E. N. Hawkins, and W. S. Yeates and E. F. Ayres.

M. E. Chevreul [3] said that when litharge is heated in a platinum crucible it yields lead dioxide and an alloy of platinum and lead. There is something wrong with this statement. While red-lead is obtained by heating lead oxide in air, lead dioxide cannot be so produced. F. Fischer and H. Plötze heated the lead oxide between 400° and 450° in oxygen under 100 atm. press. and obtained a product with the composition Pb_5O_8—*vide supra.* The action takes place at 375° in the presence of alkali hydroxide, carbonate, or borate. Lead monoxide can be oxidized to the dioxide, as L. N. Vauquelin showed, by treatment with chlorine water, or, as A. J. Balard showed, by treatment with bromine water, or a soln. of hypochlorous acid. A. Ditte found that in the chlorine process, the product is always contaminated with lead chloride. N. A. E. Millon said that chlorine water produces lead dioxide from lead chloride only when some hypochlorous acid is formed by the action of light on the chlorine water. L. Friderich and co-workers treated with chlorine a mixture of lead sulphate and magnesia suspended in hot water. A. Sobrero and F. Selmi passed chlorine into a soln. of sodium and lead chlorides, and E. W. Wescott represented the reaction $PbCl_{2solid} + Cl_{2gas} + 2H_2O \rightleftharpoons PbO_{2solid}$ 4HCl, where the equilibrium constant, $[H']^4[Cl']^4/p$, is $2 \cdot 4 \times 10^{-5}$ on the assumption that ionization is complete ; the thermal value of the reaction is eq. to 43,500 joules. W. Kubel also made the dioxide by the action of chlorine on basic lead acetate. F. Wöhler, F. Muck, and A. Geuther also oxidized lead salts with chlorine ; A. Seyewetz and P. Trawitz oxidized an alkaline soln. of lead oxide with the same agent ; and L. E. Rivot and co-workers oxidized lead sulphide, oxide, or carbonate in a hot soln. of alkali-lye by means of chlorine. E. Rupp obtained a 91 per cent. yield by the action of bromine on a dil. acetic acid soln. of a lead salt. A. Chwala and H. Colle oxidized lead iodide by iodine in the presence of potassium hydroxide. J. Pelouze obtained finely divided lead dioxide by the action of hypochlorous acid on a dil. soln. of lead acetate ; and G. C. Winkelblech added sodium hypochlorite to a boiling soln. of lead acetate so long as any precipitate is formed ; the soln. was then decanted, and the lead chloride, simultaneously precipitated, was extracted by boiling dil. nitric acid. V. Zotier used a hypobromite as the oxidizing agent. C. Puscher, and G. Iioka and K. K. S. Seisakujo, treated lead oxide with a clear soln. of bleaching powder ; C. Fahlenberg, J. Strachan, S. Glasstone, and R. Böttger also oxidized a boiling soln. of lead acetate, and A. Fehrmann, a soln. of lead chloride at 50°-60° by means of bleaching powder. F. M. Lyte used the same oxidizing agent. C. F. Schönbein, and F. Mailfert oxidized lead acetate with ozonized air ; or by evaporating soln. of litharge in turpentine. V. Zotier treated a soln. of an alkaline plumbite with hydrogen dioxide. P. Jannasch, E. Rupp and G. Schaumann used an alkaline soln. of hydrogen dioxide to oxidize soln. of lead salts to lead dioxide. A. Seyewetz and P. Trawitz oxidized lead hydroxide suspended in

water by sodium dioxide, or ammonium persulphate; G. Panopolus agitated lead oxide with a soln. of potassium persulphate: lead salts are attacked more slowly than the oxide, and much lead sulphate is formed at the same time; A. Overbeck boiled lead hydroxide with a conc. soln. of potassium ferrocyanide and hydroxide; A. Guttmann used diazobenzene perbromide as the oxidizing agent; A. Reynoso treated lead oxide with potassium permanganate in the presence of an excess of potassium hydroxide. M. E. Chevreul, and L. Michel obtained lead dioxide along with red plates of the monoxide by fusing litharge with potassium hydroxide; and W. Minor stirred some potassium nitrate in the fused mass and, after washing away the soluble matters with water, obtained lead dioxide of a high degree of purity. F. Göbel melted a mixture of lead oxide and potassium chlorate; and A. Levol, a mixture of potassium chlorate and nitrate.

N. W. Fischer found that during the electrolysis of a soln. of a lead salt, lead dioxide is deposited in crystalline scales on the anode, and he added that the deposit occurs even in soln. containing only one part of lead in 12,000 parts of liquid. W. Wernicke electrolyzed an alkaline soln. of lead tartrate. The electro-deposition of lead as dioxide has been previously discussed, and it is a well-known process in analytical chemistry. The preparation of lead dioxide by the electrolytic process was discussed by F. Wöhler, H. Bardt, W. Borchers, C. Luckow, F. Peters, S. Glasstone, H. N. Warren, M. G. Mellon and H. F. Reinhard, J. H. Mellquist, A. Rokotnitz, A. C. Becquerel, F. R. Steigelmann, W. Beetz, Konsortium für Elektrochemische Industrie, P. Ferchland, H. Blumenberg, W. Palmaer, and F. Fischer and H. Plötze. The Fabrik Griesheim-Elektron recommends the use of a diaphragm cell for the electrolysis to avoid *der Abscheidung von Blei an der Kathode*. F. Jirsa electrolyzed a soln. with 40 grms. of potassium hydroxide, and 4·5 grms. of lead monoxide per litre, using an alternating current with nickel or iron electrodes, and obtained dark brown, pulverulent lead dioxide —*vide* lead sesquioxide. W. Palmaer said the lead dioxide deposited from an acid soln. of a lead salt is free from the hydrate H_2PbO_3.

According to F. Fischer and K. Thiele, when hydrofluoplumbic acid is exposed to air, lead dioxide is formed. In a modification of C. W. Scheele's process, red-lead is treated with chlorine-water, or chlorine is passed into water in which red-lead is suspended, and the liquid frequently agitated so long as any absorption of gas occurs. Lead dioxide is precipitated, and can be readily washed free from chlorides by boiling water. In a modification of J. Priestley's process red-lead is boiled for a sufficient length of time with dil. nitric acid, when the lead monoxide is converted into the nitrate and can be washed away from the residual dioxide. J. Milbauer, and G. Grube employed this process. V. A. Jacquelain, and F. Fischer and K. Thiele treated red-lead with an excess of glacial acetic acid at 40°, and washed the resulting lead acetate away from the lead dioxide. A. C. Becquerel also extracted the lead monoxide from red-lead by fusion with potassium hydroxide; C. L. Berthollet found that no oxygen is lost in the process. G. Kassner obtained lead dioxide by digesting calcium orthoplumbate with nitric acid, or heating it under press. using an aq. soln. of an ammonium salt—*e.g.* the nitrate—which will dissolve calcium hydroxide. M. Höhnel obtained the oxide by heating sodium metaplumbate with water or with dil. nitric acid; and M. Lachaud and C. Lepierre, by the action of molten potassium hydroxide on lead chromate.

Lead dioxide can be purified by boiling it with a 10 per cent. soln. of sodium hydroxide, and then with hot dil. nitric acid. W. Reinders and L. Hamburger boiled the commercial dioxide for a long time with nitric acid, and obtained a 99–100 per cent. product by washing and drying at a temp. not exceeding 100°. Analyses reported by A. Breithaupt, T. Thomson, L. N. Vauquelin, and J. J. Berzelius correspond with PbO_2. H. Weil[4] reported that commercial lead dioxide always contains some carbon dioxide which it gives off if heated at 280°, or if treated on a water-bath with 65 per cent. nitric acid or phosphoric acid; but M. Dennstedt and F. Hassler proved that the source of the carbon dioxide is organic

contamination, for neither the monoxide nor the dioxide can absorb carbon dioxide between 100° and 350°. Sometimes sulphuric acid, or chlorine is present. W. F. Edwards reported that some commercial samples had less than 50 per cent. PbO_2, some just over 60 per cent., and some had 95 per cent. PbO_2. A. Gutbier and H. O. Meyer obtained **colloidal lead dioxide** by adding dry lead tetracetate (1·5 grms.) slowly, at the ordinary temp. and with rapid stirring, to a 0·3 per cent. soln. of gum arabic (250 c.c.) to which 0·2N-ammonia soln. (30 c.c.) has been added. The sol was filtered from small quantities of brown precipitate, and dialyzed as rapidly as possible. The pure preparation is dark brown. A white precipitate of hydrated lead dioxide separates slowly on long keeping.

J. Heyes represented lead dioxide with a quadrivalent oxygen atom : $Pb=O=O$. A. Colson showed that in the dioxide the lead is quadrivalent, $O=Pb=O$, because when an acetic acid soln. of lead acetate is treated with chlorine, lead chloride and lead tetracetate are formed. L. Marino argued that the lead is quadrivalent, and one or both the oxygen atoms quadrivalent. The unsymmetrical formula for the oxide is preferred because the lead sulphite obtained by reducing the dioxide with sulphur dioxide is unsymmetrical :

$$Pb{\lessgtr}{O \atop O} \qquad Pb{\lessgtr}{\ddot{O} \atop \ddot{O}} \qquad {Pb \atop SO_2}{>}O$$

Unsymmetrical lead dioxide.   Symmetrical lead dioxide.   Lead sulphite.
because when boiled with dimethyl sulphate in the presence of alcohol, lead methyl sulphonate is formed whether the sulphite is produced by the action of sulphur dioxide on lead dioxide, or by double decomposition. He also assumed that lead dioxide can exist in both single and double molecules :

$$Pb{\lessgtr}{O \atop O} \qquad O{<}{Pb{\equiv}O \atop Pb{\equiv}O}{>}O$$

because at low temp. and high conc., selenious acid reacts to form lead pyroselenate, $Pb_2Se_2O_7$, while in dil. soln., the single molecules react to form normal lead selenite, $PbSeO_3$.

The physical properties of lead dioxide.—Native lead dioxide usually occurs massive, sometimes in globular or mammillary forms, and rarely in crystals. It has a metallic lustre. The **colour** is iron-black, and when powdered chestnut-brown. The artificial dioxide is a reddish-brown or puce-coloured powder. F. Dolezalek and K. Finckh[5] said that the red-lead obtained by oxidation processes is crystalline, and that obtained by hydrolysis is amorphous, but gradually becomes crystalline on exposure to light. According to A. C. Becquerel, red-lead may be produced in brown, six-sided plates or scales with a yellow lustre in reflected light ; the crystals of plattnerite are transluscent or opaque. B. Wäser and R. Kühnel gave some photographs of the crystals of electrodeposited lead dioxide. According to W. S. Yeates and E. F. Ayres, the native **crystals** belong to the tetragonal system, and have the axial ratio $a : c = 1 : 0.6764$. The crystals were said to be isomorphous with rutile, TiO_2 ; cassiterite, SnO_2 ; and polianite, MnO_2. L. Michel obtained tetragonal prisms of the dioxide mixed with red monoxide when lead oxide is melted with potassium hydroxide. By a somewhat similar process, using lead hydroxide, A. Geuther claimed to have prepared small hexagonal plates, and these were examined by O. Luedecke. According to W. S. Yeates and E. F. Ayres, the **fracture** of plattnerite is subconchoidal and uneven ; no **cleavage** was observed. L. Michel found the **optical character** of artificial crystals to be negative. The **X-radiogram** has been studied by M. L. Huggins, W. P. Davey, and A. E. van Arkel. A. Ferrari showed that the results correspond with a tetragonal space lattice of the rutile type with $a = 4.98A$, $c = 3.40A$, and $a : c = 1 : 0.682$. A. Sommerfeld discussed the electronic structure.

The **specific gravity** of artificial lead dioxide, obtained by W. Herapath, is 8·902

at 16·5°; L. Playfair and J. P. Joule gave 8·756–8·897 at 3·9°; C. J. B. Karsten, 8·933; W. Wernicke, 9·045 ; P. F. G. Boullay, 9·190 ; K. Schreber, 9·3 for a visible layer deposited by electrolysis on a platinum plate ; and W. A. Palmaer, 9·360 for electrodeposited crystals. P. Niggli gave 8·56–8·90 for the sp. gr., and 27–28 for the eq. vol. A. Breithaupt gave 9·392–9·440 for plattnerite ; E. Kinch, 8·54 ; M. F. Heddle, 8·80–8·96 ; W. S. Yeates and E. F. Ayres, 8·56 ; H. A. Wheeler, 9·41 ; W. Palmaer, 9·363 at 20°/4° ; and J. D. and E. N. Hawkins, 7·25. J. Königsberger and W. J. Müller calculated the greatest **diameter of the molecule** to be 0·74$\mu\mu$ from the optical properties of electrodeposited films. T. von Hagen pressed the oxide into a smooth, compact mass,·and W. Spring found the moist powder behaved like red-lead under compression. W. A. Palmaer gave 5–6 for the **hardness** of the crystals ; E. Kinch gave 5 for that of plattnerite. A. Reis and L. Zimmermann studied the relation between the mol. vol. and the hardness. W. Palmaer gave 0·057 for the linear coeff. of **thermal expansion** between 25° and 150°. A. S. Russell gave for the mean **specific heat** of a sample dried in air at 160°, 0·0398 at −134° ; 0·0570 at −38° ; and 0·0648 at 24° ; and for the **molecular heat** respectively 9·52, 13·65, and 15·50. W. A. Palmaer gave for the sp. ht. 0·0639 between 20° and 100°, and for the mol. ht. 15·24. C. Zenghelis found signs of a very slight **volatilization** at ordinary temp. According to S. Glasstone, the **dissociation pressure** of the dioxide at 17° is 7·1 × 10^{-12} atm. ; and the oxygen dissociation press. at 0·21 atm. is 394°. W. Reinders and L. Hamburger showed that when lead dioxide is heated, a series of solid soln. with lead monoxide are formed, and their results give a much greater value for dissociation press. of lead dioxide with some monoxide in solid soln. E. Winterhalder described demonstration experiments for the dissociation of lead dioxide. I. M. Tscheltzoff gave $PbO_{solid} + O_{gas} = PbO_{2solid}$ +12·14 Cals. for the **heat of formation** at 17° ; F. Streintz gave 10·1 Cals. at 14° ; E. W. Wescott gave $Pb_{solid} + O_{2gas} = PbO_{2solid} + 219000$ joules. K. Schreber calculated 2·2 for the **index of refraction** with D-light. B. A. Dima compared the **photoelectric effect** with the lead oxides, and observed that the effect diminishes with increasing valency of the metal, and that the photoelectric fatigue is greatest with the lower oxides. B. Aulenkamp examined the **photoelectric sensitivity** of lead dioxide.

F. Streintz and G. Neumann said that the **electrical conductivity** of lead dioxide is metallic. F. Streintz found the **electrical resistance** of a wire a metre long and 1 sq. mm. sectional area to be $2·3(1 + 0·000065\theta) \times 10^{-4}$ ohm. W. Palmaer said the sp. resistance of the crystals at 18° is 0·000845 ohm and 0·0$_4$919 ohm at 20°, and the sp. electrical conductivity 10180. In the temp. range 22°–84°, the sp. resistance falls 0·06 per cent. per degree ; and therefore lead dioxide is a better conductor than mercury or bismuth. Measurements were also made by K. Bädeker, P. Ferchland, J. F. Weyde, and T. Sundorpf. According to A. C. Cumming, the **electrode potential** of lead dioxide in 7·45N-sulphuric acid against a calomel electrode is 1·479 volts, and with 4·82N-H_2SO_4, 1·434 volts. Measurements were also made by D. A. MacInnes and co-workers ; and J. Königsberg and W. J. Müller. J. Miesler gave −1·3 volts against sulphuric acid ; −0·97 volt against zinc sulphate ; and −0·89 volt against copper sulphate. A. von Oettingen, and S. B. Christy gave 0·160 volt in a normal soln. of potassium cyanide at 25°, and 0·110–0·118 volt with 0·1N-KCy ; −0·062 to +0·070 volt in 0·01N-KCy ; and −0·006 volt in 0·001N-KCy. A. C. Cumming gave for the potential of the Pb····/Pb″ electrode against the hydrogen electrode at 25°, 1·82 volt with electrolytic dioxide, and 1·75 volt with the chemically prepared dioxide. According to S. Glasstone, 1·75 volt is probably too high, but is yet the best representative value for the Pb····/Pb″- electrode ; but the lead dioxide electrode is unstable. He computed for the **solubility product** of lead dioxide [Pb][OH′]^4 = 3·25 × 10^{-66}. The e.m.f. of the cell Pb | (PbO,PbO$_2$), N-NaOH,H$_2$ (atm.) Pt = 1·078 volts at 17°. A. Hollard found that the lead dioxide deposited electrolytically on a platinized platinum anode from·a slightly acid soln. of lead nitrate has more oxygen than is required for the dioxide.

S. Glasstone also showed that the electromotive behaviour of electrodeposited lead dioxide is explained by the presence of a trace of a higher acidic oxide—possibly *lead trioxide*, PbO_3—in the deposit. K. Schreber studied the effect of the conc. of the acid on the e.m.f. of lead accumulators. L. Kahlenberg and A. S. McDaniel measured the potential difference between lead dioxide and soln. of lithium chloride in various solvents, *e.g.* with water, -1.194 volts was obtained; with acetone, -1.337 volts; with pyridine, -0.840 volt; and with amylamine, -0.476 volt. By adding water to these liquids, the effect increases slowly with pyridine and amylamine, and rapidly with acetone; with sulphuric acid in place of lithium chloride, the e.m.f. for water rises from -1.194 to -1.756 volts. J. Cayrel studied lead chloride as a **radio-detector.** S. Meyer gave for the **magnetic susceptibility** 0.302×10^{-6}; and for the mol. magnetism, 0.245×10^{-6}.

Hydrated forms of lead dioxide.—In the electrolysis of alkaline soln. of lead salts, the anodic lead dioxide contains variable proportions of water, and, according to H. Nissenson and H. Danneel,[6] the water is driven off at about 180°. H. J. S. Sand also found that at 200° lead dioxide absorbs moisture very readily, but not at 230°. The adsorbed moisture is given off but slowly when heated in a dry atm. If the temp. rises above 300°, there is a risk of the decomposition of the dioxide. H. Zocher said that the water-free dioxide is alone stable, and that the so-called hydrates are really gel-forms of the colloid. Plumbic hydroxide acts as a very feeble base, but F. Hein and H. Meininger showed that if three of the hydroxyl groups are replaced by ethyl or phenyl radicles, relatively strong bases are formed.

A number of problematic hydrates has been supposed to be acids corresponding with definite salts. Thus, G. Kassner, and F. Fischer and H. Plötze speak of *pyroplumbic acid*, or *triplumbic acid*, $3PbO_2.2H_2O$, or $H_4Pb_3O_8$, corresponding with the plumbate $CaH_2Pb_3O_8$. There are also G. Kassner's *tetraplumbic acid*, $H_6Pb_4O_{11}$, corresponding with $Ca_2H_2Pb_4O_{11}$; and *diplumbic acid*, $H_4Pb_2O_6$, corresponding with $CaH_2Pb_2O_6$. The orthoplumbates are usually regarded as salts of an *orthoplumbic acid*, H_4PbO_4. G. Grube, and K. Schreber supposed orthoplumbic acid to be formed by the hydrolysis of alkali metaplumbate (*vide infra*). N. Parravano and G. Calcagni's *hexahydroxyplumbic acid*, $H_2[Pb(OH)_6]$, has not been isolated; it is represented by the salt $K_2[Pb(OH)_6]$, and $Pb[Pb(OH)_6]$. The so-called *metaplumbic acid*, H_2PbO_3, or $PbO(OH)_2$, *lead dihydroperoxide*, was obtained by J. J. Berzelius, and W. Wernicke by the electrolysis of an alkaline soln. of lead tartrate. S. Glasstone made it by the electrolysis of dil. soln. of sodium hydroxide with anodes of lead or lead dioxide; and G. Grube by the electrolysis of a soln. of lead hydroxide in $8N$- to $12N$-KOH at 50° with a platinum anode. G. Grube, and K. Schreber suggested that the composition is $PbO_2.2H_2O$, or orthoplumbic acid, $Pb(OH)_4$, or H_4PbO_4. F. Streintz and G. Naumann confirmed W. Wernicke's observations, and found that the electrode potentials of the elements $Pb \mid PbO_2$, and $Pb \mid H_2PbO_3$ in sulphuric acid against zinc were respectively 2.41 volts and 0.96 volt. W. Wernicke said that the bluish-black deposit has a sp. gr. 6.267 at 15°; and has the refractive indices 1.801 for the C-line; 1.862 for the D-line; and 1.914 for the E-line. G. Grube, and I. Bellucci and N. Parravano have described metaplumbates corresponding with the supposed metaplumbic acid. S. Glasstone showed that the anhydrous oxide is metastable with respect to the hydrated form, and the composition of the so-called metaplumbic acid is variable; he therefore inferred that the evidence for the existence of the supposed metaplumbic acid is indecisive.

Colloidal lead dioxide, or colloidal plumbic acid.—N. Parravano and G. Calcagni found that a $0.012N$-soln. of potassium plumbate is completely hydrolyzed into potassium hydroxide, etc., and I. Bellucci and N. Parravano showed that cryoscopic measurements of the liquid indicate that the dissolved substances have a mol. wt. corresponding with $\frac{1}{2}KOH$. The plumbic acid does not pass through a parchment membrane, and the soln., which appears turbid in reflected light, can be filtered, diluted with water, heated to boiling, and allowed to solidify without in any way changing the plumbic acid. The soln. can be evaporated on the water-bath to a syrupy consistency without coagulating, and the residual gelatinous mass, provided it is not dried, is soluble in water, giving the hydrosol. In this case the impurity which is essential for the maintenance of the plumbic acid in the condition of hydrosol, the so-called *Solbildner*, is potassium hydroxide, the proportion of which is gradually diminished by continued dialysis until, after 104 hrs., the percentage

of K_2O is 1·87, and that of PbO_2, 98·13. This proportion of K_2O is of the same order as the amounts of hydrochloric acid essential for the existence of hydrosols of aluminium, chromium, and ferric hydroxides. The coagulating actions of the anions (potassium salts) decrease according to the series : (1) iodide, ferrocyanide, tartrate, fluoride ; (2) acetate, chromate, iodate, nitrate, sulphate, thiocyanate, chloride, bromide, dichromate, permanganate, chlorate, perchlorate, ferricyanide ; (3) periodate, oxalate, carbonate, arsenate ; and those of the cations (chlorides) according to the series : (1) aluminium, ferric, calcium, strontium, barium, magnesium, cadmium, mercury, manganese, nickel, cobalt, copper ; (2) ammonium, cæsium, lithium, potassium, rubidium, and sodium. The anions and cations of series (1) produce total coagulation, and those of series (2) partial coagulation, whilst the anions of class (3) are without coagulating action. On increasing the vol. of the coagulating soln. used, it was found that the coagulating action was always increased, but not to the same extent for all electrolytes. G. Grube made deep brown colloidal soln. by the hydrolysis of sodium metaplumbate with warm water.

According to A. Gutbier, E. Sauer, and M. Wissmüller, when small quantities of ammonium chloroplumbate are added to a large vol. of water, a brown, colloidal soln. of lead dioxide is obtained. The reaction may be represented by the equation : $(NH_4)_2PbCl_6 + 4H_2O = Pb(OH)_4 + 4HCl + 2NH_4Cl$. The soln. is unstable, and soon becomes colourless as a consequence of the action of the hydrochloric acid, which is liberated, on the colloid in accordance with the equation : $Pb(OH)_4 + 4HCl = PbCl_2 + Cl_2 + 4H_2O$. This may be prevented to a large extent if ammonia is added to the water in quantity sufficient to neutralize the acid which is subsequently set free. If, in addition, small quantities of gum arabic are dissolved in the water, it is possible to obtain fairly stable soln. of the dioxide. The best conditions are attained when 20 c.c. of $0·2N$-NH_3 are added to 250 c.c. of a 0·1 per cent. soln. of gum arabic and one gram of the chloroplumbate added gradually to the well-stirred soln. A. Gutbier and H. O. Meyer used a similar process, using lead tetracetate in place of the chloroplumbate. When freed from electrolytes by dialysis, the soln. can be kept for a considerable time without much decomposition. On evaporation of the soln. to dryness, the dioxide becomes insoluble. The colloidal particles move to the positive pole in an electrical field. When mixed with hydrochloric and nitric acid soln. the brown, colloidal soln. is gradually decolorized, the velocity of the reaction increasing with the conc. of the acid. Sodium hydroxide has a similar action, but the change takes place much less rapidly. Sodium chloride, barium chloride, and aluminium sulphate have no coagulating action, and in presence of these electrolytes the dioxide appears to be approximately as stable as in pure water.

V. Zotier found that when dil. alkali plumbite soln. are treated with hydrogen dioxide, colloidal plumbic acid is formed. He also showed that hydrogen dioxide reacts with basic lead acetates in two stages. In the first, colloidal lead dioxide is formed, and in the second, the lead dioxide reacts with the hydrogen dioxide. At the end of the reaction, the liquid always contains some lead dioxide in soln. Basic lead formates and nitrates react similarly, except for the fact that dil. soln. of these salts only give colloidal lead dioxide. The amount of residual lead dioxide is controlled by four factors. It is at its maximum when the hydrogen dioxide and the lead oxide of the basic salt are in equimol. proportions. It diminishes with increase in the basicity of the lead salt, and also with rise in temp. For different basic acetates it is at its maximum when the salts have undergone the same mol. dilution. The soln. of lead dioxide obtained is exceedingly stable, being unaltered by prolonged boiling. On warming, the lead dioxide is reduced by formaldehyde, dextrose, and sulphites, but not by alcohol. In several of its reactions, such as the liberation of iodine from iodides, it resembles hydrogen dioxide. It presents the characteristic properties of colloidal suspensions. It has a distinct absorption spectrum, showing a broad band from the violet to the blue or green, according to the conc. and thickness of the liquid. The Chemische Fabrik von

Heyden made colloidal lead dioxide by oxidizing a lead salt soln. containing gum arabic or starch. H. Zocher prepared plumbic acid sol in amyl alcohol. He showed that while stannic acid is a lyophile, plumbic acid is a lyophobe. The colloidal soln. of plumbic acid are not very stable, they are easily precipitated, and do not gelatinize.

Chemical properties of lead dioxide.—Lead dioxide is decomposed when exposed to **light**, forming red-lead and oxygen. According to J. E. Mackenzie,[7] at a moderate **heat**, it also furnishes red-lead, and if strongly heated, red-lead and oxygen are formed. The reported temp. of decomposition are very discordant. H. Debray said that lead sesquioxide is formed at 350°, and red-lead at 440°; T. Carnelley and J. Walker reported that it forms lead sesquioxide at about 280°; P. Sabatier and J. B. Senderens, V. A. Kroll, and J. Milbauer also made some observations on this subject. M. Dennstedt and F. Hassler said that lead dioxide gives off oxygen between 290° and 320°; and acquires a red colour at 450°; and W. Hempel and C. Schubert, and W. Stahl said that lead dioxide decomposes at 290°–390° into lead sesquioxide and oxygen; at 410°–450°, into red-lead and oxygen; and at 510°–640°, into lead monoxide and oxygen. According to W. Reinders and L. Hamburger, there is a perceptible dissociation at 100°; oxygen can be detected at 141°; and over 200°, dissociation is very marked. The electrolytic dioxide gives off oxygen in vacuo at 250°. S. Glasstone computed the dissociation press. to be 0·21 atm. at 394°—*vide supra*. F. Fischer and H. Plötze showed that in an atm. of oxygen at 100 atm. press. the residue at 410° corresponded with Pb_5O_8; and at 530°, Pb_2O_3. The oxygen which lead dioxide evolves at 400° was found by O. Brunck to contain some ozone. D. Balareff found that the heating curve of lead dioxide at atm. press. has two terraces, one at 360° and the other at 553°. The latter disappears when the press. is 180 mm. This agrees with the assumption that the lead dioxide first decomposes into lead monoxide, and that the latter is afterwards oxidized to red-lead. The temp. 360° is not a temp. at which the dioxide and oxygen are in equilibrium. W. Biltz studied the effect of temp. on valency in connection with lead dioxide.

According to W. Müller,[8] lead dioxide is reduced by **hydrogen** at 155°. C. R. A. Wright and A. P. Luff said that the reaction begins at 140°. I. W. Fay and co-workers detected signs of reduction after heating lead dioxide in an atm. of hydrogen for 6 hrs. at 150°. F. Glaser said that lead monoxide is formed at 194°; lead hemioxide, at 211°; and lead itself at 235°. P. Sabatier and L. Espil gave 150°–190° for the formation of lead monoxide; 190°–240°, for lead hemioxide; and 250°, lead. K. Frenzel and co-workers said that reduction at 300° is rapid; A. de Hemptinne, that the silent electrical discharge in hydrogen causes the reduction of lead dioxide. S. Glasstone gave for the energy of the reaction: $3PbO_2 + 2H_2 = 2H_2O + Pb_3O_4$, $4·54 \times 96540$ joules at 17°; for $PbO_2 + H_2 = PbO + H_2O$, $2·156 \times 96540$ joules; and for $2PbO_2 + H_2 = Pb_2O_3 + H_2O$, $2·224 \times 96540$ joules. H. J. S. Sand found that **water** vapour is absorbed by lead dioxide below 230°, and but incompletely expelled at 300°. The solubility of lead dioxide in water is very small. S. Glasstone said the solubility product in N-NaOH at 25° is $3·25 \times 10^{-66}$, and of the same order for water. J. Milbauer found that when lead dioxide is heated or triturated with **potassium hydroxide,** some potassium orthoplumbate, and maybe some red-lead, are formed. If a mixture of lead monoxides and dioxides in the molar proportions 3 : 2 be boiled with a conc. soln. of potassium hydroxide (150–200 grms. per 100 c.c.), red-lead is formed; with equimolar proportions, and 300 grms. of potassium hydroxide per 100 c.c. of water, a green unstable product is formed. V. Zotier found that 0·1 grm. of lead dioxide is decomposed by 20 c.c. of **sodium hydroxide** in 15–20 days at ordinary temp., and in less than an hour at 100°. H. Zocher said that freshly prepared lead dioxide soon dissolves in an aq. soln. of sodium dioxide, but the aged dioxide does not dissolve for a long time.

C. F. Schönbein [9] found that lead dioxide is reduced by **ozone**, ozonized turpentine, or by **hydrogen dioxide,** and lead monoxide is formed. A. Mailfert said that

lead oxide is converted by ozone into lead dioxide, and in the presence of alkali hydroxide into alkali plumbate. B. Brauner found that in alkaline soln. the reduction is not complete, and the composition of the product corresponds with Pb_5O_7. E. Pieszczek, and H. Schlossberg showed that in the presence of nitric acid, lead dioxide is smoothly and completely reduced to lead monoxide, oxygen, and water. T. Gigli, and E. Schöne said that the reduction occurs only in the presence of acids—*vide* red-lead.

H. Moissan [10] found that **fluorine** attacks lead dioxide at ordinary temp., forming lead fluoride or an oxyfluoride. B. Brauner said that **hydrofluoric acid** does not dissolve lead dioxide, but if freshly precipitated, F. Fischer and K. Thiele found that some dioxide is dissolved, and hydrofluoplumbic acid is formed. M. Dennstedt and F. Hassler found that lead dioxide absorbs **chlorine** at 200°–220°, and at 260°–280° the reaction is complete ; similar results were obtained with **bromine.** At 350°, chlorine forms normal lead chloride, and from 350°–450°, an oxychloride ; bromine forms oxybromides. A. Classen and B. Zahorsky found that liquid chlorine attacks lead dioxide only when hydrogen chloride is present. G. Bozza and M. Bertozzi studied the action of soln. of chlorine on peroxidized lead anodes. **Hydrogen chloride or bromide** were found by M. Dennstedt and F. Hassler to be absorbed by lead dioxide as in the case of the halogens themselves, forming lead halide, water, and free halogen ; thus, A. Alessi found that in a stream of hydrogen chloride, lead chloride, water, and chlorine are formed. With conc. hydrochloric acid, some lead tetrachloride is formed (*q.v.*). H. Zocher found that hydrochloric acid is adsorbed by colloidal plumbic acid so that after a soln. of **ammonium, potassium,** or **sodium chloride** has been shaken up with the colloid, the reaction is alkaline. M. Dennstedt and F. Hassler found that, unlike chlorine and bromine, **iodine** is not absorbed by lead dioxide ; A. Chwala and H. Colle, that **hydriodic acid** is converted into iodic acid ; and C. F. Schönbein, that **potassium iodide** is decomposed with the separation of iodine—this reaction occurs in aq. or acidic soln., but, as A. Chwala and H. Colle showed, lead dioxide is formed from lead iodide and iodine. According to A. Ditte, when hydrated lead dioxide acts on a soln. of potassium iodide out of contact with air, iodine is set free, and white brilliant needles of the oxyiodide, $(PbI_2.PbO)_2.H_2O$, are formed. In the presence of air, the potassium hydroxide set free absorbs carbon dioxide from the air ; the potassium carbonate formed complicates the reaction, and slightly yellowish needles of the compound $PbI_2.PbO.K_2CO_3.2H_2O$ separate out. When heated, the crystals lose water, and melt to a brown liquid, which forms a yellow mass on cooling : the compound is decomposed by dil. acids, carbon dioxide being given off, whilst the lead dissolves, and a residue of less soluble iodide is left. The same compound may be obtained more readily by passing a few bubbles of carbon dioxide into a mixture of potassium iodide soln. and lead dioxide, or by adding a small quantity of hydrogen potassium carbonate. If too much hydrocarbonate or carbon dioxide is added, the compound $2(PbOI_2.PbO).3K_2CO_3.2H_2O$ is formed. When a current of carbon dioxide is passed into a mixture of lead dioxide and potassium iodide, the latter being in excess, iodine is set free, and soon all the iodide is converted into brilliant needles of either $PbI_2.2KI.2H_2O$, or if the unaltered potassium iodide and the potassium carbonate formed are present in the necessary proportions, $PbI_2.2KI.K_2CO_3.3H_2O$. Both these compounds are decomposed by water. If, on the other hand, lead dioxide acts on potassium iodide in presence of an excess of potassium hydrocarbonate, iodine is set free, and a double carbonate, $2PbCO_3.K_2CO_3$, is obtained as a white, crystalline powder. All the products previously obtained were converted into this double carbonate by the action of an excess of hydrogen potassium carbonate. The product of the action of lead dioxide on potassium iodide in presence of potassium carbonate thus varies with the relative proportions of iodide and carbonate. An increase of temp. has the same effect as an increase in the proportion of carbonate present. Similar results were obtained with **sodium iodide.** A. J. Balard showed that **hypochlorous acid** transforms lead dioxide into

lead chloride with the evolution of oxygen and a little chlorine; E. Müller and O. Friedberger, that **iodic acid** produces a little periodic acid; and W. R. Hodgkinson and F. K. L. Lowndes, that lead dioxide is reduced to red-lead by fused **potassium chlorate.**

The powerful oxidizing property of lead dioxide is illustrated by its effect on **sulphur.** According to L. N. Vauquelin,[11] when lead dioxide is triturated with one-sixth its weight of sulphur, the latter is inflamed, and lead sulphide is formed; and, according to D. H. Grindel, a mixture of the dioxide with half its weight of sulphur is inflamed when touched with a drop of sulphuric acid; and if the mixture contains phosphorus, a violent explosion ensues on trituration. L. Vanino and O. Hauser showed that when **hydrogen sulphide** is passed over moist or dry lead dioxide the mass became red-hot, and there is a blue flame as the dioxide burns to sulphide. The heat of the reaction is such that explosives like gun-cotton or picrates are detonated by its means. M. V. N. Swamy and V. Simhachelan, however, found that hydrogen sulphide mixed with five vols of air does not attack 98·6 per cent. lead dioxide cold or warm, but the mass is reddened, and adsorption products are formed. When an aq. or alcoholic soln. of hydrogen sulphide is treated with an excess of lead dioxide, some lead sulphide is formed and the liquid is freed from the gas—*vide* lead disulphide. **Ammonium sulphide** is likewise decomposed into ammonia and sulphur, and lead sulphide is formed. In analytical work, S. Bogdan showed that a liquid may be freed from ammonium sulphide in a few minutes by digestion with lead dioxide. E. Priwoznik found that yellow ammonium sulphide transforms lead dioxide into lead sulphide. A. Vogel, E. J. Russell and N. Smith, and D. L. Hammick found that at ordinary temp. **sulphur dioxide** reacts with lead dioxide with incandescence, forming lead sulphate, and freshly washed and not too dry lead dioxide absorbs sulphur dioxide from gases, and if oxygen be present, only a little sulphur trioxide is formed by surface action. O. Henry, and M. Dennstedt and F. Hassler showed that lead dioxide retains sulphur dioxide as lead sulphate during the combustion of organic substances. A. Vogel found that **sulphurous acid** transforms lead dioxide into lead sulphate— slowly in the cold, rapidly when heated. P. Marino could detect no signs of the formation of a dithionate; lead sulphite is first formed and the sulphurous acid is oxidized to sulphuric acid, which forms lead sulphate. F. Streintz found that lead dioxide is soluble in a mixture of sulphurous and hydrochloric acids, forming lead sulphate with the evolution of 76·7–84·4 Cals. When lead dioxide is heated with conc. **sulphuric acid,** oxygen and lead sulphate are formed. According to V. Zotier, the complete decomposition requires 25–30 days at ordinary temp., and 3–4 hrs. at 100°. F. Dolezalek and K. Finckh showed that 1·0 millimol of crystalline lead dioxide is dissolved by a litre of conc. sulphuric acid at 22°; and is changed to lead disulphate; contrary to K. Elbs and F. W. Rixon, they found lead dioxide to be slightly soluble in acid containing less than 3 mols of H_2SO_4 per mol of water. O. F. Tower attempted to measure the oxidation potential of lead dioxide in sulphuric acid. M. Traube said that 40 per cent. sulphuric acid does not attack lead dioxide; but if the dioxide be wetted with that acid, and **persulphuric acid** be added, oxygen is immediately evolved and lead sulphate is formed. G. Chancel and E. Diacon found that hot soln. of **pentathionic acid** form water and lead tetrathionate; W. Spring, that **tetrathionic acid** has no action on lead dioxide, but **hyposulphurous acid** attacks the oxide; M. Liebig found that **sodium thiosulphate** in the presence of acetic acid is completely decomposed in the cold; and, according to A. Chwala and H. Colle, some lead tetrathionate is formed, which is partially decomposed to lead sulphide, sulphate, and thiosulphate. E. Spelta found that **sulphuryl chloride** reacts with lead dioxide in the cold, forming lead sulphate and chloride, and oxygen; in excess, with hot soln., some chlorine is produced; H. B. North and A. M. Hageman found that in a sealed tube, at 150°, lead dioxide and **thionyl chloride** form lead chloride and sulphuryl chloride. P. Marino showed that a dil. soln. of **selenious acid** does not reduce lead dioxide

even after a prolonged boiling ; a more conc. soln. forms a mixture of lead selenite with a little selenate ; and with a still more conc. soln., lead selenite and lead pyroselenate.

According to A. Smits,[12] **magnesium nitride** reacts vigorously with lead dioxide. O. Michel and E. Grandmougin showed that **ammonia** gas reacts with heated lead dioxide, forming nitrogen, lead monoxide, and ammonium nitrite and nitrate ; I. W. Fay and co-workers detected signs of reduction after lead dioxide had been heated in an atm. of ammonia for 6 hrs. at 198° ; C. A. Lobry de Bruyn, that **hydroxylamine** is decomposed with inflammation ; E. Puxeddu, that **phenyl-hydrazine** reduces lead dioxide to the hemioxide at 17°, to red-lead at 60° ; and at higher temp., some metallic lead is formed; and E. Lay, that **silicon hydro-trinitride**, Si_2N_3H, forms lead and lead monoxide. According to H. A. Auden and G. J. Fowler, lead dioxide dissolves in **hyponitrous acid,** forming lead nitrate ; **nitrous acid** is oxidized ; and **nitric oxide** gives a basic nitrate and lead. E. Müller and H. Barck found that lead dioxide at room temp. absorbs nitric oxide completely, forming lead nitrate ; at 200°, oxygen splits from the lead dioxide and forms nitrogen peroxide. B. C. Dutt and S. N. Sen found that nitric oxide acts on lead dioxide suspended in water, forming a mixture of lead nitrite and nitrate. The reaction was also examined by P. Sabatier and J. B. Senderens. P. Sabatier and J. B. Senderens found that the reduction to a basic nitrate by **nitrogen peroxide** is complete at 315° ; while **nitrous oxide** and nitric oxide give oxygen and lead monoxide ; when lead dioxide is shaken with water and nitric oxide in the absence of air, lead nitrite is formed. E. Müller and H. Barck found that nitric oxide at room temp. is completely absorbed, forming lead nitrite ; at 200°, a gram of lead dioxide absorbs 35 c.c. of nitric oxide ; and over 200°, some nitrogen peroxide is formed. The absorption of nitrogen peroxide and the higher oxides of nitrogen was discussed by F. Pregl, C. Gränacher, and M. Dennstedt and F. Hassler. The action of **nitric acid** on lead dioxide was examined by E. Franke, and J. F. Sacher. G. Grube found that a little lead dioxide is dissolved when warmed with dil. nitric acid ; and V. Zotier found that the dioxide is perceptibly attacked when stirred for 8 days with nitric acid ; in 15 days at ordinary temp., or in 3 hrs. at 100°, 20 c.c. of acid dissolved 0·1 grm. of dioxide. A. Chwala and H. Colle found $0.5N\text{-}HNO_3$ dissolves with a prolonged boiling less dioxide than $0.2N$-acid boiled for a short time. In time, however, all the dioxide is dissolved and oxygen is evolved. Probably the tetranitrate, $Pb(NO_3)_4$, is the first product of the reaction. According to A. C. Cumming, at 25°, nitric acid dissolves the following quantities of lead dioxide :

Normality of acid .	.	.	5·30	7·50	9·20	11·5
Millimol Pb per litre	.	.	0·140	0·415	0·802	1·54

F. Foerster found that lead dioxide is deposited when the soln. of lead dioxide in nitric acid is electrolyzed. E. Szterkhers showed that a mixture of nitric acid and sodium nitrite converts lead dioxide into lead and sodium nitrates. When lead dioxide and red **phosphorus** are triturated, the mass inflames ; with yellow phosphorus there is an explosion. A. Wurtz found that **hypophosphorous acid** forms lead phosphate ; A. Sänger, **phosphorous acid** forms phosphoric acid ; and V. Zotier, 50 per cent. **phosphoric acid** decomposes lead dioxide in a few months. A. Michaelis found that when lead dioxide is added to warm **phosphorus trichloride,** lead chloride, lead metaphosphate, and phosphoryl chloride are formed with incandescence ; the reaction is more vigorous if phosphorus trichloride be dropped on to lead dioxide ; and the addition of lead dioxide to cold phosphorus trichloride produces a hissing noise. According to C. F. Schönbein, finely divided arsenic is oxidized when shaken in water with lead dioxide ; and arsenic trioxide is oxidized to the pentoxide. C. Reichard said that the oxidation of arsenic trioxide does not occur in water or aq. ammonia, but only in conc. alkali-lye. T. E. Thorpe and J. W. Rodger found **thiophosphoryl fluoride** is completely absorbed by lead dioxide.

According to C. R. A. Wright and A. P. Luff,[13] **carbon** reduces lead dioxide at 260°; and **carbon monoxide** at 80°—in a sealed tube at 100° some carbon dioxide was formed. I. W. Fay and co-workers observed signs of reduction after heating lead dioxide in carbon monoxide for 6 hrs. at 110°, or in **methane** at 45°. No action was observed with **carbon dioxide**. H. Weil said that a little carbon dioxide is retained by lead dioxide, but M. Dennstedt and F. Hassler observed only a trace of adsorption below 100°, and none between 100° and 350°. A. de Hemptinne observed that under the influence of a silent discharge, the carbon monoxide behaves in a manner analogous to hydrogen. L. J. Constam and A. von Hansen found that **potassium percarbonate** is reduced. Aq. **hydrocyanic acid** furnished lead cyanide, water, and cyanogen: $PbO_2+4HCy=PbCy_2+2H_2O+Cy_2$. S. Tanatar found that a mixture of eq. proportions of potassium cyanide and hydrocyanic acid dissolve a little lead dioxide. C. F. Schönbein observed that **potassium ferrocyanide** is oxidized by lead dioxide, and **potassium ferrous ferrocyanide,** $K_2Fe(FeCy_6)$, is coloured blue. P. Sabatier and A. Mailhe found that the vap. of primary **alcohols** easily reduce the dioxide at 180°, forming lead monoxide, carbon dioxide, aldehyde, and acid; above 260°, the lead monoxide becomes active. H. Geisow showed that **formaldehyde** is oxidized to formic acid, and not carbon dioxide; J. F. Sacker, **acetic acid** reduces lead dioxide; and A. Chwala and H. Colle, **sodium acetate** soln. dissolves lead dioxide, forming the alkali plumbate. R. Böttger triturated lead dioxide with an eq. weight of **oxalic acid,** and obtained without ignition, steam, carbon dioxide, and lead carbonate; in the cold, a soln. of oxalic acid was found by A. Chwala and H. Colle to yield lead oxalate slowly and completely evolving oxygen gas. R. Böttger showed that lead dioxide becomes incandescent when triturated with one-sixth its weight of **tartaric acid, gallic acid, glucose,** or **mannite,** and with one-eighth its weight of **racemic acid, tannin,** or **cane-sugar.** F. C. Krauskopf found that a N-soln. of **potassium tartrate** dissolves lead dioxide without the evolution of oxygen; and A. Vogel, that lead oxide is formed when the dioxide is heated with sugar, or **turpentine.** C. F. Schönbein noted that the colours of many organic substances are destroyed; but tincture of **guaiacum** is coloured blue (R. Dupouy); an acetate acid soln. of **diphenylamine,** blue, by one part of the dioxide in 3,000,000 (C. G. Hinrichs); **methyldiaminodiphenylmethane,** blue (A. Trillat); and a conc. hydrochloric acid soln. of **aniline hydrochloride,** purple (W. V. Morgan). Numerous other reactions with lead dioxide as an oxidizing agent for organic substances have been examined. L. Kahlenberg and W. J. Trautmann found that lead dioxide behaves like red-lead towards powdered **silicon.** G. Rauter showed that **silicon tetrachloride** furnishes lead monoxide and chloride, silica, and chlorine; E. Lay, that with **silicon hexamminotetrabromide** lead is formed; and L. Moser, that **titanium trichloride** is oxidized when boiled with lead dioxide.

C. F. Schönbein[14] noticed that when finely divided **tin** or **lead** is shaken in water with lead dioxide, the metal is oxidized. According to G. von Hevesy, at the surface of contact of lead dioxide with a soln. containing $0.001N$-lead nitrate, and $0.001N$-nitric acid, and sat. with lead dioxide mixed with a trace of thorium-B, the rate of exchange was smaller than is the case of lead ($q.v.$), and approximated to the condition of thermodynamic equilibrium. H. Moissan noted that powdered **molybdenum** or **tungsten** mixed with lead dioxide becomes incandescent when heated, and oxidation occurs. F. de Carli found that lead dioxide reacts with **barium dioxide** but not with calcium, zinc, cadmium, or magnesium oxide. E. Müller and M. Soller found that a soln. of **chromic sulphate** furnishes chromic acid; and W. Crum, that soln. of **manganese salts** when warmed with lead dioxide and dil. nitric acid, become purple owing to the formation of a permanganate. This reaction is utilized in the colorimetric determination of manganese. C. F. Schönbein added that in the presence of dil. nitric acid, and lead dioxide, manganous salts furnish manganese dioxide; and manganese dioxide, manganese heptoxide, Mn_2O_7. D. Vitali said that under these conditions

manganese sulphate, $MnSO_4$, becomes manganic sulphate, $Mn_2(SO_4)_3$. The reaction was studied by E. I. Dyrmont, and N. A. Waljaschko. L. L. de Koninck showed that a boiling soln. of a manganese salt in fuming hydrochloric acid becomes greenish-black when treated with lead dioxide, owing to the formation of lead tetrachloride—red-lead does not act in the same way. According to H. N. Morse, in the presence of nitric acid, lead dioxide and permanganic acid both lose oxygen : $3PbO_2+2HMnO_4=H_2O+2MnO_2+3PbO+3O_2$. H. Moissan found oxygen is evolved when a mixture of carbon, and lead and manganese dioxides is heated. A. Levol said lead dioxide dissolves completely in a soln. of mercurous nitrate, forming mercuric nitrate and lead monoxide. A. Vogel found stannous chloride reacts with lead dioxide, forming lead chloride and stannic oxide. C. F. Schönbein found that ferrous salts are oxidized by lead dioxide, and, according to C. Russo and G. Sensi, the reaction is quantitative. The reaction was studied by L. Lucas, and C. Semper and C. Fahlberg, etc. When a mixture of lead dioxide and ferrous sulphate is heated, J. G. McIntosh obtained red ferric oxide—the so-called *Venetian red*. Lead dioxide is chiefly used in making safety matches, in the manufacture of accumulator plates, and in the dye industry.

§ 20. The Plumbates

According to E. Frémy,[1] **potassium metaplumbate**, $K_2PbO_3.3H_2O$, is formed by fusing lead dioxide with an excess of potassium hydroxide in a silver crucible, dissolving the product in water, and evaporating the soln., which then furnishes definite crystals. The same product is obtained by fusing potassium hydroxide and lead monoxide. The monoxide is oxidized to dioxide during the fusion, and the reaction then proceeds as before. S. Meunier, and O. Seidel used similar processes. I. Bellucci and N. Parravano added lead dioxide to a hot soln. of 100 grms. of potassium hydroxide and 20–30 grms. of water, until no more dissolved. The cold mass was dissolved in a small proportion of water, filtered, and the soln. seeded with crystals of potassium stannate or platinate. The crystals were washed rapidly with absolute alcohol, dried first between folds of filter-paper, and afterwards over potassium hydroxide in a desiccator. The yield was said to be good. G. L. Clark used a similar process. G. Grube prepared this plumbate by the anodic soln. of a lead anode in a conc. soln. of alkali hydroxide by means of a direct current of high current density on which is superposed an alternating current. In another method, a soln. of lead monoxide in alkali-lye is submitted to anodic oxidation at a platinum electrode. In both cases, alkali plumbates crystallize from the liquid during the electrolysis. F. Jirsa electrolyzed a soln. of 40 grms. of potassium hydroxide and 4·5 grms. of lead monoxide per litre, using an alternating current, and palladium electrodes. There was a deposit of yellow sesquioxide and a soln. of lead plumbate was formed—*vide* lead dioxide, and alkali plumbates. For the oxidation of plumbite to plumbate, *vide* the plumbites.

Analyses of the products, by E. Frémy, G. Grube, and I. Bellucci and N. Parravano, agree with the formula $K_2PbO_3.3H_2O$. As G. L. Clark, and I. Bellucci and N. Parravano have shown, the water is constitutional because, when it is expelled, the compound decomposes. By analogy with the isomorphous stannate, and platinate, the formula is written $K_2Pb(OH)_6$; and this is confirmed by the formation of the sesquioxide, $Pb_2O_3.3H_2O$, or rather $Pb[Pb(OH)_6]$, when the soln. is treated with potassium plumbite, K_2PbO_2. On the other hand, G. Grube found that when the sodium salt is heated, the water can be all expelled without decomposing the salt, and hence he inferred that the 3 mols of combined water are water of crystallization, and that the compound is therefore a salt of metaplumbic acid. A. Geuther claimed to have made the anhydrous salt from the product obtained by passing oxygen into a fused soln. of lead monoxide in potassium hydroxide. The pale, yellowish-brown, dichroic plates, according to O. Lüdecke, belong to the hexagonal system. As indicated above, G. L. Clark found the trihydrate decomposes as the water is expelled.

Crystals of trihydrated potassium plumbate were described by E. Frémy as colourless, transparent rhombohedra ; by O. Seidel, as six-sided plates belonging to the tetragonal system ; by O. Lüdecke, and F. Zambonini, as colourless plates belonging to the trigonal system, which, according to the latter, have the axial ratios $a : c$ $=1 : 1·9518$, and $a=70°$ 10·26', and are isomorphous with the corresponding stannate and platinate. E. Frémy said the crystals deliquesce in air, O. Seidel that

they effloresce. The moist crystals were found by O. Seidel, and F. Zambonini to turn quickly yellow, and slowly to acquire a brown colour owing to the separation of lead dioxide. The original salt is regenerated when the changed material is returned to the mother-liquid. E. Frémy said that the metaplumbate gives off oxygen and water when heated ; and O. Seidel said that the expulsion of the last mol. of water is attended by the evolution of oxygen. G. L. Clark said that the salt is stable below 100° in the presence of potassium hydroxide ; at 150°, it acquires a pale yellow colour ; and at a higher temp., it decomposes into potassium hydroxide, oxygen, lead monoxide, and water. I. Bellucci and N. Parravano said that in an indifferent gas at 100°, the metaplumbate does not lose its weight during a long period of time, but if more strongly heated, the mol. is broken down, and water and oxygen are evolved, leaving a residual mixture of potassium hydroxide and lead monoxide. E. Frémy, O. Seidel, and I. Bellucci and N. Parravano observed that water decomposes the metaplumbate with the separation of lead dioxide. G. L. Clark said that the salt is hydrolyzed by water in accord with the equation : $K_2Pb(OH)_6 + 2H_2O \rightleftharpoons 2KOH + H_2Pb(OH)_6$, and that the latter breaks down $H_2Pb(OH)_6 = H_4PbO_4 + 2H_2O$. If 20 per cent. of water be present, the hydrolysis proceeds so far that hydrated lead dioxide is precipitated. I. Bellucci and N. Parravano showed that if the soln. be cooled by a freezing mixture, and neutralized with acetic acid, a pale yellowish-brown, flocculent precipitate appears which gradually darkens, and after being filtered and dried forms chestnut-brown, anhydrous lead dioxide. O. Seidel found that alcohol behaves like water. According to E. Frémy, and O. Seidel, the metaplumbate dissolves without decomposition in potash-lye of moderate conc. G. Grube said that while the normal potential of lead against potassium plumbite in $8·42N$-KOH at 18° is $-0·613$ volt (hydrogen electrode), the potential of lead against the alkali plumbate is $-0·203$ volt. A decrease in the conc. of the alkali displaces the potential towards the more negative values. From the electric conductivity and the effect on the saponification of acetic ether, N. Parravano and G. Calcagni inferred that only in conc. soln. is any undecomposed salt present ; the hydrolysis is almost complete in $0·012N$-KOH soln. I. Bellucci and N. Parravano came to the same conclusion from their measurements of the f.p. of the soln. G. Grube showed that the conc. alkaline soln. contains ions of both orthoplumbic acid, PbO_4'''', and of metaplumbic acid, PbO_3'', or hexahydroxyplumbic acid, $Pb(OH)_6''$. The oxidation potential in alkaline soln. was also measured by G. Grube.

G. Grube showed that the conc. alkaline soln. of the metaplumbate is reduced to plumbite by lead ; and E. Frémy said that soln. of various oxides—e.g. lead, zinc, or aluminium oxide—in potassium hydroxide precipitate plumbates ; and O. Seidel found that calcium, barium, and magnesium oxides form insoluble plumbates when boiled with a soln. of potassium metaplumbate in alkali-lye. Lead, according to G. Grube, reduces the alkali plumbate to plumbite. When the soln. of alkali plumbate is mixed with one of alkali plumbite, E. Frémy found that yellowish-brown hydrated lead tritatetraoxide is precipitated ; and O. Seidel, and I. Bellucci and N. Parravano, with not very dil. soln., obtained the trihydrated sesquioxide. G. Grube found the composition of the precipitate depends on the conc. of the mixed alkali plumbite and plumbate soln.: if less conc. than $4·9N$-KOH, the hydrated sesquioxide is deposited ; and if more conc. than $6·9N$-KOH, red-lead is separated.

H. Zocher reported the formation of **trihydrated lithium metaplumbate**, $Li_2PbO_3.3H_2O$, or $Li_2[Pb(OH)_6]$, in microscopic, colourless, six-sided plates, by the action of a sat. soln. of lithium hydroxide on a soln. of sodium metaplumbate in one of sodium hydroxide. The birefringence of the crystals is small, and the salt was thought to be isomorphous with the sodium salt. G. Grube, E. Frémy, O. Seidel, and I. Bellucci and N. Parravano prepared **trihydrated sodium metaplumbate**, $Na_2PbO_3.3H_2O$, or $Na_2[Pb(OH)_6]$, by methods similar to those employed for the potassium salt. G. L. Clark mixed 150 grms. of sodium hydroxide with 50 c.c.

of water at 100°, and added lead dioxide so as to form a paste, 25 c.c. of water were then added and more lead dioxide. The resulting product was considered to be **hexahydrated sodium metaplumbate**, $Na_2PbO_3.6H_2O$. H. Zocher prepared sodium plumbate by dissolving freshly precipitated lead dioxide in small quantities at a time in boiling $8N$- to $10N$-NaOH. The salt is very sparingly soluble in this menstruum, and separates in crystals supposed to be isomorphous with sodium stannate. G. Grube said that the white crystals have a yellow tinge, and when heated under the alkali-lye, between 250° and 300°, they form the anhydrous salt. G. L. Clark could not make **sodium metaplumbate,** Na_2PbO_3, by fusing together dry sodium hydroxide and lead dioxide. A. Chwala and H. Colle obtained sodium metaplumbate from a soln. of lead dioxide in an aq. soln. of sodium acetate. M. Höhnel added sodium dioxide to a mush of lead dioxide and water until the mixture became white. The product was washed with 50 per cent. alcohol, then with 95 per cent. alcohol, until the filtrate was nearly neutral, and finally dried in vacuo over sulphuric acid. The composition corresponded with **tetrahydrated sodium metaplumbate,** $Na_2PbO_3.4H_2O$. I. Bellucci and N. Parravano showed that the product is impure owing to hydrolysis; and H. Zocher obtained only the trihydrate by this process.

E. Frémy, H. Zocher, and M. Höhnel observed that if the salt be exposed to the air for a short time it acquires a bronze colour. G. L. Clark said that the decomposition in air proceeds rapidly at 100°, and that it is more rapidly hydrolyzed than the potassium salt. M. Höhnel said that the hydrolysis is rapid and complete in boiling water. A. Bonnet showed that as with the alkali plumbite (q.v.) lead hydroxide can be deposited as a mordant on cotton by soaking the fibres in alkali plumbate followed by treatment with hot water. According to W. G. Mixter, the heats of formation are $(Na_2O,PbO_2,aq.)=15.5$ Cals.; $(Na_2,O,PbO_2)=139.7$ Cals. H. Zocher found that in the presence of a great excess of sodium hydroxide, the soln. is rich in plumbate ions and is colourless, consequently it does not contain colloidal lead dioxide; dil. soln. become yellow and then brown owing to the formation of colloidal lead dioxide; G. Grube also obtained a colloidal soln. of lead dioxide by heating the alkaline soln. The colloid is flocculated by nitric acid. On standing a few days, H. Zocher found that the conc. soln. deposits acicular crystals of red-lead on the walls of the vessel. M. Höhnel said that sodium plumbate is slowly hydrolyzed by alcohol. Cold dil. nitric, sulphuric, and acetic acids decompose the metaplumbate like boiling water; conc. sulphuric acid forms lead sulphate and oxygen; and hydrochloric acid forms lead chloride and water. According to M. Höhnel, if sodium metaplumbate is washed with water, saffron-red **sodium hydrometaplumbate,** $NaHPbO_3.3H_2O$, is formed. I. Bellucci and N. Parravano, and H. Zocher doubt the accuracy of this conclusion.

J. Milbauer reported the formation of **lead orthoplumbate,** K_4PbO_4, or $Pb(OK)_4$, by heating a very conc. aq. soln. of potassium hydroxide in a silver dish with lead dioxide; the sat. soln. of lead dioxide is allowed to stand in another dish for some days over sulphuric acid. The crystals which separate are pressed between porous tiles. The same product was obtained by triturating lead dioxide with a cold sat. soln. of potassium hydroxide. If red-lead is used some plumbite is also formed. The existence of the orthoplumbate is not definitely established. A. Geuther heated a soln. of lead monoxide in fused potassium hydroxide for a long time in air, and obtained black crystals of what was considered to be **potassium deuterotriplumbate,** $K_4Pb_3O_8$ (vide silicates, **6.** 40, 50), and the same product was said to be formed by the action of oxygen on a soln. of lead oxide in a very conc. aq. soln. of lead oxide in potassium hydroxide. The crystals were washed rapidly with cold water, dried between filter-paper over sulphuric acid. Here again there is some doubt about the identification of the product. Sodium orthoplumbate could not be prepared. K. Elbs and F. Fischer found that soln of lead sulphate in an excess of a cold 20 per cent. soln. of sodium hydroxide contains both the meta- and the ortho-plumbate. According to

A. Gutmann, if cyanogen iodide be added to a soln. of 3 grms. of lead acetate in 80 grms. of aq. sodium hydroxide, a red precipitate is formed, and after washing out the lead iodide, lead dioxide remains. G. Grube said that soln. of sodium plumbate in conc. alkali-lye contain ions of **sodium orthoplumbate,** Na_4PbO_4, but the salt cannot be isolated because, on adding more sodium hydroxide the conc. of the sodium orthoplumbate does not increase while the solubility product of $[Pb''][PbO_4'''']$ is exceeded and lead orthoplumbate—red-lead—is deposited. According to G. Kassner, when steam is passed over sodium metaplumbate, **sodium dihydrorthoplumbate,** $Na_2H_2PbO_4$, or **sodium orthodiplumbate,** $Na_4H_2Pb_2O_7$, is produced. The former gives off water, and oxygen at a temp. exceeding 300°, and furnishes sodium plumbite, Na_2PbO_2 ; in the presence of oxidizing agents, however, only water is given off, and sodium orthoplumbate remains. H. Zocher prepared **trihydrated lithium plumbate,** $Na_2PbO_3.3H_2O$, or $Na_2Pb(OH)_6$, isomorphous with the sodium salt.

By digesting tetrahydrated calcium metaplumbate with an excess of an aq. soln. of cupric acetate ; washing the product with water ; and then with dil. ammonia, M. Höhnel obtained a deep black, amorphous powder of **cupric metaplumbate**—presumably $CuPbO_3$—which loses no copper when digested with dil. ammonia. Acetic acid dissolves the copper, and leaves the lead as dioxide. B. Grützner and M. Höhnel [2] prepared **silver metaplumbate,** Ag_2PbO_3, as a grey powder consisting of microscopic cubes, by digesting calcium metaplumbate with an aq. soln. of silver nitrate. The crude product contains silver oxide which can be removed by washing with aq. ammonia.

E. Frémy [3] made the alkaline earth plumbates by heating a mixture of, say, calcium oxide and lead oxide, the required oxygen is absorbed from the air ; S. Melzer heated lead sulphate with calcium oxide and water ; and O. Seidel, J. Marx, and W. Crum employed a similar process. S. Meunier added lead to a soln. of barium or calcium oxide in molten alkali hydroxide. No definite formula was assigned to the products. G. Kassner reported anhydrous **calcium meta- plumbate,** $CaPbO_3$, or $CaO.PbO_2$, to be formed, not by heating a mixture of equi- molar proportions of lead and calcium oxides in air, but by heating the tetrahydrated orthoplumbate to 250° in the absence of the carbon dioxide of the air ; the product is said to be a mixture of equimolar proportions of calcium metaplumbate and calcium hydroxide. The latter can be removed by washing with water free from carbon dioxide. The pale brown powder is said to decompose when heated, forming calcium orthoplumbate, lead oxide, and oxygen. Calcium metaplumbate is not soluble in water ; but after it has stood a long time in water it is said to form **dihydrated calcium metaplumbate,** $CaPbO_2.2H_2O$, when the product is dried at a gentle heat, or over sulphuric acid. The brown dihydrate loses its water at 300°. B. Grützner and M. Höhnel prepared **barium metaplumbate,** $BaPbO_3$, by heating a mixture of barium dioxide and lead monoxide ; by boiling lead dioxide with a soln. of barium hydroxide ; and by the action of sodium dioxide or potassium hydroxide on barium orthoplumbate. A. Chwala and H. Colle made it by digesting, without boiling, lead dioxide or red-lead with a conc. soln. of sodium acetate ; and then adding a soln. of lead nitrate. The product is washed, and then dried at 120°. O. Seidel made the same salt by boiling a soln. of potassium metaplumbate with barium oxide. D. Balareff found evidence of a slight thermal change when mixtures of barium and plumbic oxides are heated between 360° and 365°.

B. Grützner and M. Höhnel prepared **tetrahydrated calcium metaplumbate,** $CaPbO_3.4H_2O$, by digesting the orthoplumbate with sodium dioxide and water ; a less pure product is obtained by substituting alkali hydroxide for the dioxide. G. Kassner used somewhat similar processes. According to B. Grützner and M. Höhnel, the white powder consists of microscopic cubes, and it has a faint yellow tinge. It loses a little water when dried in vacuo ; 0·26 per cent. when heated to 60°–70° ; 1·11 per cent. at 115° ; and at 120° it begins to decompose, and acquires a yellow colour. It then gives off water and oxygen leaving a yellowish-brown

residue.   G. Kassner said that in air free from carbon dioxide the tetrahydrate loses no water at 130°; at 180°, a little water is given off and a pale brown colour appears; at 250°, about three-fourths of the water is driven off, but not all is expelled at 300°.   It becomes anhydrous if heated rapidly to 350° with air excluded—some free calcium oxide is then present.   B. Grützner and M. Höhnel added that the tetrahydrate is not changed by hot or cold water; a hot soln. of alkali carbonate leads to the separation of lead dioxide; nitric acid, dil. sulphuric acid, and dil. acetic acid, when boiled with calcium metaplumbate also separate lead dioxide; conc. sulphuric acid furnishes lead sulphate and oxygen; hydrochloric acid produces lead chloride and chlorine; and carbon dioxide acts slowly in the cold, and rapidly when heated, forming lead dioxide.

W. Crum prepared an orthoplumbate by heating a soln. containing milk of lime, bleaching powder, and red-lead for 5 hrs. at 71°.   G. Kassner prepared anhydrous **calcium orthoplumbate,** from an intimate mixture of equal parts of calcium hydroxide and lead oxide, or of two mols of calcium carbonate and one mol of lead oxide by calcination in air at about 850°.   K. Wedemeyer used a similar process.   G. Kassner prepared **strontium orthoplumbate,** Sr_2PbO_4, and **barium orthoplumbate,** Ba_2PbO_4, in an analogous manner.   J. A. Hedvall and co-workers heated to 500° a mixture of the required proportions of barium dioxide and lead monoxide or red-lead.   Calcium orthoplumbate is a yellowish-red powder which looks very like litharge; the sp. gr. of a 97 per cent. orthoplumbate is 5·71.   Oxygen is gradually evolved when the orthoplumbate is heated.   On the other hand, oxygen is more quickly and completely absorbed from the air by the dioxygenated plumbate than by barium oxide.   G. Kassner recommended the following process for preparing oxygen, with carbon dioxide as a by-product:

Porous calcium plumbate is moistened with steam and subjected to the action of washed furnace gases, preferably, at a temp. below 100°.   The carbon dioxide of the furnace gases is rapidly absorbed, and the material, which retains its porous condition, then consists of a mixture of calcium carbonate and lead dioxide.   This is transferred to a retort kept constantly at a red heat, and in this oxygen is evolved, the evolution being much helped by the introduction of a current of steam.   After the evolution of the oxygen, the current of steam is continued, and the temp. raised, when carbon dioxide is liberated, and may be collected for use.   The calcium plumbate is then regenerated by means of a current of air.

H. le Chatelier said the dissociation pressures, p, are about 200° lower than those for barium dioxide, being

	880°	940°	950°	1020°	1060°	1070°	1100°	1110°
p . .	47	112	117	350	557	570	940	1040

With cold water, it furnishes the tetrahydrate; and with hot water, **calcium dihydroproterodiplumbate,** $CaH_2P_2O_6$.   If the orthoplumbate be triturated in a mortar along with potassium hydrocarbonate, and water at 40°, the mixture begins to turn brown, and the temp. then rapidly rises to the b.p. of water.   Cold dil. acids cause the separation of lead dioxide.   It is decomposed by water containing carbon dioxide in soln.   G. Kassner prepared **tetrahydrated calcium orthoplumbate,** $Ca_2PbO_4.4H_2O$, by stirring the anhydrous salt with a little warm water, free from carbon dioxide.   In a few days the product can be dried in vacuo, or over sulphuric acid.   The colourless transparent crystals lose much water at 100°, but all the water is not expelled at 145°.

According to G. Kassner, calcium orthoplumbate can be used for the preparation of oxygen; the purification of aluminium salt soln. from iron; in the match industry; in the manufacture of glass and glazes; and, according to W. Kwasnik and K. Wedemeyer, as an oxidizing agent in the analysis of ashes.

G. Kassner reported a number of **calcium polyplumbates.**   He treated calcium orthoplumbate with water under press., or at 150°, and obtained a yellowish-green, voluminous powder which was regarded as a mixture of calcium hydroxide and

calcium dihydroproterodiplumbate, $CaH_2Pb_2O_6$, which he represented graphically as indicated below. The calcium hydroxide is removed by washing the product with water free from carbon dioxide, or very dil. acids, and drying at 105°. The yellow or olive-green powder is slowly darkened or blackened by acids at ordinary temp., forming lead dioxide ; boiling acetic acid quickly produces the same change. It loses half its combined water at 310°, forming $Ca_2H_2Pb_4O_{11}$, and the other half at 380°, forming $Ca_2Pb_4O_{10}$. It loses oxygen at 550°, and forms a mixture of calcium orthoplumbate and lead dioxide. G. Kassner heated tetrahydrated calcium metaplumbate in a stream of air free from carbon dioxide at 250° ; and also tetrahydrated calcium orthoplumbate in a stream of air free from carbon dioxide, or in dry oxygen, at 260°–280° ; in nitrogen at 245°–255° ; or in an evacuated sealed tube at 240°–245°. The composition of the product corresponded with **calcium orthodiplumbate,** $Ca_2Pb_2O_7$, or else with *calcium proterodiplumbate*, $Ca_2Pb_2O_6$ (polymerized metaplumbate). Graphically, he employed the formulæ :

$CaH_2Pb_2O_6$	$Ca_2Pb_2O_7$	$CaPb_2O_6$
The reddish-brown powder of calcium orthodiplumbate is decomposed by water with the evolution of oxygen ; and the decomposition with acids—particularly nitric acid—is vigorous. Alcohol does not act on the compound.

G. Kassner treated calcium dihydroproterodiplumbate with 10 per cent. nitric acid, and obtained a greyish-brown powder resembling the original substance in general properties, and decomposing suddenly at a definite temp. into oxygen, lead dioxide, etc. The composition of the compound dried at 110°, corresponds with **calcium dihydrodeuterotriplumbate,** $CaH_2Pb_3O_8$. As previously indicated, when calcium dihydroproterodiplumbate, $CaH_2Pb_2O_6$, is heated from 300° to 320°, half the contained water is expelled, and the mol. coalesce in pairs, forming **calcium dihydrodeuterotetraplumbate,** $Ca_2H_2Pb_4O_{11}$:

$Ca_2H_2Pb_4O_{11}$
as a yellow powder which loses all its water at 380°–400°, forming **calcium triterotetraplumbate,** $Ca_2Pb_4O_{10}$. The grey powder loses practically no lime when treated with water free from carbon dioxide.

According to G. Kassner, when a mixture of calcium and lead oxides in the proportion CaO : PbO is heated at 450°–480° in a current of air freed from carbon dioxide, the product is not calcium metaplumbate, $CaPbO_3$, but appears to be a mixture of uncombined lime with a mixed salt, **calcium lead orthoplumbate,** $CaPb(PbO_4)$. This has a red colour ; hydrochloric acid acts on it with liberation of chlorine, whilst nitric and acetic acids cause a separation of lead dioxide ; above 550°, it appears to decompose in accord with the equation $4CaPb(PbO_4)=2Ca_2PbO_4 +6PbO+O_2$.

According to O. Seidel,[4] and C. Jones and co-workers, when a mixture of eq. proportions of lead and magnesium oxides is heated in a current of air at about 800°, **magnesium metaplumbate,** $MgPbO_3$, is formed. S. Meunier obtained it by the action of a soln. of magnesia in molten alkali hydroxide on molten lead; and O. Seidel found that when an alkaline soln. of potassium plumbate is boiled with an excess of magnesia, the same compound is formed as a brown powder which gives off oxygen at a dull red heat. E. Frémy, and O. Seidel, mixed soln. of potassium plumbate and potassium zirconate, and obtained yellow flocculent precipitates corresponding with Pb_4O_7. M. Höhnel treated finely divided tetrahydrated calcium

metaplumbate with a slight excess of a sat. soln. of zinc carbonate in acetic acid, for some hours, and washed the product with water, and dil. sodium hydroxide. On drying between filter-paper, and over calcium chloride, the product corresponded with dihydrated **zinc metaplumbate,** $ZnPbO_3.2H_2O$. The reddish-brown powder consisted of microscopic cubes. Hot water does not act on the plumbate, and soda lye does not dissolve it; with conc. sulphuric acid, oxygen is evolved, and with hydrochloric acid, chlorine; and dil. nitric acid or acetic acid furnishes lead dioxide. I. Bellucci and N. Parravano did not get a product suitable for analysis by the above method of preparation. E. W. Buskett said zinc plumbate is probably present in the so-called sublimed white lead. I. Bellucci and N. Parravano made brown trihydrated **thallous metaplumbate,** $Tl_2PbO_3.3H_2O$, or $Tl_2Pb(OH)_6$, by mixing alkaline soln. of potassium metaplumbate with thallous nitrate soln., washing, and drying over sulphuric acid. The compound loses very little water at 100°, and thallium readily volatilizes when heated to a higher temp. The compound is hydrolyzed by water.

§ 21. Lead Fluorides

C. W. Scheele [1] stated that lead is not dissolved by hydrofluoric acid, but the oxide dissolves in the acid, forming a sweet soln. J. L. Gay Lussac and L. J. Thénard, however, showed that the acid, heated below its b.p., attacks the metal easily ; and E. Frémy, and J. J. Berzelius and H. von Helmolt obtained **lead fluoride,** PbF_2, by dissolving lead hydroxide or carbonate in an excess of hydrofluoric acid, evaporating the soln. to dryness, and igniting the product. C. W. Scheele, and E. Frémy obtained a precipitate of lead fluoride, by adding hydrofluoric acid or an alkali

fluoride to a soln. of lead nitrate or acetate.   A. Guntz obtained lead fluoride by the action of hydrogen fluoride on lead.   H. Moissan also obtained lead fluoride by the action of fluorine on lead, or on several compounds of lead—oxides, iodide, nitrate, carbonate, etc.   O. Ruff and E. Geisel electrolyzed a sat. soln. of ammonium fluoride in a U-tube of lead at 0°, and found that lead fluoride is deposited in the tube.

E. Frémy said that lead fluoride forms a white, crystalline powder.   M. L. Dundon found that the crystals belong to the rhombic system, having an average refractive index of 1·83, and a hardness of 2.   The sp. gr. is 8·24 ; the mol. vol. 29·7 ; and the surface energy of the solid is 900 ergs at 25°.   A. Reis and L. Zimmermann gave 9·2 for the scratching hardness when that of ammonium bromide is unity.   H. Schottky gave for the sp. ht., 0·07216 between 0° and 34° ; and 17·67 for the mol. ht. ; C. Sandonnini observed no transformation on the heating curve up to 300°.   J. J. Berzelius said that lead fluoride melts easily, and C. Sandonnini added that it fuses without decomposition at about 824° ;   N. A. Puschin and A. Baskoff gave 855° for the m.p. ;   and M. Amadori, 820°.   According to H. von Wartenberg and O. Bosse, the heat of vaporization of lead fluoride formed from hydrofluoric acid and water by fusion is 39·425 Cals. ;   and the vap. press., p, in atm. is log $p=-39425/4·571T$ $+5·510$.   There is no sign of doubled mol. at 1440°.   R. Lorenz and W. Herz studied this subject.   H. von Wartenberg gave 156 Cals. for the heat of formation of PbF_2 ;   and A. Guntz gave 2·2 Cals. for the heat of precipitation, and 105·2 for the heat of formation when that of hydrogen fluoride is 37·5 Cals.—M. Berthelot and H. Moissan found 38·9 for the latter.   W. Beetz said that lead fluoride conducts electricity electrolytically.   M. le Blanc found that the electrical conductivity of the pressed powder is very small, but it increases appreciably by previously heating the mass in a current of dry air.   C. Fritsch made observations on this subject.   F. Kohlrausch gave for the electrical conductivity of an almost sat. soln., at 8·99°, 0·003310 ;   at 18°, 0·004310 ;   at 26·61°, 0·005350 ;   and at θ°, 0·004310$\{1+0·0208(\theta-18)+0·00003(\theta-18)^2\}$.   C. Tubandt found that with fused lead fluoride, the current was entirely carried by the F'-ion, so that the gain in weight in the anode compartment was exactly eq. to the cathode deposit of a silver voltameter included in the circuit.   S. Meyer gave $-0·519\times10^{-6}$ for the magnetic susceptibility, and $-0·046\times10^{-6}$ for the mol. magnetism.

C. Sandonnini said that the properties of lead fluoride stand closer to those of lead monoxide than to those of the other three lead halides.   E. Frémy found that at a red heat lead fluoride is reduced to the metal by **hydrogen ;** and, according to H. Moissan, by **sodium hydride.**   E. Frémy said that it is not oxidized at a red heat by **oxygen,** but when heated in air or the vapour of **water,** it furnishes hydrogen fluoride, and lead oxyfluoride.   It is sparingly soluble in water ; at 8·99°, F. Kohlrausch found that water dissolves 598 mgrms. per litre, or 0·05488 gram-eq. per c.c. ; at 18°, 0·05524 gram-eq. per c.c. ;   and at 26·61°, 681 mgrms. per litre, or 0·0566 gram-eq. per c.c.   M. L. Dundon also measured the solubility from conductivity data for particles of 0·3μ average diameter and found an increase of 9 per cent. above the ordinary value.   E. Brunner observed that lead fluoride dissolves very slowly in a hot 2N-soln. of **sodium hydroxide.**   C. J. Knox found that **chlorine** has scarcely any action on lead fluoride, and O. Unverdorben made a similar remark in connection with **iodine.**   J. J. Berzelius said that lead fluoride is not more soluble in **hydrofluoric acid** than in water ;   C. H. Herty said it is sparingly soluble in that acid ;   and F. Fischer and K. Thiele, insoluble.   J. L. Gay Lussac and L. J. Thénard said that it is more soluble in **hydrochloric acid,** and, according to J. J. Berzelius, lead fluoride is decomposed when evaporated with hydrochloric acid.   H. Fonzes-Diacon said it is slightly soluble in a conc. boiling soln. of **ammonium chloride or bromide ;** C. H. Herty said that the solubility in soln. of the **alkali halides** increases with the at. wt. of the halides, and, according to E. Field, the action is similar to that observed with lead chloride (*q.v.*).   O. Unverdorben showed that when lead fluoride and **sulphur** are heated in a glass retort, lead sulphide, sulphur dioxide, and silicon fluoride are formed ;   but L. Pfaundler observed no action below 140°.   J. L. Gay

Lussac and L. J. Thénard, and P. Louyet found that conc. **sulphuric acid** in the cold decomposes lead fluoride, forming hydrogen fluoride, and lead sulphate. A. Ditte studied the equilibrium conditions between potassium fluoride and **lead sulphate** (*q.v.*). A. Guntz showed that **sulphur monochloride** converts heated lead fluoride into chloride. J. L. Gay Lussac and L. J. Thénard found that lead fluoride is sparingly soluble in **nitric acid**; and J. J. Berzelius found that the aq. soln. of lead fluoride forms an oxyfluoride when treated with **ammonia.** O. Unverdorben found that **phosphorus** has scarcely any action on lead fluoride, and L. Pfaundler showed that red phosphorus acts on lead fluoride only in contact with silica. A. Guntz found that **phosphorus pentachloride,** and **phosphoryl chloride** convert lead fluoride into the chloride; and T. E. Thorpe and J. W. Rodger, that with **phosphorus pentasulphide,** thiophosphoryl fluoride is formed. E. Frémy observed that **carbon** has no action on lead fluoride, and likewise also **carbon monoxide,** and **carbon dioxide.** F. Fischer and K. Thiele found that a soln. of **ammonium formate** dissolves a small proportion of lead fluoride; and H. Mandal, that lead fluoride is insoluble in **aniline.** A. Guntz found that **carbon tetrachloride** converts heated lead fluoride into the chloride. L. Kahlenberg and W. J. Trautmann studied the reduction of lead fluoride when heated with powdered **silicon.** E. Berger found that with silicon, lead and silicon fluoride are formed—**calcium silicide** acts more vigorously than silicon, forming calcium and silicon fluorides; with a mixture of **aluminium,** and **boric oxide,** aluminium and boron fluorides are formed; with **magnesium,** only magnesium fluoride is produced. G. Sandonnini found that the f.p. curve of mixtures of lead oxide and lead fluoride shows no signs of a compound : there is a simple eutectic at 494° with 54 molar per cent. of **lead oxide** (Fig. 68).
Fig. 68.—Freezing-point Curves of Mixtures of Lead Monoxide and Fluoride.
Fig. 69.—Freezing-point Curves of Mixtures of Sodium and Lead Fluorides.

J. J. Berzelius claimed to have made *lead oxyfluoride* by decomposing lead fluoride with aq. ammonia ; by fusing alkali fluoride with lead oxide and washing away soluble matters with water ; E. Frémy, by the action of steam on lead fluoride ; and H. Moissan, by the action of fluorine on lead monoxide or dioxide. D. Strömholm said that when lead hydroxide is shaken with a soln. of ammonium or potassium fluoride, no oxyfluoride is formed, and no lead hydroxide goes into soln. The existence of the so-called lead oxyfluoride has not been definitely established. J. J. Berzelius' product was said to have a sweet, yet astringent, taste ; and to be resolved into soluble acid salt and insoluble basic salt when boiled with water.

The soln. of lead fluoride and hydrofluoric acid is said to contain *hydrofluoplumbous acid*, H_2PbF_4, but the acid has not been isolated ; nor has an *ammonium fluoplumbite* been prepared. N. A. Puschin and A. Baskoff measured the f.p. of mixtures of lead and sodium fluorides, Fig. 69, but observed no signs of the formation of *sodium fluoplumbite* ; there is a simple eutectic at 540° and 67·5 per

cent. PbF_2. No *potassium fluoplumbite* has been definitely isolated. C. H. Herty noticed that lead dissolves in a hot soln. of potassium fluoride, but the amount is smaller than in the corresponding case with the chloride, bromide, or iodide. C. Fritsch, and M. le Blanc noted the marked increase in the electrical conductivity of slabs made from mixtures of lead and potassium fluorides than from lead fluoride alone. M. le Blanc obtained similar results with mixtures of lead and barium fluorides, but no *barium fluoplumbite* has been made.

B. Brauner claimed to have made a soln. of **lead tetrafluoride,** PbF_4, by projecting powdered potassium fluoplumbate on to the surface of cold, conc. sulphuric acid. Hydrogen fluoride escapes, and a pale yellow soln. is obtained. The yellow liquid soon becomes turbid, and in about half an hour, a thick, lemon-yellow, gelatinous emulsion is produced, which he stated (without proof) to contain a colloidal form of lead tetrafluoride. At 100°–110°, some hydrogen fluoride escapes, and a heavy lemon-yellow powder is deposited which he regarded (without proof) as a third modification of lead tetrafluoride. The lead tetrafluoride was not isolated because no method of separating the sulphuric acid is known without at the same time decomposing the salt. When the sulphuric acid soln. of the tetrafluoride is heated on a water-bath, it furnishes a yellow crust of lead dioxide and hydrogen fluoride is evolved : $PbF_4+2H_2O=PbO_2+4HF$. The soln. of lead tetrafluoride liberates iodine from potassium iodide, etc. O. Ruff and G. Winterfeld could not prepare lead tetrafluoride by the action of sulphuric acid on potassium fluoplumbate by B. Brauner's process ; nor could it be prepared by heating triammonium hydrocto-fluoplumbate in vacuo ; nor by passing dry hydrogen fluoride over lead tetracetate, and digesting the product in chloroform or carbon tetrachloride. W. L. Argo and co-workers, and F. C. Mathers obtained lead tetrafluoride by heating lead dioxide with potassium hydrofluoride :

A mixture of 219 grms. of potassium hydrofluoride (containing 2 per cent. of water) and 164 grms. of lead dioxide (containing 93·5 per cent. PbO_2) was fused at from 250°–300° in a copper vessel. The heating was continued until the black colour disappeared and the mass became grey, and semi-solid. The product contained 37·5 per cent. of PbF_4. The substance was purified by leaching the finely ground material in warm hydrofluoric acid, and allowing the soln. to crystallize.

It is assumed that a soln. of lead tetrafluoride in hydrofluoric acid contains **hydrofluoplumbic acid,** H_2PbF_6. According to A. Hutchinson and W. Pollard, a 37 per cent. soln. of hydrofluoric acid dissolves lead tetracetate readily, and gives a colourless soln., which, in all probability, contains either PbF_4 or H_2PbF_6. If excess of acid is present, the soln. is stable at the ordinary temp., but, like the liquid obtained when hydrochloric acid is used, it is entirely broken up on evaporation even in vacuo ; the decomposition in this case, however, takes a somewhat different course, and results in the quantitative deposition of lead dioxide in accordance with the equation $PbF_4+2H_2O=PbO_2+4HF$. F. C. Mathers showed that while lead dioxide and red-lead are not acted upon by 50 per cent. hydrofluoric acid, the 96 per cent. acid readily acts on these oxides, forming soln. of lead tetrafluoride. The soln. is rapidly hydrolyzed by water depositing a black precipitate of hydrated lead dioxide—the presence of a little ammonium or potassium fluoride, as noted by A. Hutchinson and W. Pollard, hinders the hydrolysis. F. Fischer and K. Thiele also made soln. of lead tetrafluoride by the action of hydrofluoric acid on freshly prepared lead dioxide. G. L. Clark made **sodium hexafluoplumbate,** Na_2PbF_6, by dissolving sodium plumbate in 50 per cent. hydrofluoric acid. The short, thick, tabular crystals are hydrolyzed at 25° by water and the percentage solubility of the salt when sodium fluoride and hydrofluoric acid are present was found to be :

HF	.	.	38·61	40·0	24·5	7·9	37·23 per cent.
NaF	.	.	0·368	trace	0·4	2·33	2·33 ,,
Solubility .	.	.	9·358	10·47	Hydrolysis	5·0	,,

B. Brauner supposed the soln. of lead tetracetate in conc. hydrofluoric acid to

contain *hydroctofluoplumbic acid*, H_4PbF_8 ; and F. Fischer and K. Thiele removed most of the liberated acetic acid by keeping the soln. over soda-lime in a paraffined desiccator. B. Brauner said that the soln. is very unstable at ordinary temp. depositing lead dioxide, and the salts of the acid are easily decomposed. The acid was found by F. Fischer and K. Thiele to dissolve lead carbonate. The stabilizing effect of ammonium fluoride on soln. of hydrofluoplumbic acid was noted by A. Hutchinson and W. Pollard, and F. C. Mathers, and attributed to the formation of ammonium fluoplumbate. O. Ruff prepared **ammonium hydroctofluoplumbate,** $(NH_4)_3HPbF_8$, by dissolving lead tetracetate in conc. hydrofluoric acid and adding ammonium hydrogen fluoride, filtering, and evaporating. The salt may be heated at 190° under atm. press. or even under 10 mm. press. without change, but in a good vacuum decomposition takes place at 100°, nitrogen being evolved. B. Brauner reported **potassium hydroctofluoplumbate,** K_3HPbF_8, to be formed by treating freshly precipitated lead heptoxide with a mixture of potassium hydrofluoride and hydrofluoric acid ; by evaporating a soln. of a mol of lead tetracetate and 3 mols of potassium hydrofluoride in conc. hydrofluoric acid ; and by the action of an excess of conc. hydrofluoric acid on a fused mixture of potassium hydroxide and lead dioxide. F. C. Mathers, and G. L. Clark employed modifications of the process last described ; and O. Ruff used the lead tetracetate process. The monoclinic crystals were reported by B. Brauner to have the axial ratios $a : b : c = 0.62228 : 1 : 0.48177$, and $\beta = 86° 43'$; and to be isomorphous with the corresponding fluostannate, K_3HSnF_8. The crystals are stable in dry air, and they can be preserved in paraffined vessels without discoloration, but in glass vessels they become superficially black. They are not changed in weight by heating for 4 hrs. at 100°–110° ; at 230°, they lose hydrogen fluoride, and at 250°, some fluorine. O. Ruff said that very little decomposition occurs below 250° at which temp. potassium heptafluoplumbate, K_3PbF_7, is formed. When heated in a platinum tube in the blast gas flame the decomposition is represented $2K_3PbF_7 = K_2PbF_6 + PbF_4 + 4KF$. F. C. Mathers said that a small amount of fluorine is given off at 300°. The salt becomes brown in moist air, and is completely decomposed by a little water. G. L. Clark said that moisture decomposes the salt into H_2PbO_3, KHF_2, and hydrogen fluoride. The hydrolysis was studied by F. C. Mathers, and G. L. Clark. The latter found that in the presence of hydrofluoric acid and sodium fluoride at 25°, the solubility was :

HF .	.	.	29·1	30·0	17·0	20·0	20·0 per cent.
NaF	.	.	1·71	0	1·71	0	25·0 ,,
Solubility .	.	.	11·23	12·21	Hydrolysis	1·7	,,

With sulphuric acid, a yellow soln. of lead tetrafluoride is formed ; and when triturated in an agate mortar, it becomes brown owing to a reaction with the silica of the agate : $4K_3HPbF_8 + SiO_2 = 4PbF_4 + 12KF + SiF_4 + H_2O$. According to O. Ruff, both the hepta- and the octofluoplumbates at 400° react with sulphur, forming what is probably sulphur fluoride ; iodine produces an iodine fluoride ; silicon is not inflamed ; liquid silicon tetrafluoride acts only superficially ; and with antimony pentafluoride, below 150°, fluorine appears to be evolved.

B. Brauner reported that when a mixture of potassium hydroxide and lead dioxide (3 : 1) is fused in a silver crucible, and the cold mass treated with hydrofluoric acid, oxygen is given off, and an insoluble crystalline mass—probably *potassium oxyfluoperplumbate*—is formed.

A. Skrabal and J. Gruber reported **rubidium hexafluoplumbate,** Rb_2PbF_6, to be formed by mixing a gram of lead tetracetate and 1·5 grms. of rubidium carbonate with cold hydrofluoric acid, and after some days, separating the crystals by suction, washing with cold acetic acid, and drying between bibulous paper. The six-sided plates belong to the rhombohedral system, and have the axial ratio $a : c = 0.7884$. The crystals of the corresponding **cæsium hexafluoplumbate,** Cs_2PbF_6, have the axial ratio $a : c = 0.7885$. The crystals are decomposed by moist air.

§ 22. Lead Chlorides

H. G. Denham [1] prepared **lead monochloride, or lead subchloride,** PbCl, by passing the vap. of ethyl chloride slowly over lead hemioxide, at 311°. C. Tubandt and S. Eggert observed no sign of its formation during the electrolysis of fused lead chloride. The grey colour of the subchloride is not due to the presence of carbon, because in vacuo, at 400°, it becomes nearly white : $2PbCl=Pb+PbCl_2$, for the dark colour of the lead is masked by the whiteness of the chloride. The subchloride is fairly stable in air, and is rather more soluble in water than the corresponding subbromide and sub-iodide ; a litre of water dissolves 2·2 milli-eq. of PbCl per litre. The sub-chloride is readily decomposed by acids, forming the metal and lead chloride ; it rapidly decolorizes bromine water and permanganate soln. A sat. aq. soln. prepared in vacuo gives a faint precipitate with silver nitrate and with hydrogen sulphide.

About the beginning of our era, Dioscorides, in his *De materia medica*, said that a white substance is obtained by heating λιθάργυρος with common salt and water. This must have been impure lead chloride. Normal **lead chloride,** $PbCl_2$, has been known from the Middle Ages, the crystals being called *magisterium plumbi*, and the translucent horny mass obtained when the salt has been fused, *plumbum corneum*, or *horn lead.* Thus, J. R. Glauber,, in his *Explicatio miraculi mundi* (Amstelodami, 1656), described how hydrochloric acid precipitated *plumbum corneum* from a soln. of lead in nitric acid. T. Monticelli and N. Covelli [2] found *plombo muriato corneo* accompanied by sodium chloride, and copper sulphate and chloride, in the crater of Vesuvius after the 1817 and 1822 eruptions. He called it *cotunnia*—after D. Cotugno. According to F. Zambonini, F. von Kobell used

the name **cotunnite**. A. Scacchi obtained some at Plunto del Mauro in 1840; and afterwards A. Scacchi, and G. Guiscardi found it in the lava in the Fosso de la Vetrana after the eruption of 1855. The oxychloride reported by R. Cappa from the lava of the 1868 eruption was shown by A. Scacchi to be cotunnite. The Vesuvian occurrences have also been discussed by G. vom Rath, A. Lacroix, W. P. Jervis, and F. Zambonini. I. Domeyko, and A. Frenzel found it massive in the Sierra Gorda, Chili; A. Raimondi, in Tarapacá, Chili, and in Pallasca, Peru. A. Lacroix reported it on a lead plate which was estimated to have been submerged for 2000 years in the sea-water near Mahdia, Tunis. A. Russell found crystals of cotunnite on some metallic lead taken in 1846 from a fire-ship wrecked in Falmouth harbour in 1789. In both cases, the mineral had been formed by the action of sea-water on lead. S. Meunier observed its formation during the action of hydrochloric acid on an impure (plumbiferous) fluorite during 27 years.

Lead chloride is slowly formed when chlorine is passed over molten lead, as indicated in connection with lead. R. Weber[3] also found that lead reacts readily and quantitatively with dry chlorine, forming lead chloride. Lead reacts slowly with hydrochloric acid in the cold, but faster when heated, and hydrogen is evolved; in place of lead, the hydroxide gives better results. J. G. A. Rhodin found that lead monoxide readily reacts with hydrochloric acid in an autoclave at 200° and 15 atm. press. A. R. Davis also made it by the action of hot dil. hydrochloric acid on lead monoxide. C. Renz obtained it by triturating and shaking lead monoxide with 19–38 per cent. hydrochloric acid. As indicated in connection with lead dioxide, chlorine, hydrogen chloride, hypochlorous acid, sulphuryl chloride, and phosphorus trichloride transform the dioxide into lead chloride. W. O. de Coninck and L. Arzalier obtained lead chloride by triturating lead monoxide and ammonium chloride; S. C. C. Currie obtained it by the electrolysis of hydrochloric acid or neutral soln. of metallic chlorides—say zinc chloride—using a lead anode. E. Langguth, H. J. E. Hamilton, and others treated lead sulphide with chlorine, hydrochloric acid, sulphuryl chloride, or soln. of metal chlorides—e.g. sodium or zinc chloride. F. Becke, and O. Mügge obtained good crystals by the action of hydrochloric acid on galena; and A. Lacroix synthesized cotunnite by the action of this acid on pieces of galena at 100°. A. Levallois found lead chloride is formed when lead sulphide is heated with silver chloride or mercuric chloride; E. F. Smith treated the sulphide at 250° with sulphur dichloride.

Lead chloride is also produced when solid lead salts are treated with hydrogen chloride or chlorides, e.g. A. Conduché treated lead sulphate at 350° with the vap. of chloroform. J. W. Thomas passed dry hydrogen chloride over lead nitrate; W. C. Ebaugh, and E. F. Smith and J. G. Hibbs passed that gas over lead arsenate; and A. Ditte treated lead sulphate with a soln. of alkali chloride. Lead chloride is also obtained by adding hydrochloric acid or a soluble chloride to a soln. of a lead salt. K. Fajans and J. Fischler obtained lead chloride by a modification of this process. O. Lehmann studied the formation of these crystals microscopically. G. P. Baxter and co-workers recommended the following process in their work on the at. wt. of lead:

About 75 grms. of nitrate were dissolved in water and the soln. was filtered through platinum sponge into a quartz dish. Constant boiling hydrochloric acid which had been freshly distilled through a quartz condenser was then slowly added, with constant stirring, until an excess was present. Chlorine was never freed in the mother-liquor. After the precipitate had settled, it was thoroughly washed by decantation with chilled water and was drained in a platinum centrifugal apparatus. The last wash waters, when tested with diphenylamine, were found to be essentially free from nitrate. The salt was next recrystallized either from water or, because salt crystallized from water was subsequently found to be basic, from very dil. (0·006N) hydrochloric acid, in platinum vessels. The salt was heated to boiling with the solvent in a large platinum still, and, when the soln. was nearly sat., it was poured into a large platinum dish and was cooled with ice.

J. Schabus, and F. Stöber obtained very fine crystals by the slow evaporation

(6–8 mons.) of a soln. of lead chloride in hydrochloric acid. R. Lorenz and W. Eitel recommended heating the purest commercial lead chloride in a stream of equal vols. of dry chlorine and hydrogen chloride—the product is optically clear ; fogged crystals, containing colloidal lead, are obtained on cooling the fused salt in which some pieces of lead have been placed. F. Field obtained needle-like crystals by allowing a mixture of a lead salt soln. and aniline hydrochloride to stand in contact for some time. A. C. Becquerel obtained needle-like crystals by the slow-action (seven years) of soln. of copper sulphate and sodium chloride on pieces of lead sulphide ; and cubic crystals were formed when the pieces of lead sulphide were wrapped about with platinum wire. W. P. Dreaper found that crystals of lead chloride are slowly formed when a soln. of lead acetate in a capillary tube is dipped in hydrochloric acid.

The *rhythmic precipitation* of lead chloride in gelatine or agar-agar was studied by E. Hatschek. A. van de Veld prepared **colloidal lead chloride** by mixing two soln., one containing 379 grms. (1 mol) of sugar of lead, the other 117 grms. (2 mols) of sodium chloride per litre ; a slimy precipitate forms consisting of a mixture of amorphous lead chloride and crystals of the same substance. Excess of one or other salt does not alter the result, but the more dil. the soln. the more the crystalline predominates ; on filtering, the liquid passes through turbid, whilst that which remains on the filter becomes crystalline on washing with water. Potassium, ammonium, calcium, or barium chloride may be used instead of sodium chloride ; hydrochloric acid, however, forms only a crystalline precipitate. Basic lead acetate or lead propionate, formate, or lactate may be used instead of lead acetate ; but lead nitrate, chlorate, or perchlorate yields only fine crystals.

The physical properties of lead chloride.—Lead chloride crystallized from hot aq. soln. was found by J. Schabus [4] to furnish needles and plates ; and, according to A. Classen and B. Zahorsky, C. E. Guignet, and J. Schabus, when the salt is crystallized from solutions in hydrochloric acid it furnishes white, acicular and tabular crystals. F. Stöber showed that the **crystals** from hydrochloric acid soln. have the pseudohexagonal habit, and belong to the rhombic bipyramidal system having the axial ratios $a : b : c = 0.5952 : 1 : 1.1872$. J. Schabus gave $0.5941 : 1 : 1.1902$; and F. Zambonini, $0.5947 : 1 : 1.1855$ for cotunnite. The **cleavage** on the (001)-face is perfect. The **optic axial angle** given by F. Stöber is $2V = 67° 12'$. P. Gaubert obtained cubic crystals from ammonium chloride soln., and J. W. Retgers, octahedra from potassium chloride soln. E. Korreng obtained white rhombic crystals from the molten magma ; and O. Schott obtained microscopic tabular crystals, in part hemimorphic, from molten sodium chloride ; prisms from molten barium chloride ; and rods from molten potassium nitrate. O. Lehmann said that two kinds of doubly refracting crystals separate from the molten magma. K. Treis said the salt is monotropic. W. Biltz studied what he called the **lattice energy** of the crystals ; and A. Sommerfeld, the **electronic structure.**

C. J. B. Karsten gave 5·8022 for the **specific gravity** of the crystals which had not been fused, and 5·6824 for those which had been fused ; J. Schabus gave 5·802 for the sp. gr. of the crystals ; H. Schiff, 5·78 ; G. Brügelmann, 5·88 ; and F. Stolba, 5·80534 at 15° ; G. P. Baxter and C. F. Hawkins obtained 5·899 at 0°, 5·885 at 25°, and 5·872 at 50°. R. Lorenz and W. Eitel gave 5·840 for the sp. gr. at 17° ; and R. Lorenz, H. Frei and A. Jabs gave for the sp. gr., D, of the molten chloride at $\theta°$, $D = 4.907 - 0.00144(\theta - 500)$. R. Lorenz and W. Herz gave 4·910 for the sp. gr. and 56·64 for the mol. vol. at the m.p. F. Ephraim studied the vol. contraction attending the formation of lead halides ; and F. A. Henglein, the mol. vol. I. I. Saslawsky gave 0·93 for the ratio of the mol. vol. to the sum of the at. vols. of the constituent elements. According to D. M. Lichty, the sp. gr. of aq. soln. of lead chloride, sat. at $\theta°$, are :

$\theta°$	0°	15°	25°	35°	45°	55°	65°	80°	95°
Sp. gr.	1·00665	1·00693	1·00725	1·00600	1·00423	1·00200	0·99933	0·99474	0·98941

M. Pleissner gave 1·007 for the sp. gr. of a soln. sat. at 18°. According to V. Czepinsky, the molten liquid is yellow, transparent, and refracting at temp. between 600° and 800°, and, according to K. Treis, at higher temp. it is dark orange. L. Poíncaré gave 5·21 for the sp. gr. of the liquid at 600°, and at temp. $\theta°$ between 520° and 700°, R. Lorenz and co-workers gave $5·627-0·00144\theta$. G. Tammann and Q. A. Mansuri noted evidence of the coalescence of particles of lead chloride by recrystallization at 149°–161°. A. Reis and L. Zimmermann found the scratching **hardness** to be 6·9 when that of ammonium bromide is unity. S. Motylewsky found the **drop-weight** of the liquid at the m.p. to be 165 when that of water at 0° is 100. R. Lorenz and H. T. Kalmus gave 0·05532 for the **viscosity** constant at the m.p. 498°. W. Herz and E. Martin measured the viscosity of soln. of lead chloride in pyridine. R. Lorenz and F. Kaufler found that the mol. **surface energy** equation had the constant between 0·680 and 0·915 from 500°–600°, thus showing that the mol. is complex, for the simple molecule $PbCl_2$ would give a constant near 2·12. According to E. Jannettaz and co-workers, the crystalline powder forms a crystalline mass when compressed by 6000–8000 atm. press. R. Lorenz and W. Eitel found the **hardness** to be the same as that of rock salt. Cotunnite is easily scratched with the finger-nail. The **vapour density** at a high temp. was found by A. Scott to be 262·7—calculated 278·0 ; H. E. Roscoe gave 9·62 (air unity).

G. P. Baxter and C. F. Hawkins gave 0·00009 for the coeff. of **thermal expansion** of lead chloride between 0° and 50°. R. Lorenz and W. Herz gave 0·000294 for the coeff. of thermal expansion, a, and the product $aT_m=0·228$ is in accord with the value obtained for related halides. The following values for the **specific heat** are by G. Linder :

	0°	100°	150°	200°	250°
Sp. ht.	0·06497	0·06647	0·06779	0·06920	0·07043

while the **molecular heats** by F. Koref, below —160°, and above —160°, by A. Eucken, are :

	—257·4°	—249·0°	—211·5°	—188·6°	—156·5°	—67·5°	17·5°
C_p	0·72	1·17	3·91	4·46	4·97	17·41	18·32
C_v	0·72	1·17	3·88	4·41	4·88	—	—

Values for the sp. ht. were also obtained by H. V. Regnault, F. E. Neumann, W. Louguinine, J. N. Brönsted, and O. Ehrhardt. H. M. Goodwin and H. T. Kalmus gave 0·0778 between 260° and 493° ; 0·121 between 493° and 580°. The mol. ht. was determined by J. N. Brönsted, W. Nernst, and H. Schottky. A. Magnus gave $18·52 \pm 0·06$ between 15° and 100° ; $18·97 \pm 0·04$ from 15°–250° ; $19·26 \pm 06$ from 16°–300° ; and $19·58 \pm 0·06$ from 16°–350°. H. S. Allen calculated the sp. ht. in terms of the vibration frequency. H. F. Fernau, and C. L. von Ende measured the mol. **lowering of the freezing point**, δ, of aq. soln. of lead chloride, and found for

	0·0012N-	0·0048N-	0·0077N-	0·0154N-	0·0192N-
δ	0·004	0·014	0·017	0·035	0·037

F. Braun gave 580° for the **melting point** ; L. Graetz, 520° ; O. H. Weber, 506° ; E. Korreng, 500° (heating) and 501° (cooling) ; G. Herrmann, and K. Hachmeister, 501° (cooling) ; R. Ruer, and W. Truthe, 499° ; R. Lorenz and co-workers, G. Tammann, and C. Tubandt and S. Eggert, 498° ; T. Carnelley, 498°–501° ; K. Mönkemeyer, F. Matthes, C. Sandonnini, and E. D. Eastman and L. H. Duschak, 495° ; M. Amadori, 494° ; R. Lorenz and W. Ruckstuhl, 493° ; and W. Ramsay and N. Eumorfopoulos, 447°. The best representative value is 501°. M. Lembert gave 501° for the m.p. of lead chloride made from ordinary and radio-lead. K. Hachmeister observed no marked singularity on the cooling curve of the solid. J. Rosenthal said that the salt is quite plastic at a temp. much below the m.p. K. Mönkemeyer showed that under-cooling may occur through 6°. K. Hachmeister found that when lead chloride is melted, it loses about 0·1 per cent. in weight

presumably by volatilization. J. Davy said that the salt does not volatilize at a bright red heat in the absence of air, but J. W. Döbereiner found that in the presence of air, lead oxychloride is formed. J. B. Moyer observed that lead chloride volatilizes slightly when heated to 225° in a stream of hydrogen chloride. T. Carnelley and W. C. Williams gave 861° for the **boiling point** ; O. H. Weber, 956° ; E. D. Eastman and L. H. Duschak, 948·5° at 754 mm. ; and C. G. Maier, 954·4° at 760 mm. Measurements of the partial press. of the chlorine at different temp. were made by K. Jellinck and R. Uloth. C. G. Maier gave for the **vapour pressure:**

	400°	500°	600°	700°	800°	900°
Vap. press . .	0·00174	0·141	2·82	22·4	116	433 mm. Hg.

H. von Wartenberg and O. Bosse represented the vap. press., p atm., by $\log p = -28\cdot518/4\cdot571T + 5\cdot085$. C. G. Maier, and R. Lorenz and W. Herz studied this subject. The molecular **heat of fusion** was given as 5·607 Cals. per mol by O. H. Weber ; 5·806 Cals. by F. Rudberg ; 5·81 Cals. by O. Ehrhardt ; and 5·15 Cals. by H. M. Goodwin and H. T. Kalmus. E. D. Eastman and L. H. Duschak gave 40,600 cals. for the latent **heat of vaporization ;** and H. von Wartenberg and O. Bosse, 28,518 cals. per mol. C. G. Maier gave for the mol. heat of vaporization 29,510 cals. at 954·4° ; 29,800 cals. at 888·0° ; 30,200 cals. at 834·9° ; 32,110 cals. at 762·7° ; and 34,010 cals. at 718·9°. W. Braunbek discussed the relations between the sp. ht., m.p., and latent heat of fusion.

For the **heat of formation** of lead chloride, using gaseous chlorine with solid lead, J. Thomsen [5] gave 82·77 Cals., and M. Berthelot, 83·9 Cals. F. Pollitzer considers these values to be 2·0–3·0 Cals. too small, and this was confirmed by the calculations of E. Cohen, and F. Koref and H. Braune. A. Guntz gave 85·2 Cals.; F. Koref, and H. Braune, 85·57–85·70 Cals. ; and P. Günther, 85·39 Cals. C. Krahmer calculated from the e.m.f. of some cells, 85·491 Cals. ; R. Lorenz and M. Katayama, 82·6 Cals. ; M. de K. Thompson, 82·7 Cals. (and from the solubility, 74·3 Cals.) ; F. H. Getman, 84·44 Cals. ; and G. D. Roos, 296 cals. per gram. W. C. McC. Lewis calculated 77·66 Cals. from the quantum theory, and the vibration frequency. For the reaction $Pb + 2AgCl = 2Ag + PbCl_2$, R. Lorenz and M. Katayama gave 23·6 Cals. ; A. Magnus, 24·59 Cals. ; and W. C. McC. Lewis, 21·3 Cals. For the reaction $Pb + 2HgCl = 2Hg + PbCl_2$, P. Günther gave 21·8 Cals. ; W. C. McC. Lewis, 23·19 ; and F. H. Getman, 21·84 Cals. For the heat of formation of lead chloride in the molten state, R. Lorenz and M. G. Fox calculated 82·4 Cals. ; V. Czepinsky, 86·2–95·0 Cals. ; R. Lorenz gave 82·569 Cals. between 466° and 766° ; and O. H. Weber, 77·9 to 78·35 Cals. between 506° and 890°. J. Thomsen gave —3·4 Cals. for the integral **heat of solution** per mol at 18° ; M. Berthelot, —2·98 Cals. ; and J. N. Brönsted, —3·282 Cals. M. de K. Thompson gave 74,800 cals. for the **free energy** of formation of lead chloride, and 82,700 cals. for the **total energy** with the halogen gaseous. The **entropy** of the reaction $Pb + Cl_2 = PbCl_2$ was discussed by K. Wohl, and A. Eucken and F. Fried.

C. Tubandt and S. Eggert [6] found that, on electrolysis, in light, solid lead chloride is rapidly coloured red and violet. This is not due to the production of a subchloride. J. A. Wilkinson observed a feeble **fluorescence** when lead reacts with chlorine ; and he found that lead chloride exhibits a bluish fluorescence. According to H. Rubens, the rays reflected from lead chloride have the mean wave-length of 91·0μ. A. Balandin examined the **ultra-red spectrum.** The energy curves show interference effects due to water vapour. B. A. Dima found that the **photoelectric effect** is less than with lead bromide or iodide. A. T. Waterman found that when heated lead chloride emits no Pb''-ions. Cotunnite from Vesuvius was found by F. Zambonini,[7] and P. Rossi to be strongly **radioactive.** G. C. Schmidt found that when lead chloride is heated it emits negatively charged particles.

M. Faraday [8] found that solid lead chloride is a very poor electrical conductor, but the fused salt conducts fairly well, and he electrolyzed it with carbon electrodes.

E. Wartmann, and F. Beijerinck classed cotunnite as a non-conductor. H. Buff said that the **electrical conductivity** of solid lead chloride is metallic ; E. Wiedemann, that it is not wholly metallic, for with rising temp. it conducts electro-·lytically ; and C. Tubandt and S. Eggert, arguing from the transport numbers, said that the conductivity of the solid is wholly electrolytic. G. Tammann and H. Bredmeier measured the conductivity of thin films of the chloride. J. Rosenthal found the conductivity of pieces pressed from the powder is immeasurably small at 112°, at higher temp., the conductivity of pastiles pressed from the amorphous powder is less than that made from the crystalline powder ; as the temp. approaches the softening point, the conductivity of the former approaches that of the latter. C. Tubandt and H. Reinhold, M. le Blanc and M. Kröger, and R. Ketzer measured the conductivity of the compressed powder ; and observations on the conductivity of the solid were made by L. Graetz, W. E. Ayrton, R. Ketzer, V. Czepinsky, A. Benrath, and C. Tissot. C. Tubandt and H. Reinhold measured the effect of potassium and sodium chlorides on the conductivity of the solid at 275°. T. A. Heppenstall and W. J. Shutt studied the electrolysis of the fused chloride. C. Tubandt and S. Eggert were unable to verify Faraday's law for solid lead chloride because of the short-circuiting due to a bridge of metal between anode and cathode during the electrolysis. Fine delicate threads and dendritic growths of the metal spread from electrode to electrode very rapidly. They found at 498° a conductivity of 1·44 mhos ; at 508°, 1·478 ; at 548°, 1·692 ; at 578°, 1·826 ; and at 608°, 1·941 ; while W. Biltz and W. Klemm gave for the eq. conductivity $\lambda = 40\cdot7 + 0\cdot150(\theta - 498°)$. F. Braun, V. Czepinsky, and C. Sandonnini measured the conductivity of the fused salt :

	498°	518°	538°	558°	578°	598°	608°
Mhos	1·395	1·544	1·645	1·738	1·826	1·904	1·941

L. Poincaré gave $1\cdot97\{1 + 0\cdot0020(\theta - 600)\}$, and also $1\cdot56\{1 + 0\cdot003(\theta - 508) + 0\cdot0_67(\theta - 508)^2\}$; the mol. conductivity at 600° was 0·1132. R. Lorenz and H. T. Kalmus found the product of the viscosity and conductivity to be constant. A. Bogorodsky showed that the conductivity in molten sodium nitrate, is :

$PbCl_2$				3·09	7·01	8·01	per cent.
At 350°	.	.	.	1·113	1·083	1·079	mhos.
At 360°	.	.	.	1·152	1·118	1·106	,,

J. W. Frers found that the electrolytic conductivity in solid and·liquid lead chloride indicates a constitutional difference in the species of ions. The mol. electrical conductivities, μ, of aq. soln. of lead chloride obtained by H. C. Jones and co-workers are as follow, where the conc. is expressed as a mol of salt in v litres of soln. :

v	.	.	.	64	128	512	1024	2048	4096
μ {at 0°	.	.	104·41	116·27	133·10	136·89	138·88	144·70
{at 65°	.	.	331·22	379·39	452·75	476·90	502·84	515·18

The temp. coeff. were also calculated by H. C. Jones and co-workers ; the eq. conductivity was determined by F. L. Hunt ; A. A. Noyes and K. G. Falk, S. J. Bates, E. Franke, W. Böttger, and M. Pleissner. The percentage degree of ionization, α, obtained by H. C. Jones and co-workers for the above soln., were :

v	.	.	64	128	512	1024	2048	4096
α {at 0°	.	72·2	80·4	92·0	94·6	96·0	100·0
{at 65°	.	64·29	73·64	87·88	92·57	97·60	100·0

P. Fischer measured the conductivity of mixtures of lead and cuprous chlorides. A. A. Noyes, W. Böttger, and W. D. Harkins studied the **degree of ionization** of soln. of lead chloride. According to C. L. von Ende, lead chloride ionizes in aq. soln. in two stages, $PbCl_2 \rightleftharpoons PbCl' + Cl'$, and $PbCl' \rightleftharpoons Pb\cdot\cdot + Cl'$. At 25°, he estimated that a sat. aq. soln. contains 6·2 per cent. of non-ionized salt 50·1 per

cent. Pb·· and 43·7 per cent. PbCl′. The first stage is about six times stronger than the second stage, for the ionization constant of the former is 0·0009469, and of the latter 0·00006075. S. Labendzinsky, and R. Abegg showed that the soln. also contains complex ions ; and C. L. von Ende indicated that the calculations based on simple ionization are affected by hydrolysis—*vide infra*. F. Haber and S. Tolloczko [9] found the **electromotive force,** E, of two dry Daniell's cells, $PbCl_2 | AgCl$, to be 0·519 volt in agreement with theory ; O. H. Weber gave for $Pb | PbCl_2 | Cl_2$, at $\theta°$, $E = 1·2818 - 0·000584(\theta - 506)$; and between 498° and 600°, R. Lorenz and M. G. Fox gave $E = 1·263 - 0·000679(\theta - 498)$; and M. Katayama gave $E = 1·581 - 0·00065(\theta - 60)$ between 60° and 155°. R. Lorenz and M. G. Fox found that with molten salts, the e.m.f. of the cell $Zn | ZnCl_2 | PbCl_2 | Pb$, at about 500° is approximately equal to the difference in the values for the cells $Zn | ZnCl_2 | Cl_2$ and $Pb | PbCl_2 | Cl_2$. G. Tammann studied the voltages of Daniell's cell with fused chlorides with lead in contact with stannic, cuprous, and silver chlorides ; and with manganese, magnesium, aluminium, thallium, and zinc in contact with lead chloride. K. Arndt and H. Probst examined the disturbance which occurs at the anode during the electrolysis of the fused chloride. V. Czepinsky found that the polarization during the electrolysis of molten lead chloride is independent of the current density. J. N. Brönsted measured the e.m.f. of the cell $PbHg_x | PbCl_2(conc. soln.)AgCl | Ag$; and R. B. Mason and J. H. Mathews, the decomposition potential in pyridine soln. J. Thiele measured the **thermo-electric force** of the molten chloride against metals.

A. Lenert [10] found the **dielectric constant** of lead chloride to be 4·20, and after melting and freezing, 17·26. L. Ebert studied the dielectric polarization of the lead salts. S. Meyer gave for the **magnetic susceptibility,** $-0·535 \times 10^{-6}$, and for the mol. magnetism, $-0·068 \times 10^{-6}$ at 15°.

The chemical properties of lead chloride.—C. Renz [11] showed that when lead chloride—moist or dry—is exposed to an intense **light,** it becomes covered with greyish-yellow, grey, and a greyish-black film of a photochloride ; lead chloride crystallized from hot hydrochloric acid is quickly blackened. N. R. Dhar and A. C. Chatterji found that the rhythmic rings of lead chloride formed in silica gel are not affected by light. When lead chloride is heated in **air,** J. W. Döbereiner found that some decomposition occurs and lead oxychloride is formed ; and J. B. A. Dumas added that water is retained very tenaciously by the chloride, and this at 205° reacts with the chlorine giving off hydrogen chloride, and forming lead oxychloride. The apparent oxidation thus occurs in an atm. of an inert gas, say carbon dioxide. A. Benrath also noticed the reaction with adsorbed water, and possibly with the silica of the glass containing vessel. If moisture be quite absent, the chloride can be volatilized without decomposition in an atm. of carbon dioxide. The formation of oxychlorides when lead chloride is heated to its m.p. and the accompanying colour changes—grey, yellowish-brown, or yellow—were noted by E. Korreng, and K. Treis. K. Hachmeister found that ammonium chloride does not hinder the reaction. R. Ketzer said that the chloride is discoloured when melted in nitrogen, or in vacuo, but not so in chlorine. There is no sign of a transition temp. on the heating curve of lead chloride   H. Schulze found that when lead chloride is heated in **oxygen,** lead oxide is formed, and W. H. Sodeau showed that a mixture of lead chloride and chlorate gives off no chlorine at about 200°, and a mixture of lead dioxide and chlorate, none when heated to 450° in a stream of oxygen. W. Spring found that oxygen reacts at 400°–500°. A. Mailfert found lead chloride is slowly converted to the dioxide by **ozone.** According to M. Berthelot, **hydrogen** reduces lead chloride by a reversible reaction ; and A. Jouniaux found that at 600° there is very little change, while W. C. Ebaugh added that the reduction is incomplete because of the close proximity of the temp. of reduction and sublimation. K. Jellinek and R. Uloth measured the equilibrium conditions in the reaction $PbCl_2 + H_2 \rightleftharpoons Pb + 2HCl$, and found for log ($K_1^{-1} = p^2_{HCl}/p_{H_2}$) at 560°, 650°, and 760° respectively 0·773–3, 0·523–2, and 0·316–1. They also found the vap. press.

of the chlorine from $PbCl_2 \rightleftharpoons Pb + Cl_2$ at these temp. to be log $p_{Cl_2} = -14\cdot50$ atm., $-12\cdot61$ atm., and $-10\cdot69$ atm. respectively. N. Parravano and G. Malquori also studied this subject. F. de Carli studied the reaction. A. de Hemptinne found that the silent electric discharge in hydrogen produces a reduction of the contained lead chloride. The nascent hydrogen evolved from a mixture of zinc and hydrochloric acid reduces rapidly and quantitatively any lead chloride contained in the soln.; and, added A. Gawalowsky, in the presence of water, the zinc reduces lead chloride to tabular flakes; in the presence of ammonia, to a microcrystalline black powder—and in the presence of sulphuric acid, some nitric oxide is evolved and dendritic crystals of lead are produced.

Observations have been made by G. Bischof, J. C. Bell, G. André, C. L. Wagner, G. J. Mulder, C. R. A. Wright and C. Thompson, G. C. Wittstein, J. Formanek, W. D. Harkins, C. L. von Ende, A. A. Noyes, W. Böttger, M. Pleissner, G. Kernot and U. Pomilio, A. J. J. van de Velde, and K. Fajans and J. Fischler, on the **solubility** of lead chloride in water. According to D. M. Lichty, the solubility, S, expressed in grams of lead chloride, $PbCl_2$, in 100 grms. of water, is :

	0°	15°	25°	35°	45°	55°	65°	80°	95°	100°
S .	0·6728	0·9090	1·0842	1·3244	1·5673	1·8263	2·1265	2·6224	3·1654	3·342

The **solubility product** given by G. N. Lewis and T. B. Brighton is $2\cdot29 \times 10^{-5}$. J. Schürr measured the **speed of solution**. R. Flatt tried to correlate the solubility with the electronic structure. J. N. Brönsted observed no special transition point on the curve between 20° and 100°. G. von Hevesy and E. Rona measured the velocity of exchange between the mol. of lead chloride and its sat. soln. Owing to **hydrolysis,** M. Pleissner found that the aq. soln. reacts acid to litmus, and, when very dil., alkaline to iodeosin. G. P. Baxter and F. L. Grover also found that the salt is feebly hydrolyzed in aq. soln. so that the chlorine content of the salt obtained by crystallization from aq. soln., or from dil. hydrochloric acid, is short of about 0·1 per cent. chlorine. The salt melted in dry hydrogen chloride is neutral. C. L. von Ende showed that in a sat. soln. containing about 38·80 millimols per litre the hydrolysis is very small; about 1·3 per cent. in a soln. with 21·4 millimols per litre; and 4·4 per cent. with about 16·8 millimols per litre. C. Kullgren estimated that in a soln. with 128 eq. $PbCl_2$ per litre, there is a 0·495 per cent. hydrolysis at 85·5°, and 0·768 per cent. at 100°; J. K. Wood found 0·2 per cent. hydrolysis in a 0·1N-soln. at 25°; and H. Ley, 0·6 per cent. in a soln. with a 0·01 mol per litre. H. R. Fernau, and C. L. von Ende discussed the disturbing effects of hydrolysis on calculations from the lowering of the f.p., the electrical conductivity, and the e.m.f. of cells; and O. Schärer, the effects of strong electrolytes on the solubility. H. E. Armstrong and J. V. Eyre regarded the first action in the dissolution of the salt to be a depolymerization of a complex mol., and that this is followed by hydration of the salt : $mPbCl_2 + nH_2O \rightleftharpoons (PbCl_2)_m(H_2O)_n$. R. Norris found that water-vap. at 110° decomposes lead chloride; W. Spring found that hydrogen chloride is slowly given off at 110°, the reaction is faster at 150°; and very rapid at the m.p. of lead chloride. F. Koref and H. Braune found that lead chloride is soluble in a soln. of **sodium hydroxide,** forming, according to A. Ditte, a series of oxychlorides when the alkali-lye is not in excess, and lead oxide, if an excess be used. W. Herz regarded the reaction with **potassium hydroxide** as a balanced reaction : $2KOH + PbCl_2 = Pb(OH)_2 + 2KCl$, where the constant $K[KCl]^2[Pb(OH)_2] = [PbCl_2][KOH]^2$, is 0·00076. A. Schott found that oxychlorides are produced when lead chloride is added to molten sodium hydroxide. V. Kohlschütter and H. Roesti found that at ordinary temp. lead chloride is converted by alkali hydroxide into red lead monoxide without change of the crystalline form; the change with 10N-NaOH is very fast; and with 5N-NaOH, it is complete in an hour. V. Zotier examined the catalytic effect of lead chloride on the decomposition of **hydrogen dioxide.**

According to W. W. Fischer, **chlorine** does not react with dry lead chloride,

but with a soln. of lead chloride in one of potassium chloride or hydrochloric acid, it furnishes lead tetrachloride (q.v.). A. Classen and B. Zahorsky, and W. Biltz and E. Meinecke, said that liquid chlorine does not act on lead chloride provided hydrogen chloride be absent. N. A. E. Millon, and A. Ditte said that chlorine-water in sunlight oxidizes lead chloride, forming lead dioxide and evolving chlorine. A. Potilitzin found that **bromine** replaces 12·2 per cent. of the chlorine under 2 atm. press.; 20·5 per cent. at 8 atm. press.; and 33·8 per cent. at 18 atm. press. F. Ephraim did not obtain a chloro-acid by the action of dry **hydrogen chloride** on lead chloride. M. Berthelot noticed that the addition of dil. **hydrochloric acid** to a sat. soln. of lead chloride precipitates some of the salt. Hence, as noted by A. Craig, M. Pleissner, G. Bischof, J. C. Bell, etc., the solubility of the salt is depressed in the presence of dil. hydrochloric acid; on the other hand, the chloride is fairly soluble in the conc. acid as observed by G. André, A. Craig, and others. A. Ditte obtained the data indicated in Table IX. Expressing the solubility, S, of lead

TABLE IX.—THE SOLUBILITY OF LEAD CHLORIDE IN HYDROCHLORIC ACID AT DIFFERENT TEMPERATURES.

Gram HCl per 1000 grms. of water.	Grams PbCl$_2$ per 100 grms. of solution.				
	0°	20°	40°	55°	80°
0	8·0	11·8	17·0	21·0	31·0
100	2·1	1·4	3·2	5·5	12·0
150	1·5	2·0	5·0	7·5	16·0
200	3·5	5·0	8·2	11·7	21·5
250	6·5	8·0	13·0	16·2	28·5
300	10·7	12·5	17·5	22·0	35·0
400	21·5	24·0	—	—	—

chloride, and hydrogen chloride, in grams per litre, the results for dil. soln. at 0° (R. Engel), and at 25° (A. A. Noyes):

HCl .	.	0	0·5	1·0	2·0	3·0	6·0	10·0
$S \begin{cases} 0° \\ 25° \end{cases}$	.	5·83	4·5	3·6	2·2	1·6	1·4	1·2
	.	10·79	9·0	7·6	6·0	5·0	3·1	1·8

These results show that very little hydrochloric acid is sufficient to diminish considerably the solubility of lead chloride; that there is a minimum range through which the solubility is nearly constant; and that the solubility increases considerably when the soln. of hydrochloric acid is very conc. The explanation of the lowering of the solubility of dil. hydrochloric acid is in accord with the ionization theory (1. 15, 12), and has been discussed by H. R. Fernau, C. Immerwahr, C. L. von Ende, K. Beck, and P. Stegmüller, R. Kremann and H. Breymesser, and A. A. Noyes. H. E. Armstrong and J. V. Eyre applied the hydrone theory of association to the results. The increased solubility in conc. hydrochloric acid is explained by M. Berthelot, and A. Ditte on the assumption that a *hydrochloro-plumbous acid*, H_2PbCl_4, is formed.

The influence of the presence of various chlorides on the solubility of lead chloride has also been examined, and the results in Table X are by A. A. Noyes, and W. Herz and M. Hellebrandt. The results are all expressed in grams of salt per litre. With the exception of **mercuric chloride,** the solubility of the lead chloride in soln. of **potassium chloride,** etc., is depressed as in the case of hydro-chloric acid. W. W. Randall, C. L. von Ende, N. Demassieux, and J. N. Brönsted measured the effect with *ammonium chloride—vide infra*, complex salts. M. Berthe-lot, C. L. von Ende, W. D. Harkins, H. Ley, A. A. Noyes, and J. N. Brönsted studied the effect with *potassium chloride;* W. Herz and M. Hellebrandt, A. Ditte, N. Demassieux, and E. Field, the effect with *sodium chloride;* W. Herz and M. Helle-

brandt, with **potassium and sodium bromides**; G. Bischof, and A. A. Noyes, with **calcium chloride**; W. Herz and M. Hellebrandt, with calcium, **barium and strontium chlorides and bromides**; A. A. Noyes, with **magnesium, zinc, cadmium, and manganese chlorides**; A. A. Noyes, and J. Formanek, with mercuric chloride;

TABLE X.—THE SOLUBILITY OF LEAD CHLORIDE IN THE PRESENCE OF OTHER CHLORIDES
AT 25°.

Grams salt per litre.	Grams of PbCl$_2$ dissolved in aqueous solutions of						
	KCl	CaCl$_2$	MgCl$_2$	ZnCl$_2$	CdCl$_2$	HgCl$_2$	MnCl$_2$

and J. Formanek, with **ferrous and ferric chlorides.** K. Treis, and O. Schott studied the action of fused metal chlorides—*vide infra.* F. Ruyssen and E. Varenne found that the solubility of **silver chloride** in hydrochloric acid is somewhat lessened in the presence of lead chloride, but less hydrochloric acid is required to dissolve the mixed chlorides than for each taken singly. V. Thomas found that when **hydrobromic acid** is evaporated with lead chloride, lead bromide is formed; and with **potassium bromide**, a complex salt may be produced; likewise also H. Fonzes-Diacon obtained a complex salt by using **ammonium bromide** or **ammonium iodide**; and E. Field, by using **potassium iodide** or ammonium iodide. V. Thomas obtained a chloroiodide by adding a soln. of potassium iodide to one of lead chloride. E. H. Perman obtained no reaction between dry lead chloride and potassium iodide; but in a sealed tube for 7–10 days in darkness, or for 3 days at 100°, the mixture assumes a yellow colour. A soln. of **hypochlorous acid** was found by A. J. Balard to oxidize lead chloride to the dioxide.

A. Vogel found that molten **sulphur** converts lead chloride into lead sulphide; and with **sulphammonium,** H. Moissan obtained small, yellow, crystals. H. Sommerlad found that when heated with **arsenic trisulphide,** arsenic trichloride is formed by an incomplete reaction, and with **antimony trisulphide,** lead sulphanti-monite is formed. H. N. Stokes found that when **iron disulphide,** FeS$_2$, and a soln. of lead chloride are heated in a sealed tube, crystals of lead sulphide are formed. According to A. Ditte, with an excess of lead chloride, **sulphuric acid** is wholly converted into lead sulphate, but with smaller proportions there is a balanced reaction: $PbCl_2+H_2SO_4 \rightleftharpoons 2HCl+PbSO_4$; F. A. H. Schreinemakers found that in an evacuated vessel, the press. of the hydrogen chloride at 27·2° is 1 atm.; and at 43°, 2 atm.; hence, under atm. press., hydrogen chloride liberates sulphuric acid from lead sulphate until equilibrium press. is attained; he also found that the heat of the reaction is 8 Cals. A. Colson observed no reaction between sulphuric acid and lead chloride in an atm. of hydrogen chloride at 15°. M. Pleissner showed that a small proportion of sulphuric acid lowers the solubility of lead chloride in water. A. Ditte obtained complex salts by the action of **potassium and sodium sulphates.** According to J. Schröder, lead chloride reacts with a pyridine soln. of **silver sulphate,** forming lead sulphate. O. Ruff found that the conversion of **chlorosulphuric acid,** HClSO$_3$, into sulphuryl chloride, SO$_2$Cl$_2$, is catalytically accelerated by one per cent. of lead chloride. C. R. Wise found lead

chloride is insoluble in **selenyl chloride**, $SeOCl_2$. J. F. W. Herschel found that lead chloride is soluble in an aq. soln. of **sodium thiosulphate**, but less so than is the case with silver chloride, and K. A. Hofmann and V. Wölfl showed that when the soln. is exposed to a strong light, a red sulphochloride, $Pb_4S_4Cl_2$, is formed; but in diffuse daylight, or when heated in darkness, black lead sulphide is deposited. If a mixture of sodium thiosulphate and lead chloride be heated in a porcelain crucible, F. Faktor found that lead sulphide is formed.

E. P. Lewis observed that activated **nitrogen** had no effect on lead chloride. E. C. Franklin and C. A. Kraus said the chloride is slightly soluble in liquid **ammonia**. H. Rose observed that lead chloride unites with ammonia gas—the chloride swells up and much heat is evolved. W. Biltz found that the vol. increases four or five times, and very little passes into soln.—*vide infra*. W. Biltz and W. Fischer obtained **lead octamminodichloride**, $PbCl_2.8NH_3$, by the action of liquid ammonia on lead chloride dried at 100°–120°. The vap. press. of the ammonia at −78·5° is 1·8 mm.; at −50·0°, 26·6 mm.; at −36°, 100 mm.; and at −21·2°, 338 mm. The heat of dissociation per mol. of ammonia is 8·2 Cals. They obtained **lead tetritatridecamminodichloride**, $4PbCl_2.13NH_3$, from the octammine at −21·2°. The vap. press. at −21·2° is 34·1 mm.; at −13°, 100 mm.; at −11·1°, 113·2 mm.; and at 0°, 360 mm. It is possibly a mixture of some of the other ammines. The heat of formation is given as 9·4 Cals. per mol of ammonia. F. Ephraim made **lead diamminodichloride**, $PbCl_2.2NH_3$, from lead chloride and undried ammonia; and W. Biltz and W. Fischer, from the octammine or the tridecatetrammine at 0°. At 20·5°, the vap. press. is 32·8 mm.; at 30°, 100 mm.; at 34·65°, 140·5 mm.; at 46·1°, 346 mm.; and at 76°, 760 mm. The heat of dissociation is 11·0 cals. per mol of ammonia; F. Ephraim gave 12·4 Cals. H. Rose's product indicated above had a composition very near *lead sesquiammino-dichloride*, or **lead hemitriamminodichloride**, $2PbCl_2.3NH_3$; and it was made by J. White by adding lead chloride to a soln. of ammonium acetate. W. Biltz and W. Fischer gave for the vap. press., 16 mm. at 21·7°; 100 mm. at 34·65°; and 267 mm. at 46°. The heat of formation per mol of ammonia is 11·3 Cals. W. Biltz and W. Fischer also made **lead monamminodichloride**, $PbCl_2.NH_3$, from the octammine at 78·46°. The vap. press. at 78·46° is 13·2 mm.; at 80·14°, 18 mm.; at 100°, 93 mm.; and at 99·6°, 167 mm. The heat of dissociation is 13·3 Cals. G. L. Clark studied the secondary valencies of these ammines. J. Wood and J. L. Borden found that lead oxychlorides are formed when lead chloride is treated with an aq. soln. of ammonia. G. André observed no reaction between ammonia and lead chloride in a sealed tube at 150°; while W. Herz represented the equilibrium constant, K, in the reaction: $PbCl_2+2NH_4OH \rightleftharpoons 2NH_4Cl+Pb(OH)_2$, by 0·0081—*vide* the action of potash-lye. V. Kohlschütter and H. Roesti found that with $2N$- to $4N$-NH_3, the crystals of lead chloride become greenish and opaque, but no lead monoxide is produced after prolonged contact. T. W. B. Welsh and H. J. Broderson found that 100 c.c. of anhydrous **hydrazine** dissolve 3 grms. of lead chloride at ordinary temp. and the soln. becomes black. V. Thomas showed that **nitrogen peroxide** does not attack the cold solid, but when melted, a little oxychloride is formed. G. P. Baxter and F. L. Grover found that when fused lead chloride dissolves in dil. **nitric acid**, about 0·004 per cent. of black residue remains undissolved. C. L. von Ende found that the solubility of lead chloride in nitric acid increases proportionally with the amount added and some lead nitrate is formed. $0.001N$-, $0.01N$-, and $0.051N$-soln. of nitric acid dissolve respectively 38·87, 39·71, and 42·92 millimols of lead chloride per litre. He also found the solubility is increased in the presence of **potassium nitrate**; and W. D. Harkins, C. L. von Ende, and H. E. Armstrong and J. V. Eyre found that the solubility increases with increasing additions of **lead nitrate**. Expressing the results in grams of salt per litre, A. A. Noyes found:

$Pb(NO_3)_2$		0	1	4	8	10	20	40
$PbCl_2$	.	10·79	10·80	10·90	11·0	11·05	11·20	11·70

O. Schott found that molten potassium nitrate dissolves lead chloride which is deposited in rhombic crystals as the soln. cools. H. Rose found that with **phosphine,** hydrogen chloride, lead, and phosphorus are produced.

According to F. Göbel,[12] and A. G. Bloxam, lead chloride at a red heat reacts with **carbon monoxide,** forming carbonyl chloride and lead ; but A. Benrath found that the salt can be sublimed in **carbon dioxide** without decomposition provided moisture be excluded—*vide supra.* W. Spring made observations on this subject. A boiling soln. of **sodium carbonate** was found by R. Salvadori to convert the chloride into a basic carbonate. G. Gore found that **coal-gas** reduces it with the separation of carbon ; and J. Gathy, that **water-gas** reduces it at a red heat. A. P. N. Franchimont found lead chloride to be insoluble in **benzene ;** and H. Arctowsky, insoluble in **carbon disulphide.** Lead chloride and **ethyl iodide** do not react at ordinary temp., but in sealed tubes at 150°–160° the exchange of halides is nearly complete, with alcohol (R. Brix), or without (B. Köhnlein). H. E. Armstrong and J. V. Eyre, G. C. Wittstein, H. Arnold, G. Bischof, and C. J. Fritsch showed that lead chloride is virtually insoluble in conc. **ethyl alcohol,** and only silghtly soluble in cold or hot 76 per cent. alcohol. G. Kernot and U. Pomilio found that at 25° with concentrations expressed in grams per litre of soln. :

C_2H_5OH	.	0	5·75	11·51	23·02	46·05	92·10	184·20
$PbCl_2$	.	10·75	10·16	9·36	9·14	8·25	7·12	4·76

H. E. Armstrong and J. V. Eyre found that with 15·01 and 60·06 grms. of **propyl alcohol** per 1000 grms. of water, the sat. soln. contained per 1000 grms., respectively 10·08 and 9·36 grms. of lead chloride ; with 11·01 and 33·03 grms. of **acetaldehyde** per 1000 grms. of water, 1000 grms. of sat. soln. contained respectively 10·54 and 9·82 grms. of lead chloride ; with 11·01 and 33·02 grms. of **paraldehyde** per 1000 grms. of water, 1000 grms. of a sat. soln. contained respectively 10·50 and 9·96 grms. of lead chloride ; and with 15·51 and 62·04 grms. of **glycol** per 1000 grms. of water, a sat. soln. contained respectively 10·75 and 10·90 grms. of lead chloride per 1000 grms. of soln. The solubility in **glycerol** was measured by C. H. Piesse, and H. E. Armstrong and J. V. Eyre ; the former gave

Glycerol	.	.	.	12·5	25	50	100	per cent.
$PbCl_2$	.	.	.	0·91	1·04	1·32	2·0	,,

G. Kernot and U. Pomilio found with soln. containing 0–11·38, and 91·06 grms. of **mannitol** per litre, respectively 10·75, 10·64, and 11·29 grms. of lead chloride were dissolved. A. Naumann found the salt is insoluble in **acetone ;** W. Eidmann, insoluble in **methylal ;** and A. Naumann, insoluble in **benzonitrile.** F. Fischer and K. Thiele found a soln. of **ammonium formate** dissolves a little chloride. A. Benrath, W. Herz and E. Martin, A. Colson, and A. E. Hill examined the solubility in **acetic acid ;** the last-named gave

Acetic acid		0	0·5	0·10	0·20	0·465	0·929	1·845	3·680 normal
$PbCl_2$	.	10·77	10·82	10·85	10·70	10·27	9·45	7·90	5·26 grms. per litre

L. Carius, and J. White found that the solubility of lead chloride in soln. of **lead acetate** is greater than with water alone ; E. F. Anthon noted that lead chloride is very soluble in a soln. of **sodium acetate ;** A. Naumann, that it is insoluble in **methyl acetate ;** and A. Naumann, and J. White, that it is but slightly soluble in **ethyl acetate.** F. Koref and H. Braune observed that lead chloride is soluble in an alkaline amyl alcohol soln. of **sodium tartrate ;** and F. Mohr, that **oxalic acid** dissolves but a small proportion of the lead as oxalate. As with aq. ammonia, and alkali-lye, W. Herz found the equilibrium constant with **methylamine** to be 0·0066 ; and **ethylamine** behaves similarly ; A. Werner noted that lead chloride dissolves with difficulty in **ethylenediamine monohydrate.** According to H. Röhler, lead chloride forms a complex with **formamide ;** H. Mandal noted that lead chloride

is soluble in **aniline ;** H. E. Armstrong and J. V. Eyre, that 10·25 grms. of lead chloride can dissolve per 1000 grms. of a soln. of 29·82 grms. of **methyl acetanilide** per 1000 grms. of water; and A. Classen and B. Zahorsky, that it has a low solubility in **pyridine** and **pyridine hydrochloride ;** C. W. Heise gave for the solubility in grams per 100 grms. of pyridine when the solid phase is $PbCl_2.2C_5H_5N$:

	—20°	0°	22°	44°	65°	76°	90°	102°
$PbCl_2$	0·303	0·364	0·459	0·559	0·758	0·893	1·07	1·31

R. Fosse and L. Lesage observed that a complex is formed with naphthapyryl ; G. Grüttner and E. Krause, that with **magnesium chloromethide, bromoethide, or chloropropide,** lead tetralkide is formed ; W. Göbbels found **picoline hydrochloride,** and **lutidine hydrochloride** form complexes with lead chloride.

L. Kahlenberg and W. J. Trautmann [13] found that powdered **silicon** when heated with lead chloride, reacted : $2PbCl_2+Si=SiCl_4+2Pb$; and when heated in air, $2PbCl_2+3Si+3O_2=2PbSiO_3+SiCl_4$. Lead chloride is reduced by **calcium** (F. M. Perkin and L. Pratt), **calcium silicide** (E. Berger), **magnesium** (K. Seubert and A. Schmidt), and **aluminium,** or **manganese** (E. Berger). For the action of **zinc** in the presence of water or acids, *vide supra ;* J. Ball noted that the presence of lead chloride accelerates the dissolution of zinc in acids ; and H. le Chatelier, that a paste made of dil. hydrochloric acid and lead chloride dissolves zinc, but not copper zincide, $CuZn_2$. W. Reinders discussed the equilibrium $Zn+PbCl_2 \rightleftharpoons Pb+ZnCl_2$ in the electrolysis of the molten chloride ; and R. Lorenz and co-workers, and G. Tammann, that with **cadmium,** $Cd+PbCl_2 \rightleftharpoons Pb+CdCl_2$; and R. Lorenz and co-workers, that with **tin :** $Sn+PbCl_2 \rightleftharpoons Pb+SnCl_2$. Molten lead chloride was found by C. Tubandt and S. Eggert to react with **silver,** forming silver chloride. H. Rose said that **mercuric oxide** precipitates lead oxide from soln. of lead chloride, and A. Mailhe found that a complex, $2Pb(OH)_2.HgCl_2$, is formed ; A. Mailhe also obtained $Pb(OH)Cl$ by adding **cupric hydroxide** to a soln. of lead chloride. T. Carnelley and W. C. Williams found that **glass** is attacked by boiling lead chloride.

Lead tetrachloride.—When chlorine is passed into a sat. soln. of lead chloride in a conc. soln. of sodium or calcium chloride, a yellow soln. is obtained which was supposed by A. Sobrero and F. Selmi,[14] and J. Nicklès, to contain an unstable higher chloride of lead. The analysis of A. Sobrero and F. Selmi, $PbCl_4+9NaCl$; and that of J. Nicklès, $PbCl_4+16CaCl_2$, merely represented the composition of soln., not chemical individuals ; and the results do no more than indicate the possible existence of lead tetrachloride. W. W. Fischer cited some inconclusive experiments to prove the existence of lead tetrachloride. O. Seidel tried unsuccessfully to isolate lead tetrachloride and its double salts with other metals, and in 1881, A. Ditte doubted the existence of lead tetrachloride. In 1885, J. Nikoljukine isolated some chloroplumbates and established their chemical individuality. L. L. de Koninck argued that the action of hydrochloric acid on red-lead furnishes not lead tetrachloride but rather *lead trichloride*, $PbCl_3$, because a boiling soln. of a manganese salt in fuming hydrochloric acid becomes dark green in the presence of lead dioxide, but not in the presence of red-lead.

According to H. Friedrich, if ammonium chloroplumbate be added in small quantities at a time to conc. sulphuric acid, cooled with ice, a vigorous reaction occurs, and hydrogen chloride is evolved, and there is a smell of hypochlorous acid. The oily liquid which separates is purified by shaking with fresh sulphuric acid, and its composition corresponds with $PbCl_4$. The same process was used by J. M. Matthews ; and H. Erdmann and P. Köthner employed rubidium chloroplumbate in place of the ammonium salt. Lead tetrachloride is a translucent, yellow, highly refractive liquid which fumes in contact with moist air, with decomposition into lead dichloride and chlorine. H. Friedrich found the sp. gr. of lead tetrachloride at 0° to be 3·18, and it solidifies to a yellowish, crystalline mass at −15°. A. Voigt and W. Biltz found that the electrolytic conductivity of lead

tetrachloride is very small—0.0_680 mho, at $0°$; and W. Biltz and W. Klemm gave 0.0_420 for the eq. conductivity. Lead tetrachloride forms a hydrate in the presence of a little water which, by the further addition of water, decomposes into lead peroxide and hydrogen chloride; when brought into contact with a small quantity of cooled hydrochloric acid, a crystalline derivative, probably $PbCl_4.2HCl$, is formed. W. Biltz and E. Meinecke found lead tetrachloride to be completely miscible with liquid chlorine. Lead tetrachloride may be kept under cold conc. sulphuric acid. J. M. Matthews said that the liquid decomposes in 12 hrs. According to H. Friedrich, when heated with cold soln. of sulphuric acid, it decomposes with explosion into lead dichloride and chlorine. When, however, lead tetrachloride is heated in a retort with conc. sulphuric acid, and a current of chlorine passed through, a certain quantity of the tetrachloride distils over below $105°$, at about which temp. the explosion occurs. With potassium iodide, it is probable that lead tetraiodide is first formed, and this immediately decomposes into lead iodide and iodine; potassium and sodium float on lead tetrachloride and become covered with a brown protective film of lead dioxide; when heated with potassium, an explosion occurs. J. M. Matthews found that the tetrachloride is soluble in chloroform. V. Lenher and W. C. Hill found that with tellurium or tellurium dioxide, an impure tellurium tetrachloride is formed. According to J. M. Matthews, lead tetrachloride does not combine with nitrosyl chloride, nitrogen peroxide, sulphur monochloride, phosphorus chlorides, cyanogen, hydrogen cyanide, cyanogen chloride, acetonitrile, or benzonitrile, but it unites with ammonia, forming **lead diamminotetrachloride,** $PbCl_4.2NH_3$, when dry ammonia is passed into a fairly conc. soln. of lead tetrachloride in chloroform. The orange-yellow mass fumes in air, and decomposes on standing; less conc. soln. of lead chloride furnish **lead tetramminotetrachloride,** $PbCl_4.4NH_3$, which is white and stable in air. Lead tetrachloride unites with the amines—methylamine, ethylamine, propylamine, aniline, pyridine, quinoline, and β-naphthylamine. The compounds with toluidine, and diphenylamine readily decompose. There is no reaction with the acid amides of acetic and benzoic acids—*vide* silicon tetrachloride (6. 40, 57). H. Schiff examined the reaction of lead tetrachloride with alkaloids. H. L. Wells proposed separating cæsium from the other alkalies in virtue of the low solubility of cæsium chloroplumbate.

According to N. A. E. Millon, when lead dioxide is gradually added to well-cooled conc. hydrochloric acid, a yellow liquid is formed, which, when diluted with water, forms lead dioxide and chloride, and when treated with oxalic acid, furnishes carbon dioxide. O. Seidel said that no chlorine is evolved when the lead dioxide is added to the cold hydrochloric acid; and W. W. Fischer found that two gram-atoms of chlorine were needed to precipitate one gram-atom of lead as dioxide, and that the lead is precipitated quantitatively as dioxide when the soln. is treated with sodium acetate. Modifications of N. A. E. Millon's process of making the soln. of lead tetrachloride in hydrochloric acid were used by J. Nikoljukine, H. L. Wells, A. Seyewetz and P. Trawitz, J. Strachan, and L. E. Rivot and co-workers. If chlorine be passed into dil. hydrochloric acid in which lead chloride is suspended, W. W. Fischer, A. Fränkel, and A. Ditte showed that lead dioxide is precipitated, but with conc. hydrochloric acid, the amount of chlorine absorbed is greater than can be explained by the solubility of the gas. The soln. has a strong yellow colour, and when treated with ammonium chloride it furnishes clear, yellow, octahedral crystals, the composition of which can be represented by the formula $(NH_4)_2PbCl_6$. E. Krause found that lead tetrachloride which has been purified by distillation in a high vacuum gives intensely brownish-red soln. in benzene and its homologues; the colour is discharged by the addition of carbon tetrachloride, chloroform, dibromoethane, glacial acetic acid, or ether without conversion of the lead tetrachloride into the dichloride. Cold dil. soln. may be preserved unchanged in the dark during several hours, after which gradual decomposition occurs with the separation of lead dichloride. Conc. soln. decompose after some time with

explosive violence without any apparent cause. For the action of hydrogen sulphide, *vide* lead disulphide.

When ammonium chloroplumbate is treated with sulphuric acid, lead tetra-chloride is formed as a heavy, yellow, oily liquid. It is therefore inferred that · the series of salts typified by $(NH_4)_2PbCl_6$ is derived from the hypothetical **hydrohexachloroplumbic acid,** H_2PbCl_6. A. Classen and B. Zahorsky obtained a soln. of this acid by mixing fuming hydrochloric acid, lead chloride, and liquid chlorine in a press. flask cooled by a mixture of ice and salt. The flask is cooled by solid carbon dioxide and ether before it is opened. J. Strachan oxidized a solid soln. of lead acetate and conc. hydrochloric acid by means of bleaching powder ; A. Hutchinson and W. Pollard treated lead tetracetate with cold conc. sulphuric acid ; A. Nathansohn and F. Leyser treated lead sulphide and hydrochloric acid at a low temp. with chlorine or hypochlorites ; and K. Elbs and F. Fischer treated lead persulphate, $Pb(SO_4)_2$, with hydrochloric acid.

F. Försted, K. Elbs and R. Nübling, E. Müller, and M. Wissmüller obtained the acid by the electrolysis of a hydrochloric acid soln. of lead chloride. Hydro-chloric acid of sp. gr. 1·18 and at 10° was electrolyzed with an anode compounded of two lead plates and a carbon plate, and a soln. of lead chloride surrounded by a porous pot. The anode was so arranged that one-half of the current passed through the lead part of the anode and the other half through the carbon plate, where the current densities were 0·007 and 0·04 ampere per sq. cm. respectively. Under these circumstances, the lead chloride formed at the lead anode was converted into plumbic chloride by the chlorine produced at the carbon anode. The yield of the acid H_2PbCl_2 was 70–80 per cent. of the theoretical quantity. According to R. Kremann and H. Breymesser, the electro-oxidation of the soln. of lead chloride in hydrochloric acid may be due to the formation of lead tetrachloride on the anode which acts as a depolarizer on the carbon electrode, or to the formation of lead chloride on the anode and its subsequent reaction with the chlorine liberated from the carbon electrode. They compared the decomposition voltage of soln. of hydrochloric acid of sp. gr. 1·18, at 0° and 21°, with that of similar soln. with lead chloride. They found that two breaks occur in each of the current-voltage curves. The first break occurs at 0·83 volt at 0° and 0·87 volt at 21°, and is the same for both soln. The second occurs for hydrochloric acid alone at 0·99 volt at 0° and 0·95 volt at 21°, whilst for hydrochloric acid sat. with lead chloride the values are 1·04 volts at 0° and 1·00 volt at 21°. From these results it was inferred that the forma-tion of lead tetrachloride is a secondary process between the lead chloride and chlorine formed respectively on the lead and carbon anodes, and differs in no way from the chemical method of formation of this substance as described by H. Friedrich. G. von Hevesy and L. Zechmeister showed that a dynamic equilibrium exists between bivalent and quadrivalent lead ions in glacial acetic acid soln., and in consequence it follows that electrons can pass of themselves, in certain circumstances, from one ion to an isomeric ion and also to an electrode. A. Voigt and W. Biltz found that the electrical conductivity of fused lead tetra-chloride is of the order 8×10^{-7} mho. A. Sommerfeld discussed the electronic structure of the tetrachloride.

The formation of the chloroplumbates, R'_2PbO_6, as just indicated, led to the assumption that the orange-yellow liquid produced by the action of chlorine on a hydrochloric acid soln. of lead chloride contains hydrohexachloroplumbic acid, $PbCl_{2solid} + Cl_{2gas} + 2HCl = H_2PbCl_6$. E. W. Wescott determined the conditions of equilibrium of this reaction with acid of conc. down to the point where lead dioxide separates as a solid phase. The results showed that the complex acid in these soln. is **hydropentachloroplumbic acid,** $HPbCl_5$, because, with a given chlorine press. the quantity of this complex acid present in equilibrium with solid plumbous chloride is proportional to the first power of the chloride-ion conc. The hydrogen-ion conc., which would not be involved in the equilibrium if the ionization of the substances was complete, has a small secondary effect, probably owing to an

influence on the ionization of the chloroplumbic acid. The equilibrium constant corresponding with the expression $(PbCl'_6)/(Cl').p_{Cl}$ is given by the expression $K'=0.055+0.07p_{Cl}$, when the conc. are expressed in mols. per 100 grams of water; the partial press. of chlorine, in atmospheres; and the ionizations of hydrochloric acid and chloroplumbic acid are assumed equal. The equilibrium constant of the reaction $PbCl_{2solid}+Cl_{2gas}+2H_2O=PbO_{2solid}+4H\cdot+4Cl'$, is given by the expression $K=(H\cdot)^4.(Cl')^4/p_{Cl}$, is 2.4×10^{-8}, under the assumption that the ionizations of the hydrochloric acid and the chloroplumbic acid are complete. From these equilibrium constants and from other known data, the values of the decrease of free energy at 25° calculated on the assumption that the conc. of all dissolved substances are molecular, except that of chlorine, the partial press. of which is one atm., were : $PbCl_{2solid}+Cl_{2gas}+Cl'=PbCl_5'-6590$ joules, $PbCl_{2solid}+2H_2O+Cl_{2gas}=PbO_{2solid}+4H°+4Cl'-43,500$ joules, and $Pb_{solid}+O_{2gas}=PbO_{2solid}+219,000$ joules.

According to K. Elbs and R. Nübling, the orange-yellow liquid containing the acid can be preserved an indefinite time in a sealed tube, but in open vessels. chlorine is given off continuously, and lead chloride deposited. J. Strachan found the liquid is decomposed in sunlight, and by organic substances with the separation of lead chloride. O. Seidel, and A. Nathansohn and F. Leyser observed no change when the liquid stands in contact with sulphuric acid in a sealed tube. J. Nikoljukine found that the liquid is rapidly decomposed by water, forming a reddish-brown fluid. According to E. W. Wescott, the liquid is hydrolyzed to lead dioxide when less than 100 millimols of HCl is present in 100 grms. of water. W. W. Fischer found that lead dioxide is precipitated by water, alkali hydroxides, borates, carbonates, and acetates, as well as by the hydroxides of magnesium, zinc, lead, or mercury. K. Elbs and R. Nübling showed that soln. of ammonium chloride, pyridine, or quinoline in dil. hydrochloric acid precipitate the double salts in yellow crystals. E. Sakellarios,[15] and F. D. Chattaway and co-workers prepared a series of *diazonium hexachloroplumbates*, $(RN_2)_2PbCl_6$.

§ 23. Complex Salts with the Lead Chlorides—Chloroplumbites

According to A. C. Becquerel,[1] if a soln. of ammonium chloride be placed above lead dioxide, and a rod of lead be immersed therein so as to touch the oxide, the rod becomes covered with needle-like crystals which were thought to be those of a double salt of lead and ammonium chlorides. L. J. Thénard also showed that a mixed soln. of the two chlorides gives no precipitate with sulphuric acid, presumably owing to the formation of a double salt. C. L. von Ende measured the solubilities of lead chloride in $0 \cdot 25N$-, $0 \cdot 50N$-, and N-soln. of ammonium chloride to be respectively 9·47, 7·11, and 4·35 millimols per litre. G. André reported a complex series of **ammonium chloroplumbites** in which the ratios : $PbCl_2 : NH_4Cl : H_2O$ were respectively 1 : 18 : 4, 1 : 10 : 1, 2 : 18 : 3, 1 : 6 : 1, 4 : 22 : 7, 4 : 18 : 5, and 2 : 1 : 3. No one else has succeeded in verifying a single one of these preparations ; and G. André seems to have been guided solely by the analyses of crops of crystals obtained either by cooling a soln. of the lead halide in a hot soln. of the corresponding ammonium halide, or by cooling a boiling soln. of lead oxide in one of the ammonium halide. H. L. Wells and W. R. Johnston repeated G. André's directions for the preparation of this salt, and then concluded that " not one of the salts described by G. André exists."

H. W. Foote and L. H. Levy measured the solubility of lead chloride in soln. of ammonium chloride of different conc., and found for equilibrium at 25°, evidence of the existence of the double salt $NH_4Cl.2PbCl_2$. J. N. Brönsted, working at 22°, found the solubility curves of lead chloride and ammonium chloride intersect at a conc. $0 \cdot 52N$-NH_4Cl, when both solid lead chloride and the double salt $NH_4Cl.2PbCl_2$ are in equilibrium. N. Demassieux, also, found the solubility curves indicated in Fig. 70. At 17°, the two phases $PbCl_2$ and $NH_4Pb_2Cl_5$ occur with 3·48 grms. of ammonium chloride and 0·076 grm. of lead chloride in 100 c.c. of soln., and the two phases $NH_4Pb_2Cl_5$ and NH_4Cl eutectic with 26·49 grms. of ammonium chloride, and 0·64 grm. of lead chloride per 100 c.c. The compound $2(NH_4)_2PbCl_4$ is stable only above 70°. The solubility curves at 100°, Fig. 71, have the two phases $PbCl_2$ and $NH_4Pb_2Cl_5$ with 8·59 grms. of ammonium chloride and 1·76 grms. of lead chloride per 100 c.c. ; the two phases $NH_4Pb_2Cl_5$ and $(NH_4)_2PbCl_4$ with 37·62

grms. of ammonium chloride and 12·67 grms. of lead chloride per 100 c.c. ; and the two phases $(NH_4)_2PbCl_4$ and NH_4Cl with 41·90 grms. of ammonium chloride and 9·26 grms. of lead chloride per 100 c.c. The solubility curves show the presence
FIGS. 70 and 71.—Solubility of Lead Chloride in Solutions of Ammonium Chloride at Different Concentrations.

of no complex salts other than these two. The curves are shown in three dimensions in Fig. 72. K. Hachmeister was unable to melt mixtures of lead and ammonium chlorides.

H. L. Wells and W. R. Johnston found that **ammonium pentachlorodiplumbite,** $NH_4Pb_2Cl_5$, is produced under a wide variation of conditions from soln. containing 100–400 grms. of ammonium chloride, 20–80 grms. of lead chloride in 1000 c.c.
FIG. 72.—The Phases in the System NH_4Cl–$PbCl_2$–H_2O at Different Temperatures.

of water. H. Fonzes-Diacon obtained it by cooling a soln. of lead chloride in a 30 per cent. soln. of ammonium chloride, washing the crystals with a very dil. soln. of ammonium chloride, centrifuging the product, and drying. W. W. Randall, J. N. Brönsted, J. Kendall and C. H. Sloan, and H. W. Foote and L. H. Levy obtained the salt in a similar manner. The conditions of stability are indicated by N. Demassieux in Figs. 70 and 71. H. W. Foote and L. H. Levy found that this salt is formed on cooling a hot soln. of lead chloride in one of ammonium chloride. W. W. Randall, and H. L. Wells and W. R. Johnston regarded the crystals as rhombic pyramids; and H. Fonzes-Diacon, and H. W. Foote and L. H. Levy said they belong to the monoclinic system. The colourless, short, transparent prisms retain their lustre when dried. J. N. Brönsted said that the sp. ht. between 0° and 19° is 0·0866, and the mol. heat, 52·78 ; and the dissociation in boiling soln. is such that 1·26 grm.-eq. per litre of free ammonium chloride are present. H. Fonzes-Diacon found that the salt is decomposed by water, and is soluble in dil. acids or dil. alkali-lye.

G. André reported a *trihydrate*, $NH_4Pb_2Cl_5.3H_2O$, in mica-like crystals from an aq. soln. of $6NH_4Cl.PbCl_2$. This hydrate has not been found by any other worker. H. L. Wells and W. R. Johnston reported *tritahydrated ammonium trichloroplumbite*, $NH_4PbCl_3.\frac{1}{3}H_2O$, to be formed by cooling a soln. of lead chloride in a hot conc. soln. of ammonium chloride. The double salt was deposited in colourless, transparent, prismatic crystals while the soln. was somewhat warm. As indicated above, the salt does not appear as a solid phase in the system, NH_4Cl–$PbCl_2$–H_2O, between 17° and 100°, and, as H. L. Wells showed later, it probably does not exist.

H. Fonzes-Diacon, and W. W. Randall obtained **ammonium tetrachloroplumbite,** $(NH_4)_2PbCl_4$, by slowly cooling a soln. of 50 grms. lead chloride in one litre of a boiling, 30 per cent. soln. of ammonium chloride. Neither F. W. Foote and

L. H. Levy nor H. L. Wells and W. R. Johnston were able to establish the existence of this compound; but N. Demassieux showed that it is formed as a solid phase within certain limits, Fig. 71, at temp. over 70°. E. Rimbach and K. Fleck mixed molar proportions of the component salts in aq. soln., and allowed the solid phase to separate, and sat. the liquid with the same mixture, and on cooling, crystals of *ammonium hexachloroplumbite*, $(NH_4)_4PbCl_6.H_2O$, were formed. The salt does not appear on the equilibrium diagrams, Figs. 70 and 71; and it therefore appears likely to be a solid soln. of ammonium chloride with the pentachlorodiplumbite.

K. Treis,[2] and T. Liebisch and E. Korreng measured the f.p. of mixtures of *lithium and lead chlorides*, Fig. 74, and of *sodium and lead chlorides*, Fig. 73, but in no

FIGS. 73 and 74.—Freezing-point Curves of Mixtures of Lead Chloride with Lithium or Sodium Chloride.

case was any evidence of the formation of a compound found. Both the mixtures furnish the simple **V**-eutectics shown in the diagrams. N. Demassieux measured the solubility of lead chloride in soln. of lithium or sodium chloride of different conc., and obtained no evidence of the formation of a compound. J. Kendall and C. H. Sloan, however, reported the preparation of **lithium pentachlorodiplumbite**, $LiCl.2PbCl_2$, and of **sodium pentachlorodiplumbite**, $NaCl.2PbCl_2$. The
FIGS. 75 and 76.—Phases in the Systems: $LiCl-PbCl_2-H_2O$, and $NaCl-PbCl_2-H_2O$.

solubility curves are shown in Figs. 75 and 76. A. Ditte, and C. H. Herty also failed to prepare a double sodium salt, although A. C. Becquerel reported one such. C. Fritsch, R. Ketzer, and M. le Blanc measured the electrical conductivity of mixtures of the two salts.

R. Lorenz and co-workers have studied the f.p. curves of the binary system $PbCl_2-KCl$, and the results are summarized in Fig. 77. There is a flat maximum at 430° and 33·3 molar per cent. of potassium chloride corresponding with the compound $2PbCl_2,KCl$, and two breaks at 440° and 60 molar per cent. and 480° and 68 molar per cent. of potassium chloride respectively, indicating the existence of two other compounds, the compositions of which are $PbCl_2.2KCl$ and $PbCl_2.4KCl$ respectively. The latter decomposes above 480° into solid potassium chloride and a fused mass corresponding in composition with the break in the curve at 480°; the former decomposes above 440° into solid $PbCl_2.4KCl$ and a fused mass corresponding in composition with the break in the curve at that temp. The compound $2PbCl_2,KCl$ forms two series of mixed crystals from 31·7 to 33·3 and 33·3 to 34·1 molar per cent. of

potassium chloride respectively. There are two eutectic points, at 410° and 20 molar per cent. and 405° and 50 molar per cent. of potassium chloride respectively.

FIG. 77.—Freezing-point Curves of the Binary System: $PbCl_2$–KCl.

K. Treis did not verify the 440° singularity. The f.p. curves were also studied by A. Appelberg, E. Korreng, and K. Treis. The system $PbCl_2$–KCl–H_2O was studied by O. Lehmann, J. R. Strohecker, M. Berthelot, A. Immerwahr, C. L. von Ende, and J. N. Brönsted. The results of N. Demassieux are summarized in Figs. 78 and 79. Expressing the conc. of the soln. in grams per 100 grms. of soln., she found that there are two phases, $PbCl_2$ and KPb_2Cl_5, with 0·15 grm. of lead chloride and 3·79 grms. of potassium chloride; the two phases KPb_2Cl_5 and $KPbCl_3.\frac{1}{3}H_2O$ with 0·12 grm. lead chloride and 16·83 grms. potassium chloride; and the two phases $KPbCl_3.\frac{1}{3}H_2O$ and KCl with 0·20 grm. of lead chloride and 24·61 grms. potassium chloride. At 100°, Fig. 79, there are the two phases $PbCl_2$ and KPb_2Cl_5 with 0·60 grm. lead chloride and 6·50 grms. of potassium chloride; the two phases KPb_2Cl_5 and $KPbCl_3.\frac{1}{3}H_2O$ with 0·94 grm. potassium chloride and 23·60 grms. of lead chloride; and the two phases $KPbCl_3.\frac{1}{3}H_2O$ and KCl with 1·50 grms. of lead chloride and 31·24 grms. of potassium chloride. The curves at different temp. are embodied in the three-dimensional
FIGS. 78 and 79.—Solubility of Lead Chloride in Solutions of Potassium Chloride at Different Concentrations.

diagram, Fig. 80. L. J. Burrage also found for the mutual solubilities of lead and potassium chlorides, at 25°, when the conc. are expressed in grams per 1000 grms. of soln.:

KCl	.	0	0·37	30·22	49·69	129·3	187·4	225·4	264·3	264·9	265·3
$PbCl_2$	.	10·83	10·08	2·05	2·27	1·42	2·36	3·03	3·86	1·22	0

Solid phase	$PbCl_2$	KPb_2Cl_5	$KPbCl_3.\frac{1}{3}H_2O$	KCl

The sp. gr. of mixtures of the two components have been determined by R. Lorenz, H. Frei, and A. Jabs; the surface tension, by R. Lorenz and A. Liebmann; the electrical conductivity by R. Ketzer; the e.m.f. of cells Pb | KCl–$PbCl_2$ | Cl, by R. Lorenz and co-workers; the electrode potential of lead in mixed soln. of the two salts by A. Immerwahr; and the crystals, by O. Lehmann.

R. Lorenz and co-workers, K. Treis, and T. Liebisch and E. Korreng obtained **potassium pentachlorodiplumbite,** KPb_2Cl_5, from the molten constituents. The conditions of formation are indicated in Fig. 78. H. L. Wells, J. Kendall and C. H. Sloan, L. J. Burrage, and N. Demassieux obtained it in aq. soln., and the conditions of formation at different temp. are shown in Figs. 78 and 79. The white prismatic crystals are considered by K. Treis to belong to the rhombic system. They melt without decomposition at 430° (R. Lorenz) or 440° (K. Treis). J. N. Brönsted

gave 2200 cals. for the mol. heat of formation. E. Rimbach and K. Fleck, J. Kendall and C. H. Sloan, and C. H. Herty claim to have made anhydrous **potassium trichloroplumbite**, $KPbCl_3$, from soln. of the constituents, but H. L. Wells, and N. Demassieux showed that the salt which separates from the aq. soln. is the tritahydrate. H. L. Wells said that only 0·25 per cent. of this water is lost in 8 days over sulphuric acid. The water is rapidly given off at 200°. The salt **potassium tetrachloroplumbite**, K_2PbCl_4, occurs in nature as the mineral *pseudocotunnite*. It was found by A. Scacchi as acicular, yellow, opaque crystals accompanying cotunnite from the eruption of Vesuvius in 1872. He called it *pseudocotunnia*, a term altered by G. vom Rath to pseudocotunnite. A. Scacchi represented the composition by $KPbCl_3$, but F. Zambonini showed that the analyses are better represented by K_2PbCl_4. Some fluorine is present in pseudocotunnite. A. Lacroix obtained the crystals by washing with hot water the cotunnite crusts of the Vesuvian fumaroles. F. Zambonini showed that the mineral named *mellonite* —after M. Melloni—by L. Palmieri, is pseudocotunnite contaminated with chlorides and sulphates of sodium, potassium, copper, and lead. Neither H. L. Wells nor N. Demassieux could obtain the salt from aq. soln.; but R. Lorenz and co-workers found that it is formed when the constituents are melted in the proportions shown in Fig. 77. According to K. Treis, the rhombic crystals melt at 490° and decompose into molten lead chloride, and crystals of potassium chloride. N. Demassieux, and L. J. Burrage obtained **potassium trichloroplumbite**, $KPbCl_3.\frac{1}{3}H_2O$, as indicated above. R. Lorenz and co-worker also obtained **potassium hexachloroplumbite**, K_4PbCl_6, from the molten constituents as illustrated in Fig. 80. It decomposes at 480°, but K. Treis could not verify this.

O. Lehmann obtained from the system NH_4Cl–KCl–$PbCl_2$–H_2O six-sided prisms of what was thought to be *ammonium potassium chloroplumbite*, but this has not been
FIG. 80.—The Phases in the System KCl–PbCl₂–
H₂O at Different Temperatures.
FIG. 81.—Fusion Curves in the Ternary System: KCl–NaCl–PbCl₂.

confirmed. K. Treis studied the ternary system KCl–$NaCl$–$PbCl_2$, and obtained the fusion curves illustrated by Fig. 81. Expressing the composition in molar percentages, there are two eutectics; the solid phases $PbCl_2.2PbCl_2.KCl$ and $NaCl$ coexist in the eutectic point at 383°, where the composition of the fused mass is $71PbCl_2, 11KCl$, and $18NaCl$. The coexisting solid phases in the second eutectic point are $2PbCl_2.KCl.PbCl_2.2KCl$, and $NaCl$; the temp. is 387°, and the composition $48PbCl_2, 38KCl$, and $16NaCl$.

K. Treis studied the f.p. curves of mixtures of rubidium and lead chlorides, and the results are indicated in Fig. 82. Observations on this subject were also made by T. Liebisch and E. Korreng. H. L. Wells made **rubidium pentachlorodiplumbite**, $RbPb_2Cl_5$, from hot soln. of mixtures of rubidium and lead chlorides; E. Rimbach and H. Fleck employed the process used for the corresponding potassium salt; and

K. Treis obtained it from a molten mixture of the component salts as indicated in Fig. 82. The prismatic crystals are probably rhombic and isomorphous with the corresponding potassium salt. They melt without decomposition at 423°. H. L. Wells and G. F. Campbell, and E. H. Ducloux made white tabular crystals of caesium **pentachlorodiplumbite**, $CsPb_2Cl_5$, by a process similar to that employed for the rubidium salt. K. Treis obtained crystals of **rubidium trichloroplumbite**, $RbPbCl_3$, from the molten constituents as indicated in Fig. 82. Above 310°, the crystals are cubic; below 310°, they are probably rhombic. They melt at 440° without decomposition. H. L. Wells and G. F. Campbell, and E. H. Ducloux obtained crystals of **caesium trichloroplumbite**, $CsPbCl_3$, from a hot soln. of lead and caesium chlorides. K. Treis obtained **rubidium tetrachloroplumbite**, Rb_2PbCl_4, from a mixture of the molten constituents at 448°; it also decomposes at that temp., Fig. 82; H. Erdmann and P. Köthner also made it by melting rubidium hexachloroplumbate. The white, acicular crystals are probably isomorphous with the rhombic crystals of the corresponding potassium salt; they melt at 448° into molten lead

FIG. 82.—Freezing-point Curves of the Binary System: $PbCl_2$–$RbCl$.

chloride and crystals of potassium chloride. H. L. Wells obtained the *hemihydrate* from a hot soln. of the component salts. The colourless, transparent, prismatic crystals lose about 25 per cent. of their water at 100° in 12 hrs., and all is rapidly expelled at 200°. E. H. Ducloux made **caesium tetrachloroplumbite**, Cs_2PbCl_4. E. Rimbach and K. Fleck obtained only the pentachlorodiplumbite by a method analogous to that employed for making potassium hexachloroplumbite. H. L. Wells and G. F. Campbell obtained **caesium hexachloroplumbite**, Cs_4PbCl_8, from a hot soln. of lead chloride in a hot soln. of caesium chloride nearly sat. when cold. E. H. Ducloux prepared this salt; and J. Vermande also obtained it by the action of a sat. soln. of caesium chloride on lead sulphate. The white crystals are rhombohedral, and serve as a microchemical test for lead.

No compounds have been prepared with *lead chloride, and copper, silver, or gold chloride.* K. Treis found that mixtures of lead and silver chlorides furnish simple V-curves as illustrated in Fig. 83; C. Tubandt and co-workers measured the electrical conductivity of mixtures of the fused silver and lead chlorides; and obtained a curve analogous to Fig. 83. C. Sandonnini, and O. Menge measured the f.p. curves of mixtures of *calcium and lead chlorides,* Fig. 84. The results are summarized in Fig. 84. O. Menge observed that calcium chloride does not form solid soln. with lead chloride. R. Otto and D. Drewes claimed to have made **calcium hexachloroplumbite**, $Ca_2PbCl_6.nH_2O$, as a precipitate when a conc. soln. of lead chloride is added to a boiling conc. aq. soln. of calcium chloride; and J. Kendall and C. H. Sloan reported the formation of **calcium tetrachloroplumbite**,

FIG. 83.—Freezing Points of Mixtures: $PbCl_2$–$AgCl$.

$CaCl_2.PbCl_2.6H_2O$; and also of **strontium tetrachloroplumbite**, $SrCl_2.PbCl_2$. C. Sandonnini found that *lead and strontium chlorides* form mixed crystals in all proportions, and the f.p. curves are illustrated in Fig. 85. Similar results were obtained with mixtures of *lead and barium chlorides,* Fig. 86. O. Ruff and W. Plato made solid soln. of these chlorides. R. Lorenz and co-workers measured the sp. gr. of the mixtures. A. C. Becquerel reported the formation of crystals of a double salt, but this has not been confirmed. J. Kendall and C. H. Sloan claimed to

have made **barium tetrachloroplumbite**, $BaCl_2.PbCl_2$; as well as **magnesium tetrachloroplumbite**, $MgCl_2.PbCl_2.6H_2O$. O. Menge found that the f.p. curves of mixtures of *lead and magnesium chlorides*, Fig. 87, give no evidence of the
FIGS. 84 to 86.—Freezing-point Curves of Binary Mixtures of Lead Chloride with Calcium, Strontium, or Barium Chloride.

formation of a double salt. R. Otto and D. Drewes reported the formation of tridecahydrated **magnesium hexachloroplumbite**, by adding a soln. of 17 grms. dried lead chloride to a hot 32 per cent. soln. of magnesium chloride. The crystals were separated from the mother-liquor by suction; pressed between filter-paper; and dried over sulphuric acid. H. Hof and B. Rirck also obtained the same salt by dissolving lead oxide or lead sulphate in a boiling conc.
FIGS. 87 to 89.—Freezing-point Curves of Binary Mixtures of Lead Chloride with Magnesium, Zinc, or Cadmium Chloride.

soln. of magnesium chloride of sp. gr. 1·32. The crystals are either tetragonal or hexagonal plates. They deliquesce and decompose in air; they are decomposed by water and alcohol into lead and magnesium chlorides. They are not blackened by dry hydrogen sulphide, but they are blackened by the moist gas and also by the vapour of ammonium sulphide. The crystals lose their water at 200°. J. Kendall and C. H. Sloan reported the formation of **mercuric tetrachloroplumbite**, $HgCl_2.PbCl_2$. G. Hermann measured the f.p. curve of mixtures of *lead and zinc chlorides*, Fig. 88, and obtained no evidence of a double salt. Similar remarks apply to G. Herrmann's and C. Sandonnini's observations on the f.p. of mixtures of *lead and cadmium chlorides*, Fig. 89—*vide supra*, the action of cadmium on soln. of lead chloride. C. Sandonnini and G. Scarpa found no sign of a compound of *lead and manganese chlorides* on the f.p. curve of mixtures of the two chlorides. There is a simple V-curve with a eutectic at 408° and 70 molar per cent. of lead chloride. The beginning of the crystallization with the different molar percentages of lead chloride is as follows :

$PbCl_2$.	.	0	10	20	40	50	60	80	100
F.p.	.	650°	627°	600°	540°	510°	463°	429°	495°

According to E. Korreng, molten mixtures of *lead and thallous chlorides* furnish two compounds : **thallous pentachloroplumbite,** Tl_3PbCl_5, melting at 407°, and **thallous trichloroplumbite,** $TlPbCl_3$, melting at 435°. The f.p. curves are shown in Fig. 90. J. Barlot obtained the last-named salt by crystallization from a boiling
FIG. 90.—Freezing-point Curves of Mixtures of Thallous and Lead Chlorides.
FIG. 91.—Freezing-point Curves of Mixtures of Lead and Stannous Chlorides.

aq. soln. of eq. proportions of the constituent salts ; and F. Ephraim and P. Barteczko obtained it from a hydrochloric acid soln. of these salts. J. Barlot described the crystals as white, rhombic plates. A. A. Noyes obtained thallous pentachloroplumbite by adding a half sat. soln. of lead chloride to one of thallous chloride, and recrystallizing from hot water. J. Barlot found the electrical conductivity curves of the mixed salt soln. intersect at a point corresponding with Tl_2PbCl_4, but he was unable to prepare this salt. There is a break in the curve corresponding with the trichloroplumbite. F. Ephraim and P. Barteczko obtained what were probably mixed crystals with the composition $TlCl : PbCl_2 = 4 : 3$, and $3 : 4$. J. Nicklès reported *ammonium thallic chloroplumbite* to be formed by the action of ammonium hexachlorothallate on a soln. of a lead acetate. G. Herrmann, and C. Sandonnini and G. Scarpa found no evidence of a stannous chloroplumbite on the f.p. curves, Fig. 91, of mixtures of *stannous and lead chlorides*. The two chlorides form a continuous series of solid soln. A. Benrath and H. Tesche measured the electrical conductivity of mixtures of the two salts between 100° and 480°.

C. Sandonnini [3] examined the f.p. curve of mixtures of lead fluoride and chloride
FIG. 92.—Freezing-point Curves of Mixtures of Lead Fluoride and Chloride.

(Fig. 92). Starting from the m.p. of the pure chloride, the curve descends to an eutectic point at 454°, the conc. being about 10 molar per cent. of fluoride. It then rises to a maximum at 601°, which corresponds to 50 molar per cent. of fluoride, and it afterwards descends again to another eutectic point at 554° (composition 75 molar per cent. of fluoride). When the conc. of fluoride is further raised, the curve rises slowly to 570° (composition 80 molar per cent.), where an evident pause occurs. Finally, the curve ascends rapidly to the m.p. of the pure fluoride. The existence of a **lead fluochloride,** $PbCl_2.PbF_2$, melting without decomposition is thus established, whilst the pause at 570° shows the existence of a **lead octofluodichloride,** $Pb_5Cl_2F_8$, or $PbCl_2.4PbF_2$, which decomposes on fusion. J. J. Berzelius obtained lead fluochloride, $PbFCl$, by adding a soln. of sodium fluoride to a boiling soln. of lead chloride ; and by adding lead acetate to an aq. soln. of 2 parts of sodium fluoride and 3 parts of sodium chloride. H. Fonzes-Diacon made it by boiling for a long

time a soln. of lead fluoride in a conc. soln. of ammonium chloride. The white crystals belong to the tetragonal system. C. Sandonnini said that the salt melts at 601° without decomposition. J. J. Berzelius found it to be slightly soluble in water without decomposition; G. Starck showed that 100 grms. of water at 0° dissolve 0·0211 grm. of the salt; at 18°, 0·0325 grm.; at 25°, 0·0370 grm.; at 100°, 0·1081 grm. The solubility is greater in the presence of a little hydrochloric or acetic acid; and it is practically insoluble in a dil. soln. of lead chloride. J. J. Berzelius said that it is easily soluble in nitric acid. H. Fonzes-Diacon could not obtain *ammonium fluochloroplumbite* from mixed soln. of ammonium chloride and lead fluoride.

§ 24. Chloroplumbates

As previously indicated in connection with lead tetrachloride, impure chloro-plumbates were possibly made by A. Sobrero and F. Selmi [1] in 1850, by J. Nicklès in 1867, etc. J. Nikoliukin first isolated double salts of lead tetrachloride with ammonium and potassium chlorides. He dissolved lead dioxide in conc. hydro-chloric acid in a sealed tube, and added a conc. soln. of ammonium chloride to the product so obtained. The yellow crystals were washed with a conc. soln. of ammonium chloride, at 0°, and pressed between paper. The analysis approxi-mated **ammonium chloroplumbate,** $(NH_4)_2PbCl_6$. A. Classen and B. Zahorsky said that the aq. soln. of ammonium chloride decomposed the salt to some extent. H. L. Wells showed that the sealed tube was unnecessary; he added slightly dil. hydrochloric acid to an excess of lead dioxide at 0°; filtered the soln. through asbestos; added a cold sat. soln. of ammonium chloride until an abundant, yellow, crystalline precipitate was produced; pressed the salt between filter-paper; and dried the product in air. H. Friedrich passed chlorine into a soln. of lead chloride in hydrochloric acid; and obtained ammonium chloroplumbate on adding ammonium chloride to the product. J. M. Matthews, and A. Fränkel used a somewhat similar process—vide lead tetrachloride. A. Seyewetz and A. Trawitz added ammonium persulphate to a cold soln. of lead chloride in hydrochloric acid; K. Elbs and F. Fischer treated a soln. of lead persulphate, in cold hydrochloric acid, with ammonium chloride; A. Hutchinson and W. Pollard added ammonium chloride to a soln. of lead tetracetate in cold, conc. hydrochloric acid; A. Gutbier and M. Wissmüller treated a soln. of lead tetrachloride with ammonium chloride; and K. Elbs and R. Nübling added ammonium chloride to a soln. of hydrochloro-plumbic acid. According to A. Seyewetz and H. Tatu, ammonium chloroplumbate can be economically prepared by adding a slow stream of nitric acid to an agitated suspension of 1 mol. of lead chloride (or sulphate) and 2 mols. of ammonium chloride in four times the theoretical quantity of conc. hydrochloric acid. The filtered product, freed from acid with alcohol and ether, and heated at 80°, is a yellow powder, insoluble in the common organic solvents, which turns bright red at 70°–80° and loses chlorine at 140°. F. Förster electrolyzed a soln. of hydrochloric acid saturated at 0° with lead chloride, and mixed with some ammonium chloride.

The lemon-yellow, octahedral crystals are isomorphous with ammonium chloro-platinate (K. Elbs and R. Nübling), and with ammonium chlorostannate (H. Fried-rich, and E. Carozzi). E. Carozzi gave 2·925 for the sp. gr. The crystals are not hygroscopic in air. M. Wissmüller said that the colour becomes orange-red at 100°, and pale yellow on cooling. K. Elbs and R. Nübling found that the crystals can be kept many hours at 115° without decomposition, and at a still higher temp. for a short time. J. Nikoliukin said that the salt decomposes at 120°, and H. L. Wells said 225°. When decomposed by heat, chlorine is first evolved, then ammonium chloride vap., and lead dichloride remains. The salt is soluble in water, but H. Friedrich, and A. Seyewetz and P. Trawitz, found an excess of water de-composes the salt, forming, according to A. Gutbier and E. Sauer, the hydrosol of lead dioxide. A. Seyewetz and H. Tatu said that in a 0·08 per cent. aq. soln. it forms colloidal lead dioxide, which slowly settles; in this form, it may be used as an active oxidizing agent. Soln. between 4 per cent. and 22 per cent. (saturation) decompose into lead chloride and an oxygenated chlorine compound; with con-centrations between 0·08 per cent. and 4 per cent., both reactions occur. The second type of decomposition is avoided by dissolving in conc. hydrochloric acid, but can be favoured by carefully regulating the quantity and conc. of the acid. Phosphoric acid in all concentrations does not hinder the second type of decom-position. It stabilizes dil. soln. in which the first type of decomposition occurs, by retarding the flocculation of the oxide, even at concentrations slightly below

that at which the formation of the oxide is hindered. Acetic acid behaves similarly to phosphoric acid, although much higher concentrations are necessary. H. Friedrich said that cold conc. hydrochloric acid does not readily dissolve the salt, and that the soln., when warmed, gives off chlorine without depositing lead dichloride; dil. hydrochloric acid acts similarly, but lead chloride is then deposited. K. Elbs and R. Nübling said that about 0·25 grm. of the salt dissolves in 20 per cent. hydrochloric acid at room temp. H. Friedrich found that with potassium iodide, iodine eq. to two gram-atoms of chlorine per mol. separates. J. M. Matthews showed that fuming sulphuric acid of sp. gr. 1·879 furnishes lead tetrachloride; H. Friedrich found that the salt is soluble in conc. nitric acid without decomposition, and when the soln. is warmed, nitrogen oxides are evolved and a precipitate is formed which is sparingly soluble in water. Dil. nitric and sulphuric acids act similarly. A warm soln. of sodium carbonate colours the salt pale brown, while lead and carbon dioxides are formed. A. Seyewetz and co-workers found that aromatic hydrocarbons, as well as their chlorine and nitroxyl derivatives, are chlorinated when heated in a sealed tube with the chloroplumbate. Above 120° in a non-aqueous medium, plumbic ammonium chloride yields nascent chlorine, and so may be used as a chlorinating agent.

A. Classen and B. Zahorsky considered that the salt indicated above is impure, and that the composition of the purified product is *ammonium tridecachlorodiplumbate*, $(NH_4)_5Pb_2Cl_{13}$, but H. Friedrich showed that it is probable that the salt analyzed by these investigators contained free ammonium chloride.

The soln. prepared by A. Sobrero and F. Selmi had the composition $PbCl_4$ $+9NaCl$, and for a time this was represented as the composition of the complex salt—*e.g.* D. J. Carnegie used the formula $PbCl_4.9NaCl$ in support of a theory of the double halides. H. L. Wells, however, was unable to make the double *sodium chloroplumbate*. K. Elbs and co-workers, A. Gutbier and M. Wissmüller, J. Nikoliukin, and H. L. Wells made **potassium chloroplumbate,** K_2PbCl_6, by a method resembling that employed for the ammonium salt. The general properties of the two salts are similar. M. Wissmüller found the potassium salt to be rather less stable in air and water than the ammonium salt. H. L. Wells said that it decomposes at about 190°. J. Nikoliukin said that it is easily soluble in a conc. soln. of potassium chloride. H. L. Wells found that hydrochloric acid, sat. with chlorine, is best used for washing the salt; it is decomposed by boiling hydrochloric acid, while it can be preserved under conc. hydrochloric acid. H. Friedrich, A. Gutbier and M. Wissmüller, and H. L. Wells made **rubidium chloroplumbate,** Rb_2PbCl_6, by methods analogous to those employed for the ammonium salt. H. Erdmann and P. Köthner used the method employed by H. Friedrich, and obtained yellow, regular octahedral crystals. Conc. sulphuric acid acts on it, liberating hydrogen chloride, and precipitating lead tetrachloride as an oil (*q.v.*), whilst the dil. acid converts the metals into sulphates, and liberates chlorine. Rubidium chloride may be precipitated almost quantitatively from its soln. in methylic alcohol sat. with chlorine by adding a soln. of lead tetrachloride, the precipitate being washed with 80 per cent. alcohol. Potassium chloroplumbate is much less stable than the rubidium salt, and evolves chlorine when dried in air; the same change takes place when the rubidium salt is heated, the chloroplumbite, $PbRb_2Cl_4$, being produced. The rubidium salt is also indifferent towards dil. hydrochloric acid and 96 per cent. alcohol, the potassium salt being decomposed by both agents; the changes produced under the influence of water and ammonia are less rapid than those which the potassium salt undergoes. In spite of these differences in behaviour, the estimation of rubidium in the presence of potassium by means of lead tetrachloride is inaccurate. H. L. Wells, and A. Gutbier and M. Wissmüller made **cæsium chloroplumbate,** Cs_2PbCl_6, by similar methods. The lemon-yellow crystals are regular octahedra. They are stable in air, and decompose at 280°. One c.c. of a soln. of fuming hydrochloric acid (1 : 1) containing twice the theoretical

amount of lead chloride sat. with chlorine, dissolved 0·000068 grm. of Cs_2PbCl_6 ; with rubidium chloroplatinate, the solubility was 0·003 grm. per c.c.

J. Nicklès prepared a soln. which had the composition $PbCl_4+16CaCl_2$, but no *calcium chloroplumbate* was isolated ; H. L. Wells also failed to make this compound.

§ 25. Lead Oxychlorides

A large number of lead oxychlorides have been reported. Starting from $PbO : PbCl_2 : H_2O$, $1 : 3 : 0$, there are $1 : 2 : 0$, $1 : 2 : 1$, and $1 : 2 : 2$; $1 : 1 : 0$, $1 : 1 : 1$, $1 : 1 : 1\frac{1}{2}$, and $1 : 1 : 2\frac{1}{2}$; $2 : 1 : 0$; $3 : 1 : 0$, $3 : 1 : \frac{1}{2}$, $3 : 1 : 1$, $3 : 1 : 3$, and $3 : 1 : 4$; $4 : 1 : 0$, and $4 : 1 : 2$; $5 : 1 : 0$, and $5 : 1 : 5$; $6 : 1 : 0$, and $6 : 1 : 2$; and $7 : 1 : 0$. C. F. Cross and S. Sugiura reported some oxychlorides with an excess of oxygen or chlorine above that required for plumbous salts—*e.g. octolead oxyhexadecachloride*, Pb_8OCl_{16}, was obtained as a grey, crystalline mass by the action of a mixture of air and chlorine on lead monoxide ; when red-lead was used, *pentalead oxyenneachloride*, Pb_5OCl_9, was formed ; and with lead dioxide, *dodecalead tetrahenicosichloride*, $Pb_{12}O_4Cl_{21}$, was formed. With lead dioxide at a red heat and chlorine, *tetralead oxyheptachloride*, Pb_4OCl_7, was formed. None of these compounds could be prepared by R. Ruer. He obtained only $PbCl_2.PbO$, *matlockite ;* $PbCl_2.2PbO$, *mendipite ;* and $PbCl_2.4PbO$ on the f.p. curves. The graphic formulæ were given as :

FIG. 93.—Freezing-point Curves of Mixtures of Lead Monoxide and Dichloride.

$$\begin{matrix} Cl-Pb \\ Cl-Pb \end{matrix}{>}O$$
$PbCl_2.PbO$

$$\begin{matrix} Cl-Pb.O \\ Cl-Pb.O \end{matrix}{>}Pb$$
$PbCl_2.2PbO$

$$\begin{matrix} Cl-Pb.O.Pb.O \\ Cl-Pb.O.Pb.O \end{matrix}{>}Pb$$
$PbCl_2.4PbO$
The equilibrium conditions of the ternary system $PbO-PbCl_2-H_2O$ have not been established. Consequently the distinction between those which are truly chemical individuals, and those which are mere mixtures, has not been established. Several of these oxychlorides have been reported in nature. The binary system has been investigated—Fig. 93—by R. Ruer.[1] There are no signs of *lead oxyhexachloride*, $PbO.3PbCl_2$, reported by L. N. Vauquelin to be formed by melting a mixture of the two constituents. The curve shows two maxima at 693° and 62 per cent. and 711° and 76 per cent. by weight of lead oxide, corresponding with

the composition of the compounds $PbCl_2.2PbO$ and $PbCl_2.4PbO$ respectively; three eutectic points at 438° and 20 per cent., 691° and 64 per cent., and 703° and 82 per cent. of lead oxide respectively, as well as a break in the curve at 524° and 36 per cent. of the oxide. The latter arises from the fact that the compound, $PbCl_2.2PbO$, which separates primarily from mixtures containing 47–62 per cent. by weight of lead oxide, reacts below 524° with the fused mass to form a third compound, $PbCl_2.PbO$. Between 68 and 78 per cent. of lead oxide, the compound $PbCl_2.4PbO$ forms mixed crystals with $PbCl_2.2PbO$ and PbO respectively.

There is no evidence of the formation of **lead oxytetrachloride**, $PbO.2PbCl_2$, on R. Ruer's equilibrium diagram, although A. Wächter reported it to be formed, as a yellow mass, by heating lead chlorate for a long time at a temp., according to W. H. Sodeau, at 225°. F. A. Genth reported it to have been formed in white, hexagonal prisms by the action of sea-water on the ancient slags of Laurion, Greece; he called the mineral **penfieldite**—after S. L. Penfield. S. L. Penfield gave for the axial ratio of the hexagonal crystals $a:c=1:0.8967$. According to A. Lacroix and A. de Schulten, the crystals are uniaxial, and have a feebler birefringence than the other lead oxychlorides; the optical character is positive. A. Raimondi reported a specimen from Challacollo, Tarapaca, with a rather smaller proportion of chloride than $PbO.2PbCl_2$. G. vom Rath reported monoclinic crystals of a mineral in the lead slags of Laurion; he called it **fiedlerite**—after K. G. Fiedler. A. Lacroix and A. de Schulten showed that its composition corresponds with **monohydrated lead oxytetrachloride**, $PbO.2PbCl_2.H_2O$, or _lead dihydroxytetra-chloride_, $PbCl_2.2Pb(OH)Cl$. The rectangular plates were shown by G. vom Rath to be monoclinic with a rhombic habit, and to have the axial ratios $a:b:c$ $=0.81918:1:0.89152$, and $\beta=102°$ 40'. G. F. H. Smith gave $0.8299:1:0.7253$, and $\beta=77°$ 31'; and for the refractive indices with Na-light, $\alpha=1.816, \beta=2.1023$, and $\gamma=2.026$. A. Lacroix and A. de Schulten found the sp. gr. to be 5.88, and the hardness over 3. The mineral decrepitates when heated, and it becomes opaque and anhydrous at 150°; thereafter it melts and sublimes. It is easily attacked by cold water, and becomes opaque in about an hour; it is dissolved by cold nitric acid. G. André obtained fine, needle-like crystals of **dihydrated lead oxytetra-chloride**, $PbO.2PbCl_2.2H_2O$, by pouring the mother-liquor from the salt, $(NH_4)_6PbCl_8.H_2O$, into an excess of water, and heating the product for 5 hrs. in a sealed tube at 200°. The product dissolves in boiling soda-lye, forming a yellow soln.

The mineral **matlockite** reported by R. P. Greg to occur along with phosgenite in an old mine at Cromford, near Matlock, Derbyshire, is a **lead oxydichloride**, $PbO.PbCl_2$. A. Lacroix found matlockite about the old slag heaps of Laurion, Greece; A. Raimondi, and I. Domeyko reported it at Challacollo, Tarapaca, Chile; W. F. Petterd, at Zeehan, Tasmania; and W. P. Jervis, R. Cappa, and A. Scacchi in the sublimation product of Vesuvius. The conditions of equilibrium for lead oxydichloride are indicated in R. Ruer's diagram, Fig. 93. J. W. Döbereiner obtained a product of the same composition by heating lead chloride in air until fumes were no longer evolved; and also by fusing a mixture of lead chloride and carbonate in equimolar proportions. G. André obtained a similar product by precipitating a soln. of lead chloride with the calculated quantity of potassium hydroxide, washing with cold water, and drying at 100°; S. Ganelin, by adding water to a mixture of lead chloride with half an eq. amount of magnesia, or to a similar mixture of magnesia with lead sulphate and sodium chloride; V. Thomas, by subliming the iodine from the product by the action of nitrogen peroxide on lead chloroiodide; A. Voigt, by heating monohydrated lead trioxydichloride, $3PbO.PbCl_2.H_2O$, to redness; G. André, by pouring into cold water a sat. soln. of lead oxide in a hot soln. of ammonium chloride (1 : 2), washing the product with cold water, and drying at 100°; and R. Brandes, by heating the washed product obtained by the action of a conc. soln. of lead acetate on lead chloride. The synthesis of matlockite was also discussed by F. Fouqué and A. M. Lévy, and

C. W. G. Fuchs. Matlockite was found by A. C. Becquerel among the products obtained in the synthesis of cotunnite. Analyses were reported by R. P. Greg, R. Brandes, V. Thomas, C. F. Rammelsberg, etc. P. Groth represents its composition by the formula Cl–Pb–O–Pb–Cl. The crystals were examined by R. P. Greg and W. G. Lettsom, G. Rose, G. A. Kenngott, P. Groth, A. Lacroix, H. Buttgenbach, K. Treis, etc. R. Ruer obtained the salt in yellowish-brown needles. W. H. Miller found the tabular crystals of matlockite belong to the tetragonal system, and have the axial ratio $a : c = 1 : 1 \cdot 7627$. The colour of matlockite is yellow, sometimes with a greenish tinge. The artificial salt may be greyish-white. The cleavage parallel to (001) is imperfect. Besides the uniaxial crystals, A. Lacroix observed some which consisted of four biaxial sectors ; he gave for the optic axial angle $2E = 55°$. A. des Cloizeaux found the optical character is negative. According to R. P. Greg, the sp. gr. is 7·21 ; and the hardness, 2–3. C. F. Rammelsberg's 5·3947 for the sp. gr. is too small. R. Ruer found the salt melts at 524° with decomposition. G. André gave 3·26 Cals. for the heat of formation from anhydrous lead oxide and chloride ; and the heat of soln. of the salt in a soln. of hydrochloric acid sat. with lead chloride, was 9·04 Cals. at 10°. H. Buttgenbach measured the indices of refraction. K. Keilhack found the crystals phosphoresce when exposed to the X-rays. A. Braley studied the blowpipe reactions of matlockite.

R. Köchlin found groups of colourless, clear crystals associated with phosgenite and cerussite in cavities in the lead slags at Laurion, Greece ; they appear to have been formed by the action of sea-water on the slag which has been exposed for some 2000 years. The crystals analyzed by G. vom Rath, and A. de Schulten had the composition of **monohydrated lead oxydichloride,** $PbO.PbCl_2.H_2O$, or *lead hydroxychloride,* $Pb(OH)Cl$. The mineral was called **laurionite.** The salt has been synthesized in many ways. H. L. Pattinson obtained monohydrated lead oxydichloride by adding a sat. soln. of a cubic metre of lime-water to a soln. of 1·2 krgms. of lead chloride in a cubic metre of water. The product, once used as a pigment, was called *Pattinson's white-lead.* The manufacture was described by J. Percy. H. Hof made the salt by dissolving lead oxide in a conc. soln. of magnesium chloride, and decomposing the hot soln. with water. The product was contaminated with magnesium hydroxide and chloride. M. Pleissner prepared the same product by shaking 5–10 grms. of lead chloride, 4 grms. of lead hydroxide, $3PbO.H_2O$, and 500 c.c. of water for 4 or 5 days at 18° ; washing the product with 400 c.c. of water renewed from time to time until the lead in soln. was very small ; and drying in vacuo over soda-lime. J. Wood and J. L. Borden heated 5–7 grms. of lead chloride with 140–145 c.c. of aq. ammonia until the smell of ammonia was no longer perceptible. The product was washed, and dried in air. H. L. Wells and W. R. Johnston saturated a boiling sat. soln. of ammonium chloride with lead chloride, added an equal vol. of a sat. soln. of ammonium chloride, and then an excess of ammonia. The product was washed and dried. G. André heated a double chloride of ammonium and lead with much water in a sealed tube at 200° for 5 hrs., and dried the product between bibulous paper ; he obtained a similar result by repeatedly boiling the double salt with much water. A. de Schulten added a hot soln. of 50 grms. of sodium chloride in 250 c.c. of water to a boiling soln. of one kgrm. of lead acetate in 2·5 litres of water ; the filtrate was heated 12–16 hrs. on a water-bath, and the crystalline precipitate washed with cold water, alcohol, and ether.

G. André reported the *hemitrihydrate,* $PbO.PbCl_2.1\frac{1}{2}H_2O$, to be formed by the action of an excess of water on the filtrate from a mixed soln. of lead and manganese chlorides. The product was washed and dried at 100°. A. Mailhé obtained the *hemipentahydrate* in white or grey rhombic or hexagonal plates by the action of brown copper oxyhydroxide, $Cu_4O_3(OH)_2$, on a conc. soln. of lead chloride ; and an amorphous mass of the same composition by using blue cupric hydroxide in place of the oxyhydroxide.

Lead hydroxychloride appears as a voluminous, white or pale yellow powder ; the mineral laurionite occurs in colourless, clear, minute, prismatic crystals flattened

parallel to the (010)-face, and with feather-like striations on the (010)-faces. According to R. Köchlin, the axial ratios of the rhombic crystals are $a:b:c$ $=0.7328:1:0.8315$, and, according to G. F. H. Smith, $0.7385:1:0.8346$. The crystals were described by E. Repossi, G. vom Rath, V. Goldschmidt, A. Lacroix, A. de Schulten, F. Grünling, G. Cesaro, and C. A. Ktenas. W. Biltz studied the mol. vol. The salt is dimorphous—*vide infra*, paralaurionite which occurs in monoclinic crystals. The indices of refraction obtained by G. F. H. Smith were $a=2.0767$, $\beta=2.1161$, and $\gamma=2.1580$; and the optic axial angle $2V=81° 32'$. The birefringence is $\gamma-a=0.098$, and $\gamma-\beta=0.040$. A. de Schulten gave 6.241 for the sp. gr. at 15°. When heated, laurionite decrepitates; according to A. de Schulten, the artificial salt is not changed at 100°, but at dull redness, it loses all its water and melts. G. vom Rath said laurionite loses all its water at 142°. M. Pleissner said that the sat. aq. soln. contains 99 mgrms. of salt per litre, and the sp. conductivity is 0.0_4682. A. de Schulten said that the salt is attacked very slowly by cold water, and that it rapidly becomes opaque in boiling water. G. André found that the soln. in boiling soda-lye has a yellow colour. A. de Schulten found that artificial laurionite in the presence of water is attacked by carbon dioxide first forming phosgenite, and then cerussite. A. Braley studied the blowpipe reactions of laurionite.

M. Websky reported a colourless or greenish mineral occurring as an incrustation and in crevices in a gangue of galena, etc., from Mina Beatriz, Sierra Gorda, Atacama, about 20 miles from Caracoles, Chili. The mineral was named **caracolite.** Its composition corresponds with **sodium lead hydroxychlorosulphate**, $2Pb(OH)Cl.Na_2SO_4$, and it was analyzed by F. Sandberger, and L. Fletcher. The crystals have the form of a hexagonal pyramid with base and prism, but they are supposed to be pseudohexagonal with trillings, like aragonite. The crystals are supposed to be rhombic, and M. Websky gives for the axial ratios $a:b:c=0.5843:1:0.4213$. The sp. gr. is 4.5. Water extracts sodium sulphate, and the aq. extract of the mineral, on evaporation, yields sodium chloride, etc.

G. F. H. Smith obtained from the lead slags of Laurion, monoclinic crystals of a mineral with the same chemical composition as laurionite; and, accordingly, the mineral was called **paralaurionite.** The crystals were found to be identical with those of *ein neues Bleioxychlorid* obtained by A. Arzruni from the San Rafael mine in Sierra Gorda, Chili, and called *rafaelite*—but for which no quantitative analysis has been made. The monoclinic crystals have the axial ratios $a:b:c$ $=2.7036:1:1.8019$, and $\beta=62° 47'$. The crystals may be tabular or prismatic; and they usually appear pseudorhombic on account of twinning on the (100)-plane. The cleavage on the (001)-plane is perfect. The optic figure seen through the (100)-plane is complex owing to the overlapping of two plates in the twin position; in this respect, paralaurionite is easily distinguished from the dimorphous mineral laurionite which shows no such figure, and fiedlerite in which the figure is not central. Paralaurionite is white; rafaelite was coloured violet-red, and exhibited a strong pleochroism. The crystals were also examined by A. Lacroix and A. de Schulten. The sp. gr. of paralaurionite given by G. F. H. Smith is 6.05 at 15°; the refractive index for Na-light is $\beta=2.1463$; and the water is given off at 180°. According to C. A. Ktenas, a comparison of the twinning, corrosion figures, and optical properties of crystals of laurionite and paralaurionite is in agreement with the hypothesis that the rhombic crystals of laurionite are formed by submicroscopic twinning lamellæ of monoclinic paralaurionite. The two minerals have similar chemical properties.

The lead mines of the Mendip Hills, Somersetshire, are thought to have been worked from pre-Roman times, and descriptions of the lead minerals collected by J. Woodward, P. Rashleigh, and A. F. Cronstedt enabled L. J. Spencer and E. D. Mountain to identify the mineral which was later on called **mendipite.** This mineral was examined by J. J. Berzelius in 1823, and shown to be **lead dioxydichloride,** $2PbO.PbCl_2$. He called it *saltsydradt Bly, i.e. Salzsaures Blei*. F. S. Beudant confused it with phosgenite and called it *kerasine* or *cerasite;* A. Breithaupt

called it *Chlorspath* ; W. Haidinger, *peritomous lead-baryte* ; A. Lévy, *berzelite* ; E. F. Glocker, *mendipite* ; and P. A. Dufrénoy, *churchillite*. Analyses were reported by C. F. Rammelsberg, R. Rhodius, C. Schnabel, and L. J. Spencer and E. D. Mountain, in addition to those by J. J. Berzelius. P. Groth represented the constitution Cl–Pb–O–Pb–O–Pb–Cl. The mineral has been also reported from the Kunibert Mine near Brilon, Westphalia, by R. Rhodius, and C. Schnabel ; and from the Altai Mountains, Siberia, by P. P. Pilipenko. Mendipite has been synthesized by A. Ditte, G. André, and R. Ruer. The conditions of equilibrium of lead dioxydichloride are shown in R. Ruer's diagram, Fig. 93 ; and it is also formed when the oxydichloride is heated to 524°. A. Ditte made it by gradually adding potassium hydroxide to lead chloride suspended in water, constantly agitated, until the liquid has an alkaline reaction. The product was washed with water. G. André employed an analogous process. A. Ditte also made it by shaking lead hydroxide with enough of a soln. of potassium chloride to give an alkaline reaction.

The crystals of mendipite are colourless or tinged pale yellow, red, or blue. They occur in fibrous or columnar masses, often radiated. R. Ruer's preparation was in silky, yellowish-brown needles. The crystals belong to the rhombic system, and, according to W. H. Miller, they have the axial ratios $a : b : c = 0.8115 : 1 : —$; or, according to L. J. Spencer and E. D. Mountain, $0.8002 : 1 : —$. The crystals have also been examined by W. Haidinger, J. J. Berzelius, A. Lévy, L. Fletcher, E. S. Larsen, A. Breithaupt, J. F. L. Hausmann. The (110)-cleavage is perfect ; and the (100)- and (010)-cleavages, less perfect. The cleavage angle is from 77° 19' (L. Fletcher) to $77\frac{1}{2}$° (J. J. Berzelius). E. S. Larsen found the optic axial angle $2V =$ nearly 90° ; and the indices of refraction $a = 2.24$, $\beta = 2.27$, and $\gamma = 2.31$; the dispersion and birefringence are high. W. Haidinger gave 7.077 for the sp. gr. ; A. Breithaupt, 7.377–7.400 ; R. Rhodius, 7.0 ; and L. J. Spencer and E. D. Mountain, 7.240 at 16.2°/4°. R. Ruer gave 639° for the m.p. of the mineral, and this is not attended by decomposition. According to L. J. Spencer and E. D. Mountain, when heated in a bulb tube, mendipite becomes yellow, decrepitating violently, and splitting up into dark yellow fibres ; before melting, a cloud of lead chloride vapour begins to fill the bulb, and condenses on the side of the tube. The fibres then melt to a yellow liquid (lead oxide) which spreads over the surface of the bulb, and the sublimate on further heating furnishes yellow drops (lead chloride). G. André gave 4.62 Cals. for the heat of formation from anhydrous lead oxide and chloride ; and 19.98 Cals. for the heat of soln. in hydrochloric acid sat. with lead chloride. The salt acquires a reddish-brown surface coloration when exposed to light. According to A. Ditte, if potash-lye be slowly added to lead dioxydichloride, suspended in water, about 110 grms. of the salt dissolve in a litre of liquid at 19°, and the soln. acquires a yellowish colour, forming potassium chloride and lead oxide. The mineral readily dissolves in nitric acid. A. Braley studied the blowpipe reactions of mendipite.

L. Fletcher found a colourless mineral resembling mendipite sparingly associated with the anglesite at the Mina Beatriz, Sierra Gorda, Atacama ; and he named it **daviesite**— after T. Davies. The minute prismatic crystals are sometimes striated horizontally ; they belong to the rhombic system, and have the axial ratios $a : b : c = 0.7940 : 1 : 0.4777$. The optical character is positive. No cleavage was observed. The mineral is lead oxychloride, but analyses have not been made. Meanwhile it is thought to be a form of mendipite from which it differs in cleavage and in speed of dissolution in nitric acid. Daviesite remains unchanged after being 8 weeks in contact with cold water, and also after being a short time in hot water. It is rapidly attacked by dil. nitric and sulphuric acids. W. H. Twelvetrees reported a lead oxychloride from Zeehan, Tasmania, which he named *petterdite*—after W. F. Petterd—but C. Anderson showed that it is probably an impure mimetesite.

J. W. Döbereiner obtained a yellow substance by fusing a mixture of a mol of lead chloride with three mols of lead oxide ; and he also obtained a similar product by heating one of the hydrated forms indicated below. L. N. Vauquelin, and J. Wood and J. L. Borden also obtained it from the hydrated forms. M. Pleissner,

however, questioned whether the product obtained by dehydration is really a compound; and R. Ruer observed no evidence of **lead trioxydichloride,** $3PbO.PbCl_2$, in his study of the equilibrium diagram, Fig. 93; and he regarded the alleged compound as a mixture of lead dioxydichloride and tetroxydichloride. G. André claimed to have made this compound by adding potassium hydroxide to a soln. containing the calculated quantity of lead chloride, and heating the washed product at 100°. He added that the heat of formation from the anhydrous oxide and chloride is 5·30 Cals., and that the heat of soln. in hydrochloric acid sat. with lead chloride is 31·60 Cals. The yellowish-green, scaly mass is sometimes called *J. Turner's yellow—vide infra.* **Tetrahydrated lead trioxydichloride,** $3PbO.PbCl_2$. $4H_2O$, was obtained by J. J. Berzelius by treating a soln. of lead chloride with alkali hydroxide; G. André used aq. ammonia, and said that crystals are not produced when the precipitate is heated for a day with water in a sealed tube at 250°. J. J. Berzelius also made it by treating a soln. of lead acetate with sodium chloride; and C. W. Scheele, by decomposing a soln. of sodium chloride with lead monoxide. According to L. N. Vauquelin, one part of sodium chloride requires 7 parts of powdered lead oxide. When the mixture is worked up with water into a thick pulp, it turns white and thickens by the swelling of the lead oxide; consequently, it is necessary to add more water and work up the mixture again. After standing 4 days, the mixture is diluted with water, and the soln. filtered. The filtrate contains sodium hydroxide, and a little lead chloride, but no sodium chloride. According to E. F. Anthon, the sodium chloride is but half decomposed even when ten times its weight of lead oxide is used, and the mixture frequently agitated for 12 days. The manufacture of sodium hydroxide by this reaction has been previously discussed (**2. 20, 11**); and the reaction was examined by F. R. Curaudau, F. M. Bachet, R. C. Clapham, J. Morrison, etc. According to G. Austerweil, the reaction is reversible: $2NaCl+4PbO+H_2O \rightleftharpoons 2NaOH+3PbO.PbCl_2$, and the equilibrium constant at 18° is 0·7 for $2N$-NaCl, and 0·5 for $5N$-NaCl. L. N. Vauquelin said that when the white flocculent mass is heated, it loses 7 per cent. of water; that acids dissolve out the lead oxide leaving behind the chloride; and that the compound is insoluble in water, but slightly soluble in a soln. of sodium hydroxide. E. Berl and G. Austerweil showed that at 18°, a litre of water dissolves 0·059 millimol; at 48°, 0·14 millimol; and at 74°, 0·74 millimol. It is less soluble in a soln. of sodium chloride than is lead sulphide.

G. André said that if the precipitate obtained by adding aq. ammonia to a soln. of lead chloride be dried between bibulous paper, **trihydrated lead trioxydichloride,** $3PbO.PbCl_2.3H_2O$, is formed; and he obtained the same hydrate by treating lead oxychloride with an excess of water and drying the washed precipitate at 100°. J. Wood and J. L. Borden reported **monohydrated lead trioxydichloride,** $3PbO.PbCl_2.H_2O$, to be formed by heating lead chloride with aq. ammonia on a water-bath for 12 hrs.; A. Voigt, by boiling lead oxide with a conc. soln. of magnesium chloride for a long time, and drying the washed product at 100°; and M. Pleissner, by shaking a mixture of 6·2 grms. of finely divided lead hydroxide, $3PbO.H_2O$, 2·5 grms. of lead chloride, and 500 c.c. of water, for 5 days at 18°, and drying the washed product over soda-lime. The light yellow powder was found by A. Voigt to lose water at 130°, and, according to M. Pleissner, is anhydrous at 250°, and then takes up oxygen, forming a canary-yellow mass which melts at a red heat. A. Voigt said that the monohydrate is very sparingly soluble in hot water, and M. Pleissner said that a litre of water at 18° dissolves 25 mgrms. of the salt, and that the soln. has a sp. conductivity of $0·0_419$. A. Voigt found that the salt is slightly soluble in aq. ammonia, and is readily dissolved by mineral acids, and acetic acid, particularly if heated. D. Strömholm reported a pale yellow voluminous precipitate of **hemihydrated lead trioxydichloride,** $3PbO.PbCl_2.\frac{1}{2}H_2O$, consisting of small needles, to be formed by adding conc. aq. ammonia to a soln. of lead chloride until the liquid is about $0·61N$ with respect to ammonia, and $0·18N$ with respect to chlorine.

R. Ruer obtained yellow, tabular crystals of **lead tetroxydichloride**, $4PbO.PbCl_2$, from a fused mixture of the components, Fig. 93 ; the salt melts at 711°.   E. Berl and G. Austerweil prepared white coloured **dihydrated lead tetroxydichloride**, $4PbO.PbCl_2.2H_2O$, from a mixture of lead oxide, and a soln. of sodium chloride below normal conc.   The reaction is reversible, and the equilibrium constant at 18° is 1 ; at 48°, 0·75 ; and at 74°, 0·6.   The product is less soluble than lead sulphide in a soln. of sodium chloride, and $2N$-NaCl converts the tetroxydichloride into the trioxydichloride.   Lime-water in excess converts the salt into lead mon-oxide.   J. W. Döbereiner reported *lead pentoxydichloride*, $5PbO.PbCl_2$, to be formed by melting the constituents in the right proportions, but R. Ruer obtained no evidence of the formation of such a compound, Fig. 93.   J. Kersten said that *pentahydrated lead pentoxydichloride*, $5PbO.PbCl_2.5H_2O$, is produced by the action of a boiling dil. soln. of alkali chloride on lead hydroxide, $3PbO.H_2O$, but the individuality of the product requires confirmation.

R. C. Wells and E. S. Larsen obtained honey-yellow, slabby masses of a mineral from Loretto, Tennessee, which they called **lorettoite**.   Its composition corre-sponded with **lead hexoxydichloride**, $6PbO.PbCl_2$, or $13PbO.2PbCl_2$.   There is no evidence of the formation of such a compound on the fusibility curve.   The mineral has an adamantine lustre, and a bladed structure, with a perfect cleavage along the blades.   The crystals are probably tetragonal—E. Rimann said rhombic.   The substance is optically uniaxial and negative.   The sp. gr. 7·39 is possibly low because small gas cavities are present ; these are arranged along planes at right angles, and impart a cloudiness to the material.   The hardness is 3 ; and the indices of refraction with Li-light are $\omega=2\cdot40$, and $\epsilon=2\cdot37$.   The mineral is readily soluble in acids.   D. Strömholm reported **dihydrated lead hexoxydichloride**, $6PbO.PbCl_2.2H_2O$, to be slowly formed in fine microscopic needles when fresh lead hydroxide is kept in contact with $0\cdot05N$-KCl ; or when hemihydrated lead trioxydichloride is kept in contact with $0\cdot095N$-NaOH.   The pigment called *Turner's yellow*, *Cassel's yellow*, *Veronese yellow*, or *Mineral yellow* is obtained by melting a mixture of one part of ammonium chloride with 10 parts of lead monoxide, red-lead, or white-lead.   Part of the ammonium chloride is sublimed.   The yellow crystalline mass has approximately the composition *lead heptoxydichloride*, $7PbO.PbCl_2$; but there is no evidence that this represents a chemical individual. P. Berthier obtained a similar yellow pigment by using the chlorides of sodium, barium, or calcium.   H. Corti reported a mineral of approximately this com-position from Las Coronas, Argentine.   E. Rimann represented the mineral *chubutite* by $14PbO.2PbCl_2$, or $Pb_8O_7Cl_2$, *lead heptoxydichloride*.   He suggested that the oxychlorides form a continuous series of mixed crystals, and that the dimorphism of lead monoxide persists in the mixed crystals of the oxychlorides, although the dimorphism has not been observed.

H. J. Brooke reported a sky-blue mineral, supposed to be from Sonora, Mexico, which was named **percylite**—after J. Percy.   The composition corresponded with hydrated **lead copper hydroxychloride**,$PbCu(OH)_2Cl_2$, or $PbCl.PbO.CuCl.CuO.nH_2O$, or according to P. Groth, $Pb(OH)Cl.Cu(OH)Cl$.   N. S. Maskelyne and W. Flight reported specimens from South Africa ; J. R. Gregory, and A. Raimondi, samples from Cerro de Challacollo, Tarapaca, Chili, and Mina San Rafael, Galeria al Norte, Bolivia ; and L. Fletcher, and M. Websky, samples from Mina Beatriz, Sierra Gorda, Atamaca, Chili.   H. Schulze reported a sample from Challacollo, Chili, containing some silver chloride—*silver percylite*—*vide* boleite.   The cubic or dodecahedral crystals of percylite are pseudocubic and belong to the tetragonal system ; the hardness is $2\frac{1}{4}$.   C. Friedel obtained it by the action of a soln. of cupric chloride on lead hydroxide for a few weeks.   G. Friedel reported dark blue crystals of a mineral accompanying boleite and pseudoboleite in the copper deposits of Boleo, Lower California, and he called it **cumengite**—after E. Cumenge.   The analysis corresponded with $4PbCl_2.4CuO.5H_2O$, or **pentahydrated lead copper tetroxy-chloride**.   The tetragonal crystals have the axial ratio $a:c=1:1\cdot625$; A. Hadding

found 1 : 1·6186 to 1·7011. According to G. Friedel, the (101)-cleavage is very good, the (110) is poor. The sp. gr. is 4·67 at 18·7° ; A. Hadding gave 4·77. G. Friedel found that the refractive indices are $\omega=2·026$, and $\epsilon=1·965$; the birefringence $\omega-\epsilon=0·061$. A. Hadding gave $\omega=2·041$ and $\epsilon=1·926$ for green light with $\lambda=510\mu\mu$. The optical character is negative. The mineral called **pseudoboleite,** found by G. Friedel in the same locality as cumengite, has a composition corresponding with **hexahydrated lead copper tetroxydecachloride,** $5PbCl_2.4CuO.6H_2O$. The tetragonal crystals are indigo blue, and have the axial ratio $a : c=1 : 2·023$. It frequently occurs as a parallel growth on boleite, or as crystalline masses on the different pseudocubic faces of boleite, leaving re-entrant angles along the cubic edges, or it may completely envelop the edges. The (001)- and (101)- cleavages are perfect. The optical character is negative ; and the birefringence is $\omega-\epsilon$ $=0·032$. G. Friedel also found a mineral which he called **boleite** associated with the cumengite and pseudoboleite of Boleo, Lower California. The mineral was also examined by A. Lacroix, F. E. Mallard, and C. Friedel. H. Schulze reported samples from Tarapaca and Challacollo ; and A. Liversidge, from Broken Hill, New South Wales. The composition of the Prussian-blue crystals is $PbCl_2.3AgCl.8CuO.9H_2O$, or **enneahydrated copper silver lead octoxyhenacosichloride.** The blue crystals were analyzed by G. Friedel, F. E. Mallard, E. Cumenge, and A. Liversidge. C. Friedel synthesized boleite by the prolonged action of a soln. of cupric chloride on lead hydroxide. The crystals are in cubes ; each crystal being made up of three individuals each with its c-axis parallel to a cubic axis. The individuals are tetragonal, with the axial ratio $a : c=1 : 3·996$. The (001)-cleavage is perfect, the (100)-cleavage is poor, and the (101)-cleavage is good. The optical character is negative. The sp. gr. is 5·054 at 18·78° ; the hardness is 3 ; and the birefringence 0·020. The thin sections of the crystals have an isotropic interior and a birefringent border. A. Hadding found that the outer layers are richer in lead and the interior richer in silver. He believed that the mineral is truly cubic, and that the variation in the sp. gr. of different crystals 4·802–5·155, and in the refractive indices of different parts of the same crystals, 2·081–2·087, is due to variations in composition. The X-radiogram of boleite points to the cubic system. G. Friedel said that the mineral is not attacked by water, but is soluble in nitric acid. L. J. Spencer and E. D. Mountain reported green, blade-like crystals of hydrated **copper lead trioxydichloride,** $3PbO.CuCl_2.H_2O$, stabbing the mendipite from the Mendip Hills. They called it **chloroxiphite**—from $\chi\lambda\omega\rho\acute{o}s$, green ; $\xi\acute{\iota}\phi os$, a blade or sword. The colour is dull olive-green, or pistachio-green, not unlike epidote ; and the habit, degree of symmetry, cleavage, and pleochroism of the crystals is not unlike that of epidote. The cleavage parallel to (100) is poor, that parallel to (001) is perfect. The crystals and cleavage-flakes lying on the (001)-face are bright emerald-green parallel to the length, and yellowish-brown across blades. The optic axial angle is about 80°. The crystals are monoclinic with the β-angle $62\frac{3}{4}°$. The index of refraction and birefringence are high. The sp. gr. is 6·763 at 16·2°/4° ; and the hardness $2\frac{1}{2}$. No change occurs when the mineral is heated to 100°, but at 250°, all the water is expelled. The colour of the mineral is then black. Chloroxiphite readily dissolves in nitric acid ; and weathers into hydrocerussite. L. J. Spencer and E. D. Mountain found both a **lead copper tetrahydroxydichloride,** $2Pb(OH)_2.CuCl_2$, which they called **diaboleite**—from $\delta\iota\acute{a}$, apart ; and boleite : in sky-blue crystals embedded in the mendipite of the Mendip Hills. The axial ratio of the tetragonal crystals is $a : c=1 : 0·95$. The sp. gr. is 6·412 at 17·6°/4°, and the hardness $2\frac{1}{2}$. The refractive index is 1·98 ; and the crystals are dichroic, ω being deep-blue, and ϵ pale-blue or colourless. The mineral is quite soluble in nitric acid. All the water is expelled at 250°. Diaboleite weathers into hydrocerussite.

According to G. André, if a conc. soln. of calcium chloride is boiled with an excess of lead oxide, care being taken to prevent evaporation, and the liquid is filtered, the filtrate deposits an abundant precipitate, which after washing with alcohol and drying corresponds with **calcium lead trioxydichloride,** $CaCl_2.CaO.2PbO.4H_2O$.

When boiled with water it becomes yellow. If the water is left out of account, this compound may be regarded as crystallized calcium oxychloride in which 2 mols. of calcium oxide have been replaced by 2 mols. of lead oxide. When the mother-liquor, which is slightly alkaline, is poured into a large excess of cold water, the compound $CaCl_2.3PbO.2H_2O$ is obtained as an amorphous white precipitate. A soln. of barium chloride when treated in a similar manner yields small slender needles which seem to be a **barium lead oxychloride,** but they are decomposed immediately by water and yield lead oxychloride. Strontium chloride yields small, distinct, brilliant crystals which when washed with alcohol and dried correspond with **strontium lead dioxydichloride,** $SrCl_2.2PbO.5H_2O$. If the mother-liquor is poured into excess of water the compound $PbCl_2.3PbO.3H_2O$ is precipitated. Lead oxide is dissolved by either a hot or a cold soln. of magnesium chloride, but the filtered liquid deposits no precipitate, and only a very slight precipitate is obtained when the soln. is poured into an excess of water.

§ 26. Lead Bromides

H. G. Denham [1] prepared **lead subbromide**, or **lead monobromide**, PbBr, by the action of the vap. of ethyl bromide at 261° on lead hemioxide, Pb_2O. The grey product is oxidized very slowly by dry air, but more rapidly by moist air. When heated for 2 hrs. at 280° in vacuo, it forms normal lead dibromide and lead. Water at 25° dissolves 0·4 milliequivalent per litre. Bromine-water acts slowly on the subbromide at ordinary temp., more rapidly at 50°, forming the white normal bromide. Nitric acid and acetic acid decompose it at once, forming lead and lead dibromide.

Normal **lead bromide**, $PbBr_2$, is formed by the action of bromine on lead ; and, as shown by J. A. Wilkinson,[2] a feeble luminosity occurs when lead is warmed in the vapour of bromine. J. Nicklès, and T. Hjortdahl found that bromine reacts slowly with lead in the presence of alcohol, forming lead bromide. A. J. Balard prepared lead bromide by the action of hydrobromic acid on lead oxide. R. S. Norris employed this process. If bromine-water be used, lead dioxide is produced. A. J. Balard also made this salt by treating a soln. of a lead salt with one of potassium bromide ; hydrobromic acid and other soluble bromides can be used as the precipitant. This method was employed by C. L. von Ende, and G. P. Baxter and co-workers. The latter treated an aq. soln. of purified lead nitrate with an excess of hydrobromic acid, drained the product on a centrifuge, and dissolved the washed product in hot conc. hydrobromic acid. The soln. was diluted with water, and the precipitate washed by decantation with ice-cold water, and dried on a centrifuge. This treatment was repeated a number of times, and the product dried in vacuo over fused potassium hydroxide. It was then melted in a current of hydrogen or nitrogen charged with the vap. of hydrogen bromide. E. H. Büchner and J. Kalff obtained no colloidal lead bromide by dropping a soluble bromide into a soln. of a lead salt.

A. Jeltekoff treated lead oxide or lead carbonate with a mixture of methylene bromide and water at 140°–150°. J. A. Wilkinson made lead bromide by the electrolysis of a soln. of potassium bromide using a lead anode. W. F. O. de Coninck and L. Arzalier obtained it by exposing an intimate mixture of lead oxide and ammonium bromide to a high press. M. Barre passed the vapour of sulphur dibromide over lead monoxide or red-lead at about 700°. The lead oxide should be in a thin layer or the crust of lead bromide will prevent access of the sulphur bromide to the oxide below. V. Lenher showed that lead sulphide dissolves readily in conc. hydrobromic acid ; hydrogen sulphide is evolved, and lead bromide is formed ; M. Berthelot, that lead iodide is converted by bromine into lead bromide ; and A. Ditte, that lead sulphate dissolves in a soln. of potassium bromide, forming lead bromide, and as the potassium sulphate accumulates in the liquid, the complex salt $K_2Pb(SO_4)_2$ is formed. Hydrobromic acid was also found by A. Ditte to decompose lead sulphate in the reversible reaction, $PbSO_4 + 2HBr \rightleftharpoons PbBr_2 + H_2SO_4$. W. C. Ebaugh observed that lead arsenate, $Pb_3(AsO_4)_2$, is gradually converted into lead bromide when heated in a stream of air charged with the vapour of hydrobromic acid.

The physical properties of lead bromide.—Lead bromide occurs as a white crystalline powder. O. Lehmann [3] found that when soln. of lead nitrate and potassium bromide are mixed, globular masses are first formed, then acicular needles, and finally these pass into six-sided plates. C. Löwig found that a hot aq. soln., on cooling, furnishes needle-like **crystals.** According to T. Hjortdahl, the action of alcoholic bromine on lead furnishes rhombic, bipyramidal crystals with the axial ratios $a : b : c = 0.5883 : 1 : 1.1833$. A. E. Nordenskjöld also obtained good crystals by slowly cooling hot aq. soln., and he found them to be isomorphous with those of lead chloride. The (001)-cleavage is perfect. W. Biltz studied what he called the lattice-energy of the crystals. C. J. B. Karsten found the **specific gravity** to be 6.6302 ; P. Kremers, 6.611 at 17.5° ; F. W. Clarke, 6.572 at 19.2° ; G. P. Baxter and F. L. Grover, 6.659 ; and G. P. Baxter and C. F. Hawkins, 6.676 at 0° ; 6.669 at 25° ; and 6.644 at 50°. R. Lorenz, H. Frei and A. Jabs gave for the sp. gr., D, of the molten bromide, at $\theta°$ between 600° and 800°, $D = 6.175 - 0.00145\theta$; and R. Lorenz and W. Herz, 5.634 for the sp. gr. and 65.14 for the mol. vol. at the m.p. F. A. Henglein studied the mol. vol. D. M. Lichty gave for the sp. gr., D, of soln. of lead bromide sat. at the temp. named (*vide infra*) :

	0°	15°	25°	35°	45°	55°	65°	80°	95°
D	1.00433	1.00530	1.00608	1.00598	1.00593	1.00455	1.00282	1.00003	0.99946

I. I. Saslawsky gave 0.97 for the ratio of the mol. vol. to the sum of the at. vols. of the constituent elements. S. Motylewsky found the **drop-weight** of the molten bromide to be 143° referred to that of water, 100, at 0°. R. Lorenz and H. T. Kalmus gave for the **viscosity** :

	372°	392°	412°	432°	452°	472°	492°
η	0.10190	0.08060	0.06970	0.06133	0.05384	0.04700	0.04073

G. P. Baxter and C. F. Hawkins gave for the cubical coeff. of **thermal expansion** between 0° and 25°, 0.00010 ; and between 25° and 50°, 0.00009. R. Lorenz and W. Herz found the coeff. of thermal expansion, a, of the liquid to be 0.000266, and $aT_m = 0.172$ to be in accord with the factor obtained with related halides. H. V. Regnault found the **specific heat** between 16° and 98° to be 0.0533 : and O. Erhardt, 0.0534 between 190° and 430°. O. H. Weber gave 0.0532 from 190° to 430° ; 0.0709, 190° to 440° ; 0.1099, 190° to 460° ; and 0.2055, 190° to 480°. H. M. Goodwin and H. T. Kalmus found 0.0566 between 199° and 488° ; and 0.0780 between 488° and 587°. W. M. Latimer and H. D. Hoenshel found the mol. ht. of lead bromide, per mean gram-atom, to be :

	−254.6°	−244.5°	−233.4°	−217.5°	−192.4°	−142.8°	−91.0°	1.8°	24.0°
C_p	1.22	2.12	3.15	4.33	5.05	5.70	6.00	6.33	6.34

H. Burschall gave 17·0 for the mol. ht. between —75° and —183°; and H. Schottky gave 18·97 for the mol. ht. at ordinary temp. J. Rosenthal showed that lead bromide becomes plastic below its **melting point.** A. J. Balard noted that when heated, lead bromide forms a red liquor, which, according to C. Löwig, freezes to a horn-like mass, and O. H. Weber said that the red liquid forms a pale yellow solid which finally becomes white. W. Ramsay and N. Eumorfopoulos gave 363° for the m.p.; C. Sandonnini, 366°; G. Sandonnini, 368°; R. Lorenz and M. G. Fox, 367°; K. Mönkemeyer, and F. Matthes, 370°; C. Tubandt and G. Eggert, 373°; G. Herrmann, 380°; A. Helfenstein, 480°; H. M. Goodwin and H. T. Kalmus, 488°; O. Ehrhardt, and O. H. Weber, 490°; and T. Carnelley, 499°. K. Mönkemeyer observed an undercooling of about 3°. The mol. **heat of fusion** given by H. O. Weber is 5·101 Cals.; by O. Ehrhardt, and V. Czepinsky, 4·515 Cals.; and by H. M. Goodwin and H. T. Kalmus, 3·65 Cals. T. Carnelley and W. C. Williams observed that lead bromide does not boil before the blowpipe flame; O. H. Weber gave 918°–920° for the **boiling point,** and A. Helfenstein, 921°. H. von Wartenberg and O. Bosse found the mol. **heat of vaporization** to be 28·180 Cals., and the **vapour pressure,** p, in atm., $\log p = 28180\ 4·571T + 5·183$; and there is a slight dissociation during vaporization. R. Lorenz and W. Herz studied this subject. W. Braunbek discussed some relations between the sp. ht., m.p., and latent heat; and K. Jellinek and R. Uloth calculated values for the partial press. of the bromine at different temp. A. T. Waterman said that no lead ions are emitted when lead bromide is heated. J. Thomsen gave for the **heat of formation** from its elements—bromine liquid—64·456 Cals.; M. Berthelot gave 66·3 Cals.; M. de K. Thompson, 69·5 Cals.; H. Braune and F. Koref, 66·35 Cals.; P. Günther, 67·1 Cals.; C. Krahmer, and T. J. Webb, 65·58 Cals.; V. Czepinsky, 73·5 at 389°; 78·58 Cals. at 452°; 75·01 at 474°; and 89·5 Cals. at 700°; R. Lorenz, 76·18 Cals. between 450° and 650°.; R. Lorenz and M. Katayama, 71·6 Cals. between 60° and 162°; and R. Lorenz and M. G. Fox, 71·5 Cals. between 498° and 600°. C. Krahmer gave for the heat of the reaction : $Pb + 2AgBr = 2Ag + PbBr_2 - 17·962$ Cals. at 25°. O. H. Weber gave 69·5 Cals. for the **free energy** between 430° and 480°; and 68·3 Cals. between 490° and 800°; M. de K. Thompson calculated from the solubility data 62·3 Cals. at ordinary temp., and 64·7 Cals. from the e.m.f. of the cell $Pb : PbBr_2$. W. M. Latimer and H. D. Hoenshel gave 39·7 units for the **entropy** of lead bromide per mean gram-atom from —257·15° to 25°; this is in agreement with W. M. Latimer's value 39·2.

T. Hjortdahl said that the **index of refraction** of lead bromide is high. B. A. Dima found that with **ultra-violet light,** the electrical effect is higher than with lead chloride and less than with lead iodide. T. Volmer observed the emission of positively charged particles by lead bromide at relatively low press. W. Hampe showed that pulverulent and molten lead bromide are electrical conductors. C. Tubandt and G. Eggert found that the solid conducts electrolytically. J. Rosenthal showed that the **electrical conductivity** of pressed rods is, when cold, better with crystalline than with amorphous lead bromide. R. Ketzer found the sp. conductivity of pressed rods is $7·4 \times 10^{-8}$ mho. G. Tammann and H. Bredmeier measured the conductivity of thin films of the bromide. G. Wiedemann, and A. Gockel observed polarization effects with these rods at 260°. C. Sandonnini gave 1·030 mhos for the sp. conductivity of the molten bromide. Observations were made by V. Czepinsky; and R. Lorenz and H. T. Kalmus found for the sp. conductivity at different temp. :

	372°	392°	412°	432°	452°	472°	492°
Sp. cond. . .	0·5397	0·6479	0·7202	0·7900	0·8570	0·9220	0·9835

W. Biltz and W. Klemm gave for the eq. conductivity $\lambda = 18·9 + 0·120(\theta - 373)$. L. Graetz said that the sp. resistance changes from 2700×10^8 (mercury unity) at 0 atm. press. to 327×10^8 at 4000 atm. press. C. Tubandt and G. Eggert found that during the electrolysis of the solid, the lead dendrites extend to the anode

more rapidly than with lead chloride. W. Böttger found the conductivity of a soln. of lead bromide at 19·96° to be 0·03692, and he calculated that about 5 per cent. of non-ionized lead chloride to be present. C. L. Wagner found the sp. conductivity of $\frac{1}{256}N$-soln. to be 0·000505; of $\frac{1}{512}N$-soln., 0·000265; and of $\frac{1}{1024}N$-soln., 0·000139. L. C. von Ende calculated that a sat. aq. soln. at 25·20° contained 1·06 millimols per litre of $PbBr_2$ mols.; 9·19, of $PbBr'$-ions; 16·03, of Pb''-ions, and 41·25, of Br'-ions. The **ionization constant** for the first stage of the ionization is 0·0003790, and for the second stage, 0·00002727. M. Katayama found the **electromotive force** of the cell $Pb\,|\,PbBr_2\,|\,C$ sat. with Br at 60°–162°, to be $E=1\cdot138+0\cdot00065(60-\theta)$; O. H. Weber gave for the cell $Pb\,|\,PbBr_2\,|\,Br_2$ between 490° and 800°, $E=1\cdot0571-0\cdot000500(\theta-490)$, and R. Lorenz and M. G. Fox gave between 367° and 460°, $E=1\cdot0945-0\cdot000714(\theta-367)$; and A. Klein gave for the cell $Pb\,|\,PbCl_2\,|\,0\cdot01N\text{-}KCl\,|\,0\cdot01N\text{-}KBr\,|\,PbBr_2\,|\,Pb$, at 23·1°, 0·0062 volt, and free energy 304·6 cals., and thermal value, 3560 cals. According to R. Lorenz, the e.m.f. of the cell $Zn\,|\,ZnBr_2\,|\,PbBr_2\,|\,Pb$, between 434° and 593°, is equal to the difference between those of $Zn\,|\,ZnBr_2\,|\,Br_2$ and $Pb\,|\,PbBr_2\,|\,Br_2$. Observations were also made by C. C. Garrard, A. Helfenstein, and V. Czepinsky. P. Fischer measured the conductivity of mixtures of silver and lead bromides; and J. Thiele the **thermoelectric force** of the molten lead halides against metals. A. Lenert gave $K=4\cdot89$ for the **dielectric constant**, and after melting and freezing, 18·78 owing to some decomposition. L. Grätz and O. Fromm gave 41·79 for $\lambda=100$; 42·94 for $\lambda=122\cdot3$; 43·7 for $\lambda=130\cdot4$; and 48·64 for $\lambda=180\cdot0$. L. Ebert studied the dielectric polarization of the lead salts. S. Meyer gave for the **magnetic susceptibility,** $-0\cdot525\times10^{-6}$; and for the mol. magnetism, $-0\cdot095\times10^{-6}$.

The **chemical properties of lead bromide.**—According to G. P. Baxter and F. L. Grover,[4] lead bromide, after being melted in an atm. of hydrogen bromide, is neutral. R. S. Norris, H. L. Wells, and A. K. Sanyal and N. R. Dhar found that lead bromide becomes almost black when exposed to **light** owing to its decomposition into lead and bromine. The darkening occurs in dry oxygen or in dry hydrogen. If kept under water the lead bromide is darkened in a few days by light. F. de Carli studied the reducing action of **hydrogen.** A. J. Balard, A. L. Potilizin, R. Ketzer, and O. H. Weber said that when melted in **air** or **oxygen** lead bromide emits white fumes, and on cooling forms a yellow mass containing lead oxybromide; but, according to G. P. Baxter and F. L. Grover, and R. Ketzer, if melted in a neutral atm. or in bromine, decomposition does not occur. A. L. Potilizin, and W. C. Ebaugh found that lead bromide is partially reduced by **hydrogen,** and A. Jouniaux found the bromide to be less readily reduced than the chloride.

C. Löwig found lead bromide to be sparingly soluble in cold **water,** and readily soluble in hot water. C. Löwig showed that lead bromide dissolves more quickly in water containing hydrochloric, nitric, or acetic acid than in water alone. R. S. Norris said that the salt is completely soluble in water only on the addition of one or two drops of nitric acid; and G. P. Baxter and co-workers found that the salt which has been fused in an atm. of hydrogen bromide is hydrolyzed when it dissolves in water, furnishing some insoluble basic salt. G. André said that water dissolves about 5 grms. of the salt per litre at 11°; G. P. Baxter and F. L. Grover, 9 grms. per litre at ordinary temp.; W. Böttger, 8·34 grms. per litre at 19·96°; G. L. Wagner, 9·74 grms. per litre at 25°; C. L. von Ende, 26·28 millimols per litre at 25·20°. D. M. Lichty found the solubility in grams per 100 c.c. at different temp. to be:

	0	15	25	35	45	55	65	80	95	100
S .	0·4554	0·7285	0·9701	1·3124	1·7259	2·1024	2·5161	3·2350	4·1767	4·5500

The solubility at 0° is greater than that of lead iodide at 100°; and at 35°, the solubility is about the same as that of lead chloride, and at 95°, about one-third greater than that of the chloride. G. N. Lewis and T. B. Brighton computed the

solubility product to be 8.46×10^{-6}. H. Braune and F. Koref found lead bromide to be soluble in a soln. of **sodium hydroxide** ; and A. Ditte showed that lead bromide is decomposed by alkali hydroxide, forming an oxybromide. V. Zotier examined the catalytic effect of lead bromide on **hydrogen dioxide.**

V. Thomas showed that boiling **hydrochloric acid** transforms lead bromide into the chloride by a reversible reaction. G. C. Wittstein found the salt to be slowly soluble in a cold, and easily soluble in a warm soln. of **ammonium chloride** ; with 24 grms. of ammonium chloride in 500 c.c. of water, 4 grms. of lead bromide are all converted into lead chloride. W. Herz and M. Hellebrandt studied the solubility in soln. of **potassium, sodium, calcium, strontium, and barium chlorides.** G. André found that a $\frac{1}{2}N$-soln. of **hydrobromic acid** at 11° dissolves 1·25 grms. of lead bromide per litre, and when the sat. soln. is neutralized with lead oxide, 14 Cals. of heat are evolved. M. Berthelot found that a cold, sat. aq. soln. is precipitated by dil. $\frac{1}{2}N$-hydrobromic acid, but a potassium bromide soln. of the same conc. gives no precipitate. A. Ditte found that when hydrobromic acid is gradually added to a sat. aq. soln. of lead bromide at 10°, lead bromide is at first precipitated, some of the precipitate then redissolves so that 100 grms. of water, containing 72 grms. of HBr, dissolve 55·0 grms. of lead bromide per 100 grms. of solvent at 10°, and the soln. has a sp. gr. 2·06. When the conc. of the hydrobromic acid is very great, the lead bromide becomes very soluble, and by passing hydrogen bromide into a hot soln. of lead bromide in hydrobromic acid in the presence of an excess of lead bromide, the cooling soln. furnishes white, needle-like crystals of **hydrobromoplumbous acid,** $H_2Pb_5Br_{12}.10H_2O$, or $5PbBr_2.2HBr.10H_2O$. G. André, and H. Fonzes-Diacon showed that lead bromide dissolves in soln. of **ammonium bromide,** forming complex salts. C. H. Herty said that lead bromide is less soluble in a soln. of **potassium bromide** than lead iodide in one of potassium iodide ; and that lead bromide is less soluble in a dil. than in a conc. soln. of potassium bromide. The subject was studied by W. Herz and M. Hellebrandt, with **sodium bromide** as well as potassium bromide, and **calcium, strontium, and barium bromides.** C. L. von Ende said that the soln. in $\frac{1}{2}N$-KBr is perceptibly acid towards litmus. The solubility is augmented by the addition of nitric acid owing to the formation of complex nitratobromides. V. Thomas found that **hydriodic acid** rapidly transforms lead bromide into the iodide ; E. Field, that soln. of **ammonium iodide** or **potassium iodide** form complex bromoiodides ; and C. H. Herty showed that if the soln. of potassium iodide be sufficiently concentrated, $KPbI_3.2H_2O$ crystallizes from the soln.

A. J. Balard said that conc. **sulphuric acid** decomposes lead bromide with the evolution of hydrogen bromide. According to A. Ditte, a soln. of **zinc sulphate,** in contact with excess of lead bromide, gives bromide of zinc and sulphate of lead. At high temp., the amount of action is less than it is at low temp. The same effect is seen in the action of zinc bromide on lead sulphate. E. C. Franklin showed that lead bromide is moderately soluble in liquid **ammonia** ; and G. André observed no reaction when lead bromide and ammonia are heated in a sealed tube at 150°. W. Biltz found that with liquid ammonia, at −78·5°, **lead octamminobromide,** $PbBr_2.8NH_3$, is formed and that the heat of formation is 8·2 Cals., while the dissociation press. at −52° is 27·3 mm.; at −29·4°, 100 mm.; at −38°, 202·3 mm.; and at −10·9°, 700 mm. Between −52° and 0°, the octammine furnishes **lead hemihenamminobromide,** $PbBr_2.5\frac{1}{2}NH_3$, with a heat of dissociation 9·0 Cals., and a dissociation press. of 17 mm. at −45° ; 71·9 mm. at −28° ; 100 mm. at −23° ; and 432 mm. at 0°. Between 0° and −28°, the octammine forms **lead triammino-bromide,** $PbBr_2.3NH_3$, which has a dissociation press. of 23·3 mm. at −28·7°, 100 mm. at −9°, 188·3 mm. at 0°, and 596 mm. at 18·5°. At 34·4°, the octammine passes into **lead diamminobromide,** $PbBr_2.2NH_3$. F. Ephraim found that at ordinary temp., ammonia forms the diammine which has a vap. press. of 760 mm. at 70°, and a heat of dissociation of 12·16 Cals. W. Biltz gave 11·4 Cals., and said that the vap. press. is 57·8 mm. at 34·74°, 100 mm. at 42·5°, 235·3 mm. at 55·6°,

and 311·4 mm. at 61·2°. At 110·6°, the diammine passes into lead monammino-bromide, $PbBr_2.NH_3$, with a heat of dissociation 15·6 Cals.; and vap. press. of 16·7 mm. at 110·6°, 76·9 mm. at 139·4°, 100 mm. at 144°, 152·7 mm. at 156·6°, and 459 mm. at 184·35°. C. L. Clark studied the secondary valencies of these ammines. V. Thomas observed very little reaction with nitrogen peroxide at ordinary temp., an oxybromide being very slowly formed. A. J. Balard said that nitric acid decomposes lead bromide with the evolution of bromine. C. L. von Ende found that $0.001N$-HNO_3 dissolves 39·11 millimols of lead bromide per litre; $0.01N$-HNO_3, 39·87 millimols; and $0.051N$-HNO_3, 42·56 millimols. G. C. Wittstein found lead bromide is slowly dissolved by a cold soln. of ammonium nitrate, and rapidly by a warm soln. C. L. von Ende found the solubility is greater in a $0.04N$-soln. of potassium nitrate containing $0.01N$-HNO_3 than in $0.051N$-HNO_3.

J. Spiller found lead bromide is not precipitated in the presence of sodium citrate. A. P. N. Franchimont found lead bromide to be insoluble in benzene; J. Nicklès, insoluble in alcohol, and in ether; A. Naumann, difficultly soluble in acetone; H. Lecher and A. Goebel, insoluble in bromoform, and also in methyl acetate, ethyl acetate, or benzonitrile; H. Mandal, soluble in aniline; H. Braune and F. Koref, soluble in an alkaline amyl alcohol soln. of sodium tartrate; and W. Goebbels, sparingly soluble in pyridine. G. W. Heise found the solid phase between −26° and 19° is $3C_5H_5N.PbBr_2$, and above that temp. $2C_5H_5N.PbBr_2$.

F. L. Shinn showed that with ethylamine an insoluble compound is formed. T. Carnelley and W. C. Williams found that glass is attacked when heated with lead bromide.

Mixed salts.—C. Sandonnini [5] measured the f.p. curves of mixtures of lead fluoride and bromide, and the results are summarized in Fig. 94. The system is analogous to that with lead chloride and fluoride. There is a eutectic at 349° and 7·5 molar per cent. of lead fluoride, and at about 561°, lead bromofluoride, PbBrF, is formed. With 75 molar per cent. of lead fluoride there is a second eutectic at 533°. There is a compound—lead dibromoocto-fluoride, $Pb_5Br_2F_8$—formed at 585°, but it decomposes on melting. H. Fonzes-Diacon obtained the fluobromide. It is decomposed by an excess of water. F. Matthes, K. Mönkemeyer, and C. Sandonnini showed that the f.p. curve of mixtures of lead bromide and chloride is almost a straight line, Fig. 95, representing an unbroken series of mixed crystals. C. H. Herty and T. R. Boggs obtained isomorphous mixed crystals from aq. soln. The sensitiveness of the mixtures to light depends on the proportion of lead bromide present. G. Meyer found the partition law to be valid between mixed crystals and their soln. in the system $PbCl_2$–$PbBr_2$–H_2O; W. Würfel did not always find it so, owing to equilibrium not being attained. M. W. Iles found dendritic crystals of a lead chlorobromide, PbClBr, from the smelting furnaces at Lead-ville, and V. Thomas claimed to have made this compound by the action of bromine on lead chloroiodide. Boiling hydriodic acid converts it into lead iodide. V. Thomas also claimed to have made lead trichlorobromide, Pb_2Cl_3Br, or $3PbCl_2.PbBr_2$, from hot soln. of a gram of potassium bromide and 5 grms. of lead chloride in 250 c.c. of water, and by slowly cooling a soln. of 10 c.c. of a 10 per cent. soln. of potassium bromide and 5 grms. of lead chloride in 240 c.c. of water. The crystals are stable
FIG. 94.—Freezing-point Curves of Mixtures of Lead Fluoride and Bromide.
FIG. 95. — Freezing Curves of Mixtures of Lead Chloride and Bromide.

in light; decomposed by water; insoluble in cold alcohol; sparingly soluble in hot alcohol; and insoluble in chloroform. The bromine is not quantitatively displaced by nitrogen peroxide; nitrous acid attacks it vigorously at a low temp. The salt is insoluble in acetic acid; soluble in cold hydrochloric acid, and the hot soln. on cooling deposits lead chloride and the unchanged mixed salt. It is easily soluble in hydrobromic acid, forming lead bromide.

Complex salts.—G. André[6] reported a number of **ammonium bromoplumbites**, with $PbBr_2 : NH_4Br : H_2O$, as $2:14:3$, $1:6:1$, $7:12:7$, and $3:2:1$, but H. L. Wells and W. R. Johnston were unable to confirm a single one of these salts. They say that no mention is ever made of any of these products having been produced more than once, and it seems probable that whenever G. André obtained a crop of crystals or a precipitate, it was considered to be a new compound without regard to the number of different substances that it might contain. H. L. Wells and W. R. Johnston were also unable to prepare *ammonium tribromoplumbite*, NH_4PbBr_3. J. W. Retgers, and P. Gaubert studied the effect of lead bromide on the crystallization of ammonium bromide. H. Fonzes-Diacon obtained **ammonium pentabromodiplumbite**, $NH_4Pb_2Br_5$, by cooling a soln. of lead bromide in a hot 120 per cent. soln. of ammonium bromide. H. L. Wells and W. R. Johnston also obtained the same salt, using dil. soln. of the component salts. The salt forms square plates which, according to H. Fonzes-Diacon, resemble those of boric acid. The crystals darken a little on exposure to light, and do not lose their lustre when dried. H. Fonzes-Diacon reported white, acicular crystals of **ammonium tetrabromoplumbite**, $(NH_4)_2PbBr_4$, to be formed from the hot sat. soln. of lead bromide in 65 per cent. ammonium bromide. H. L. Wells and W. R. Johnston obtained **hydrated ammonium tetrabromoplumbite**, $(NH_4)_2PbBr_4.H_2O$, from a soln. of lead bromide or lead oxide in a hot conc. soln. of ammonium bromide. The radiating tufts of highly refracting, slender prisms are monohydrated. H. Fonzes-Diacon reported tetragonal plates of **ammonium chlorotetrabromodiplumbite**, $NH_4Cl.2PbBr_2$, to be formed from a sat. soln. of lead chloride in a boiling, 100 per cent. soln. of ammonium bromide. He also reported rhombic plates or prismatic crystals of **ammonium tetrachlorobromodiplumbite**, $NH_4Br.2PbCl_2$, from an aq. soln. of the two salts; and monoclinic needles of **ammonium dichlorodibromoplumbite**, $2NH_4Br.PbCl_2.4H_2O$, by cooling a soln. of lead chloride in a hot soln. of 65 per cent. ammonium bromide. The crystals are decomposed by water; and are soluble in acids and alkali-lye. No *ammonium fluobromoplumbite* could be prepared from mixed soln. of lead fluoride and ammonium bromide.

The crystallization of mixed soln. of potassium and lead bromides has been examined by O. Lehmann.[7] A. C. Becquerel observed the electrolytic formation of the complex salt from soln. of lead acetate and potassium bromide separated by a porous partition, and connected electrically by lead wires. R. Lorenz and co-workers found the sp. gr. of molten mixtures of n mol of lead bromide, and $1-n$ mol of potassium bromide, by $D=3.48-0.001667+(2.786+0.000667\theta)^n$. R. Ketzer found the electrical conductivity of solid lead bromide is raised when some potassium bromide is present. C. Immerwahr measured the potential of lead in soln. of lead and potassium bromides. M. Berthelot's *potassium octobromotriplumbite*, $K_2Pb_3Br_8$, is considered by H. L. Wells to be a mixture; and M. Berthelot's *potassium hexadecabromoplumbite*, $K_{14}PbBr_{16}$, is probably also a mixture.

H. L. Wells prepared quadratic plates of **potassium pentabromodiplumbite**, KPb_2Br_5, from soln. of 400 grms. of potassium bromide and 130 grms. of lead bromide made up to 1050 c.c. with water; from soln. of 400 grms. of potassium bromide and 150 grms. of lead bromide made up to 1250 c.c. with water; and 200 grms. of potassium bromide and 75 grms. of lead bromide made up to 1000 c.c. with water. The product rapidly turns pale green in daylight, and after long exposure, or rapidly in sunlight, the colour turns dirty brown. This compound was found by L. J. Burrage in his study of the ternary system:

$PbBr_2$–KBr–H_2O at 25°. Expressing conc. in grams per 1000 grms. of soln., he found for the mutual solubility of lead and potassium bromides :

KBr	. 0	0·56	22·92	49·67	56·09	256·9	301·1	319·7	388·7	393·2	405·2
$PbBr_2$	9·69	9·46	2·56	3·10	2·95	14·94	31·60	36·22	72·05	49·29	0

Solid phase	$PbBr_2$		KPb_2Br_5		$KPbBr_3.\frac{1}{3}H_2O$		KBr	

H. L. Wells reported **tritahydrated potassium tribromoplumbite,** $KPbBr_3.\frac{1}{3}H_2O$, in colourless crystals, from soln. of 500 grms. of potassium bromide and 130 grms. of lead bromide in 950 c.c. or 1050 c.c. of liquid ; of 500 grms. of potassium bromide and 140 grms. of lead bromide in 900 c.c. of liquid ; and of 500 grms. of potassium bromide and 120 grms. of lead bromide in 1050 c.c. or 1125 c.c. of liquid. The crystals are stable in air ; and they lose water very slowly over sulphuric acid at 100°. C. H. Herty made **monohydrated potassium tribromoplumbite,** $KPbBr_3.H_2O$, by dropping, with constant stirring, a sat. soln. of lead nitrate at 20° into a sat. soln. of potassium bromide at 20°, and allowing the mixture to stand for some days ; and also from a boiling soln. of 7 grms. of lead bromide, 27 grms. of potassium bromide, and 40 grms. of water. H. L. Wells obtained it from the mother-liquor from potassium pentabromodiplumbite by cooling in a freezing mixture. L. J. Burrage obtained the tritahydrate, $KPbBr_3.\frac{1}{3}H_2O$—*vide supra.* The colourless, prismatic crystals are usually stable in air, and, on drying, become opaque. Two-thirds of their water is lost over conc. sulphuric acid. C. Löwig reported **potassium tetrabromoplumbite,** K_2PbBr_4, to be formed by evaporating a filtered soln. of lead nitrate and an excess of potassium bromide. The octahedral crystals are dissolved without decomposition by a small proportion of water, but with an excess of water lead bromide separates out. H. L. Wells suggested that C. Löwig was mistaken in assuming that these crystals are anhydrous since **monohydrated potassium tetrabromoplumbite,** $K_2PbBr_4.H_2O$, is formed in prismatic crystals from soln. of lead bromide in sat. soln. of potassium bromide ; and of 400 grms. of potassium bromide and 70, 90, 120, or 130 grms. of lead bromide respectively made up to 700, 800, or 650 c.c. of liquid or of 500 grms. of potassium bromide and 130 grms. of lead bromide in 850 or 775 c.c. of water. C. H. Herty obtained this salt from a boiling soln. of 7 grms. of lead bromide and 27 grms. of potassium bromide in 40 c.c. of water. The prismatic crystals are stable in air, the water is slowly lost over sulphuric acid, and when heated above 110°, H. L. Wells prepared a perbromide, *potassium octobromodiplumbite,* $K_3Pb_2Br_7.Br.4H_2O$, by allowing 400 c.c. of a cold sat. soln. of potassium and lead bromides and 20–30 c.c. of bromine, to stand over-night. The product was dried in an atm. of bromine. The dark brown, tetragonal prisms lose bromine and become white on exposure to air. They are not appreciably decomposed in the cold in a sealed tube. The bromine may be simply adsorbed—*vide* the corresponding iodide. H. L. Wells prepared quadratic plates of **rubidium pentabromodiplumbite,** $RbPb_2Br_5$, from hot soln. of lead and rubidium bromides ; and **rubidium tetrabromoplumbite,** $Rb_2PbBr_4.\frac{1}{3}H_2O$, by the process employed for the corresponding chloride. H. L. Wells made white, tabular crystals of **cæsium pentabromodiplumbite,** $CsPb_2Br_5$, from soln. of lead bromide in one containing 50 grms. of cæsium bromide in 1250 c.c. of water. H. W. Foote obtained it from soln. of the lead bromide in a 12·83–17·24 per cent. soln. of cæsium bromide at 25°. H. L. Wells prepared pale orange, prismatic or acicular crystals of **cæsium tribromoplumbite,** $CsPbBr_3$, from hot soln. of lead bromide in soln. of cæsium bromide sat. in the cold ; and H. W. Foote found this salt to be the solid phase in soln. with 18·58–19·57 per cent. of cæsium bromide at 25°. The salt is dimorphous. H. L. Wells could not make *cæsium tetrabromoplumbite,* Cs_2PbBr_4, although the potassium salt has been made. H. L. Wells prepared white rhombohedral crystals of **cæsium hexabromoplumbite,** by the method employed for the corresponding chloride. The salt is deposited from hot soln.

of lead bromide in cold sat. soln. of cæsium bromide. H. W. Foote obtained it from soln. with 46·40–51·15 per cent. of cæsium bromide at 25°. H. L. Wells obtained a series of **cæsium chlorobromoplumbites** from hot soln. of lead bromide and cæsium chloride. The salts of the type $CsPb_2(Cl,Br)_5$ were white plates with Cl : Br=2·8—1·5 : 1 ; those of the type $CsPb(Cl,Br)_3$ were yellow prisms with Cl : Br=1·2—4·8 : 1 ; and those of the type $Cs_4Pb(Cl,Br)_6$ were rhombohedra with Cl : Br=3·8—11·2 : 1. C. H. Herty reported *sodium tribromoplumbite*, $NaPbBr_3.H_2O$, to be formed like the corresponding potassium salt ; but it exists only in soln. C. Löwig made **sodium tetrabromoplumbite**, Na_2PbBr_4, by the process used for the potassium salt. The crystals are decomposed by water. R. Ketzer found the electrical conductivity of lead bromide to be increased by admixture with sodium chloride. C. Tubandt and S. Eggert studied the electrolysis of fused mixtures of lead and silver bromides. They also found that the f.p. curves of mixtures of these two bromides, Fig. 96, show the formation of **silver pentabromoplumbite**, $2PbBr_2.AgBr$, or $AgPb_2Br_5$, and the existence of a eutectic at 276° and 46 molar per cent. of lead bromide, and a break at 295°.

R. Otto and D. Drewes prepared **magnesium hexabromoplumbite**, Mg_2PbBr_6. $16H_2O$, by dissolving magnesium carbonate in hydrobromic acid, evaporating the soln. until a skin formed on the surface, and then adding as much lead bromide as the liquid would dissolve. On cooling the filtered liquid, the salt was deposited
FIG. 96.—Freezing-point Curves of Mixtures of Lead and Silver Bromides.
FIG. 97.—Freezing-point Curves of Mixtures of Lead and Mercuric Bromides.

in monoclinic, hygroscopic prisms. The salt becomes anhydrous at 100°–140°, and is decomposed by water and alcohol. The solid is immediately attacked by hydrogen sulphide. The results of C. Sandonnini's examination of the f.p. of mixtures of *lead and mercuric bromides* are shown in Fig. 97. There is a simple eutectic at 232° with 5 molar per cent. of lead bromide. Solid mercuric bromide probably does not dissolve the lead bromide, nor does lead bromide dissolve mercuric bromide. J. Kendall and co-workers found evidence of **aluminium octobromoplumbite**, $2AlBr_3.PbBr_2$, m.p. 274°, on the f.p. curves of mixtures of lead and aluminium bromides. The two-liquid layers extend from 0·8 to 16·2 per cent. of $PbBr_2$ in equilibrium with the solid phase $2AlBr_3.PbBr_2$ at 210·4°. J. Barlot found that conductivity measurements and measurements of the magnetic susceptibility of mixtures of lead and thallous bromides showed the existence of the complex salts. A soln. of equimolar proportions of the component salts furnishes pale yellow acicular crystals of **thallous tribromoplumbite**, $TlPbBr_3$. The salt is decomposed by boiling with water. J. Nicklès obtained possibly *ammonium thallic bromoplumbite*, by adding ammonium tetrabromothallate to soln. of lead acetate.

The higher lead bromides.—K. Elbs and R. Nübling [8] could not make *lead tetrabromide*, $PbBr_4$, by the electrolysis of hydrobromic acid between lead electrodes, since the anode liquor decomposes, giving off bromine. A. Hutchinson and W. Pollard could not make it by the action of hydrobromic acid on lead tetracetate ; nor could H. Friedrich make it by treating lead dioxide with cold fuming hydrobromic acid, or lead bromide with hydrobromic acid and bromine. In the latter

case, there was evidence that a tetrabromide is formed; but J. M. Matthews, however, did not find evidence of the existence of the tetrabromide. H. L. Wells could not prepare alkali salts of definite *hydrobromoplumbic acids*, but A. Classen and B. Zahorsky obtained the quinoline salt $2C_9H_7N.HBr.PbBr_4$.

The lead oxybromides.—G. Sandonnini[9] examined the f.p. curve of mixtures of lead bromide and oxide, and the results are shown in Fig. 98. The curve descends from 368°, the m.p. of lead bromide, to the eutectic at 349° and 13 molar per cent.

FIG. 98.—Freezing-point Curves of Mixtures of Lead Bromide and Oxide.

of lead oxide; it rises to 475° where there is an unstable **lead oxydibromide,** Pb_2OBr_2; it then rises to 712°, a maximum corresponding with **lead dioxydibromide,** $Pb_3O_2Br_2$, and thereafter falls to the eutectic at 700° and 75 molar per cent. of lead oxide; it then rises and shows a break at 740° corresponding with the unstable **lead tetroxybromide,** $Pb_5O_4Br_2$; and finally it rises to 892°, the m.p. of lead oxide. Lead dioxydibromide was made by G. André, and he gave 3·03 Cals. for its heat of formation from anhydrous oxide and bromide; and 24·97 Cals. for its heat of soln. in hydrobromic acid sat. with lead bromide at 10°. R. Weinland and F. Paul made **dihydrated lead dioxydibromide,** $2PbO.PbBr_2.2H_2O$, or $[Pb_3(OH)_4]Br_2$, as a yellow microcrystalline powder, by the action of potassium bromide on lead tetrahydroxydichloride.

A. J. Balard obtained lead oxydibromide by igniting lead bromide in air until it ceased to emit white fumes; C. Löwig, by heating lead bromocarbonate until all the carbon dioxide was expelled; R. Brandes, by leaving lead bromide for some days in contact with a soln. of lead acetate and agitating the mixture from time to time—the filtrate contained free acetic acid; and G. André, by treating a soln. of lead bromide with potassium hydroxide, washing with cold water, and drying at 100°. The yellowish-white powder when completely dried at 140° becomes yellow. When heated, it becomes lemon-yellow, then reddish-yellow, and brownish-red; on cooling, the original colour is restored. When fused, it emits dense white fumes, and on cooling, it forms a yellowish-white translucent solid. G. André gave 2·00 Cals. for the heat of formation from the anhydrous oxide and bromide, and 12·00 Cals. for the heat of solution in hydrobromic acid sat. with lead bromide at 10°. D. Strömholm reported **monohydrated lead oxydibromide,** or **lead hydroxybromide,** $PbO.PbBr_2.H_2O$, or $Pb(OH)Br$, to be formed by adding aq. ammonia to a soln. of lead bromide until the mixture has an alkaline reaction; G. André could not crystallize the precipitate by heating it with water in a sealed tube at 250°. A. de Schulten called it *bromolaurionite*, and obtained it by heating a soln. of lead acetate and sodium bromide on a water-bath for 12 hrs.; and G. André, by heating the mother-liquor from $(NH_4)_6PbBr_8.H_2O$ with an excess of water in a sealed tube at 200°. R. Weinland and F. Paul called it *diol-diplumbous bromide*, and made it by the action of sodium bromide on a boiling soln. of lead hydroxychlorate. The white needle-like crystals prepared by A. de Schulten were rhombic bipyramids with the axial ratios $a : b : c = 0·7310 : 1 : 0·8043$; the sp. gr. was 6·721 at 19°. W. Biltz examined the mol. vol. The salt melts to a red liquid which, on cooling, becomes white; the water is expelled on melting. The salt is attacked by water less readily than the corresponding chloride. G. André reported needle-like crystals of **hemitrihydrated lead oxydibromide,** $PbO.PbBr_2.1\frac{1}{2}H_2O$, by heating $(NH_4)_6PbBr_8.H_2O$ with much water in a sealed tube at 200°; before the hemitrihydrate is formed, needle-like crystals of **trihydrated lead oxydibromide,** $PbO.PbBr_2.3H_2O$, are formed. The individuality of these two hydrates has not been established.

A number of oxybromides have been reported, but their individuality has not been established. E. A. Atkinson reported **lead oxydecabromide**, PbO.5PbBr$_2$, to be formed by passing hydrogen bromide over heated lead oxide for 4 hrs. D. Strömholm reported microscopic needles of **lead trioxydibromide**, 3PbO.PbBr$_2$.$\frac{3}{4}$H$_2$O, to be formed by adding sodium hydroxide to a soln. of lead bromide in the proportions OH : Br$=0\cdot001$: $0\cdot070N$. It was also made by G. André, who said that the heat of formation is $4\cdot20$ Cals., and its heat of soln. $37\cdot80$ Cals. in hydrobromic acid sat. with lead bromide at 10°. D. Strömholm also reported **lead hexoxydibromide**, 6PbO.PbBr$_2$.2H$_2$O, to be formed by the action of $0\cdot05N$-KBr on lead hydroxide ; and by the action of $0\cdot095N$-NaOH on the trioxydibromide. The salt is a white powder consisting of microscopic needles. The salt becomes yellow when heated. C. F. Cross and S. Sugiura found that *lead dioxyhenabromide*, Pb$_7$O$_2$Br$_{11}$, is formed as a pale brown or yellow crystalline mass by the action of bromine vapour on lead monoxide or dioxide ; *lead dioxyheptabromide*, Pb$_6$O$_2$Br$_7$, as a grey powder by the action of air charged with bromine on lead monoxide ; and *lead dioxypentabromide*, Pb$_5$O$_2$Br$_5$, by the action of air charged with bromine vap. on red-lead. H. L. Wells could not make *lead dihydroxypentabromide*, Pb$_2$(OH)$_2$Br$_5$, analogous with the corresponding iodide. M. Dennstedt and F. Hassler reported an oxybromide either with plumbous lead and an excess of bromine, or with plumbic lead, by the action of bromine or hydrobromic acid on lead dioxide.

land and F. Paul, *ib.*, **129**. 254, 1923 ; R. Brandes, *Liebig's Ann.*, **10**. 275, 1834 ; A. de Schulten, *Bull. Soc. Min.*, **20**. 188, 1897 ; C. Löwig, *Das Brom und seine chemischen Verhältnisse*, Heidelberg. 1829 ; H. L. Wells, *Amer. Journ. Science*, (4), **1**. 21, 1895.

§ 27. Lead Iodide

H. G. Denham[1] prepared **lead subiodide,** or **lead monoiodide,** PbI, by treating lead suboxide with the vapour of methyl iodide, free from oxygen, at 262°. The product is pale yellow, and it takes up oxygen slowly in air. In vacuo, at 300°, it decomposes into lead and normal lead iodide, and the colour darkens. Water dissolves 0·35 millieq. per litre. The subiodide is decomposed by hot sulphuric acid, hydrochloric, and acetic acids.

According to A. Frenzel,[2] **plumbous iodide,** or **lead iodide,** PbI$_2$, occurs in nature as an incrustation in the Cuatro Ties Mine, Sierra Gorda, Caracoles. As shown by H. Davy, and J. L. Gay Lussac, normal lead iodide is formed by the direct action of iodine on lead. G. Tammann observed the rate of formation of iodide films on lead confined with iodine over sulphuric-acid in a desiccator. H. Braune and F. Koref introduced finely divided lead into a soln. of iodine and potassium iodide. H. St. C. Deville said that lead is attacked by hydriodic acid, forming lead iodide which dissolves in the acid. J. A. Wilkinson obtained it by the electrolysis of a soln. of potassium iodide with a lead anode ; and H. S. Taylor, by the action of lead on silver iodide : Pb+2AgI=PbI$_2$+2Ag+11·55 Cals. W. F. O. de Coninck and L. Arzalier observed that lead iodide is formed when a mixture of lead oxide and ammonium iodide is strongly compressed. As J. L. Gay Lussac first showed, lead iodide is conveniently prepared by precipitation from a soln. of a lead salt by hydriodic acid, potassium iodide, or other soluble iodide. L. J. Girault used a similar process. T. Huraut used calcium iodide as the precipitant. P. Boullay treated a soln. of lead nitrate or acetate with potassium iodide ; and, added J. Inglis, and R. Brandes, if the lead acetate be in excess, some lead oxyiodide will be precipitated along with the lead iodide. O. Henry showed that if lead acetate be gradually added to a soln. of potassium iodide, the lead iodide is first precipitated as a yellow powder, and afterwards in yellow plates, and the liquid becomes acid. If a soln. of one part of potassium iodide in ten parts of water be mixed with a small proportion of acetic acid, the addition of lead acetate produces crystals of lead iodide at once, but if too much acetic acid be present, the lead iodide remains in soln., and separates only when the acid is neutralized by potassium hydroxide or ammonia. The more dil. the soln., the finer the crystals. E. Boudet said that in the use of potassium salts there is a loss owing to the formation of soluble potassium iodoplumbite. L. Hopff, and O. Lehmann recommended adding a dil. soln. of lead acetate to a soln. of one part of potassium iodide in 10 parts of water, with sufficient iodine to give the liquid a yellow colour. The lead iodide can be purified by crystallization from its soln. in boiling water. A. A. Noyes and E. H. Woodworth purified the iodide by precipitation from its potassium iodide soln. by an excess of water ; and crystallization from its hot aq. soln. The rhythmic precipitation of lead iodide, forming yellow *Liesegang's rings*, is obtained by placing a crystal of lead nitrate in agar-agar containing one per cent. of potassium iodide. This subject has been discussed by R. E. Liesegang, K. Notboom, E. Küster, and E. Hatschek. H. H. Holmes obtained them by adding an iodide to a soln. of a lead salt in gelatinous silica. V. Lehner obtained lead iodide by the action of hydriodic acid on lead sulphide ; R. Benedikt, by the action of that acid on lead sulphate ; and G. Campani, by shaking lead sulphate or phosphate with an aq. soln. of potassium iodide. A. Findlay added a mixture of sodium sulphate and iodide to a soln. of a lead salt, and found the equilibrium constant in the reaction PbSO$_4$+2NaI⇌PbI$_2$+Na$_2$SO$_4$ to be 0·25–0·30 at 25°. A. C. Becquerel obtained octahedral crystals of lead iodide by separating soln. of potassium iodide and lead nitrate by a porous plug, and

electrically connecting the two soln. by a lead wire. V. Thomas found that lead bromide is rapidly converted into the iodide by hydriodic acid. Natural lead compounds are converted into lead iodide by heating a mixture of the mineral with sulphur and potassium iodide (F. von Kobell, and H. B. Cornwall), or with a mixture of silver iodide and carbon (P. Casamajor). According to P. Fischer, lead iodide is formed when a lead plate and a plate of platinum covered with iodine are dipped in a 5 per cent. soln. of potassium nitrate, and connected by a copper wire.

E. H. Büchner and J. Kalff obtained **colloidal lead iodide** by dropping the precipitating agent into a soln. of lead salt. W. Reinders used gelatinous soln. W. Leuze treated 5 c.c. of a 5 per cent. soln. of sodium protalbinate with 15 grms. of a 20 per cent. soln. of lead acetate, and dissolved the lead salt in sodium hydroxide, and treated it with potassium iodide. After dialysis, lead iodide sol was obtained, which was reddish-brown in transmitted light, and greenish-yellow in reflected light. The filtered liquid can be evaporated to dryness. The product furnishes a sol on treatment with water. H. Zocher examined the properties of the sol; and H. Lachs, the scintillation effects in the ultramicroscope, and found that the scintillation effect diminishes with long standing owing to the development of crystals.

The physical properties of lead iodide.—According to P. F. G. Boullay,[3] M. Denot, and J. Inglis, lead iodide appears as an orange-yellow powder, or as golden-yellow, flexible, six-sided, plates or prisms. The **crystals,** according to A. E. Nordenskjöld, belong to the hexagonal system having the axial ratio $a : c = 1 : 1.2945$. The crystals are isomorphous with those of cadmium and mercuric iodides. A. des Cloizeaux found them to be uniaxial and negative. L. W. Fisher and F. L. Simon studied the effects of acidity and concentration of colloidal soln. on the growing crystals; and M. Volmer, growing crystals of lead iodide, in a mixed soln. of lead nitrate and potassium iodide, by means of the **X-radiograms**; and P. Terpstra and H. G. Westenbrink found that the unit cell of the hexagonal parallelopiped $a = 4.59$ A., $c = 6.78$ A.; and each cell contains one mol of PbI_2. W. Biltz studied what he called the lattice-energy of the crystals. G. F. Rodwell found the coeff. of expansion indicated that lead iodide has a transition point between 253° and 265°; but F. Matthes's, and K. Mönkemeyer's thermal observations lend no support to the view that lead iodide is dimorphous. A. Findlay said that the velocity of crystallization is greater than that of lead sulphate. The **specific gravity** given by P. F. G. Boullay is 6.11; by C. J. B. Karsten, 6.0212; by E. Filhol, 6.384; by R. Schiff, 6.07; by H. G. F. Schröder, 6.207; and G. F. Rodwell, 6.12, and in the molten state at 383°, 5.6247. F. A. Henglein studied the mol. vol. of lead iodide. D. M. Lichty found the sp. gr. of soln. of lead iodide:

	0°	15°	25°	35°	45°	55°	65°	80°	95°
Sp gr...	1.00056	0.99983	0.99798	0.99508	0.99153	0.98723	0.98268	0.97452	0.96709

M. L. Dundon gave 6.16 for the sp. gr.; 74.8 for the mol. vol.; and 130 ergs for the surface energy of the solid. S. Motylewsky found the drop weight of the molten iodide to be 106, when that of water is 100. G. F. Rodwell found the vol. of solid lead iodide at different temp. to be:

	0°	205°	253°	265°	383° (solid)	383° (liquid)
Volume .	1.000000	1.015608	1.019595	1.027248	1.048488	1.078080

The cubical coeff. of **thermal expansion** is 0.0_47614 between 0° and 205°; 0.0_48317 from 205° to 253°; 0.0_36378 from 253° to 265°. H. Fizeau gave 0.0_33598 for the linear coeff. of expansion. H. V. Regnault gave 0.04267 for the **specific heat** between 14° and 110°; O. Ehrhardt, 0.04303, between 160° and 315°. F. Koref gave 0.0407 between −190.8° and −80.8°; and W. Nernst and F. Schwers gave the following results below −177.4°, and A. Magnus the following values above that temp.:

	−250.7°	−234.8°	−210.9°	−177.4°	100°	200°	250°
Sp. ht. .	0.0153	0.0233	0.0324	0.0375	0.0427	0.0438	0.0504
Mol. ht. .	7.05	10.74	14.8	17.3	19.70	20.18	20.75

H. Schottky gave 19·49 for the mol. ht. at 18° ; and H. Burschall, 17·7 between
−75° and −183°. According to A. Heiduschka, and J. H. Kastle, when cooled
in liquid air, lead iodide becomes pale yellow ; and when heated, O. Henry, and
R. Brandes noted that its colour deepens, becoming reddish-yellow, brick-red, and
finally dark reddish-brown. J. Rosenthal, and G. F. Rodwell noted that before
melting lead iodide becomes plastic. As J. L. Gay Lussac showed, lead iodide fuses
when strongly heated, and G. F. Rodwell showed that it may be fused out of contact
with air with little appreciable loss ;. in air, rapid decomposition ensues, and, as in-
dicated by V. Czepinsky, iodine is evolved, and an oxyiodide is formed. R. Brande's
also observed this decomposition, and A. Benrath said that a little iodine is given
off above the m.p. During the cooling of the molten iodide, G. F. Rodwell, and
C. Tubandt and G. Eggert noted the production of harsh crackling noises recalling
the cry of tin. The yellow cold mass, according to V. Czepinsky, may contain some
free iodine or possibly lead tetraiodide. T. Carnelley and co-workers gave 350°–383°
for the **melting point** of lead iodide ; F. Matthes, and K. Mönkemeyer, 358° ;
O. Ehrhardt, 375° ; W. Ramsay and N. Eumorfopoulos, 373° ; C. Sandonnini, 400° ;
and C. Tubandt and G. Eggert, 402°. The **heat of fusion** given by O. Ehrhardt
is 11·5 cals. per gram, or 5·28 Cals. per mol ; V. Czepinsky gave 5·278 Cals. per mol ;
and G. D. Roos, 210 cals. per at. vol. According to H. Crompton, the heat of fusion,
L, the sp. gr. D, and the absolute temp. T, are related as $LD=0·11T$. Lead iodide
volatilizes at a strong red heat ; and G. F. Rodwell, and M. Schtscherbakoff sublimed
this salt unchanged by heating it in a current of carbon dioxide. T. Carnelley and
W. C. Williams gave 861°–964° for the **boiling point.** W. Braunbek discussed
some relations between the sp. ht., m.p., and latent heat. K. Jellinek and
R. Uloth calculated values for the partial press. of the iodine in lead iodide at
different temp. C. Zengelis considered that he had proved lead iodide can
volatilize at ordinary temp. J. Thomsen gave 39·8 Cals. for the **heat of formation,**
from solid iodine, and 53·4 Cals. from the gas. M. Berthelot gave 39·6 Cals. M. de
K. Thompson gave 39·8 Cals. ; H. Braune and F. Koref, 41·85 Cals. ; P. Günther,
42·4 Cals. ; V. Czepinsky gave 53–96·4 Cals. at 405°–700° ; and G. D. Roos, 86 cals.
per gram referred to the at. vol. 1580. M. de K. Thompson gave 41·7–42·3 Cals.
for the **free energy** of formation.

The **spectrum** of lead iodide was shown by E. Wiedemann [4] to be continuous,
and J. A. Wilkinson found that it exhibits a green **fluorescence.** B. A. Dima
observed that, with ultra-violet light, the **photoelectric effect** is greater than with
the chloride or bromide. W. W. Coblentz and J. F. Eckford said that lead iodide is
the only lead halide which is photoelectrically sensitive.

M. Faraday electrolyzed molten lead iodide and noted the formation of a per-
iodide. W. Hampe found that the fused and pulverulent iodide has a measurable
electrical conductivity, and as the temp. rises the conductivity becomes more
electrolytic and less metallic. J. Rosenthal measured the conductivity of the
pulverulent iodide pressed into rods. G. Tammann and H. Bredmeier measured the
conductivity of thin films of the iodide. C. Tubandt and S. Eggert found that
below 344° the electrical resistance is very high, and it then conducts electro-
lytically. According to A. Benrath, and L. Graetz, by repeated heating, the con-
ductivity of the solid iodide is augmented. L. Graetz found that if k represents
the conductivity, mercury unity :

	290°	300°	320°	340°	360°	380°	400°
k	0·0₇6	0·0₄450	0·0₄1000	0·0₄2100	0·0₄3000	0·0₄4000	0·0₄4600

The conductivity increases with pressure, thus, with a press. of 4000 atm., the
resistance falls from about 2000×10^8 ohms to about 200×10^8 ohms. F. Quincke,
A. Gockel, and V. Czepinsky studied the polarization of the solid and molten
iodide ; and C. C. Garard, A. Helfenstein, R. Lorenz, G. Auerbach, M. Schtscher-
bakoff, and V. Czepinsky, the electrolysis of the molten iodide. W. Böttger gave
0·003384 for the sp. conductivity of the aq. soln. sat. at 20·10° when the degree of

ionization was 9·7 per cent. H. G. Denham, C. L. von Ende, and G. N. Lewis and T. B. Brighton also measured the conductivity of aq. soln. C. L. von Ende said that the salt is completely ionized in water, and H. Crompton calculated the degree of ionization. A. Klein measured the e.m.f. of the cell Pb | PbCl$_2$ | 0·01N-KCl, 0·01N-KI | PbI$_2$ | Pb. J. Thiele measured the thermoelectric force of the molten lead halides against metals. A. Lenert gave 2·35 for the **dielectric constant,** and after melting and freezing, 62·47. L. Graetz and O. Fromm gave 113 for $\lambda=101$; 147·7 for $\lambda=130·4$; and 172·8 for $\lambda=180$. L. Ebert studied the dielectric polarization of the lead salts. S. Meyer found the **magnetic susceptibility** to be $-0·623 \times 10^{-6}$, and the mol. magnetism, $-0·118 \times 10^{-6}$.

The chemical properties of lead iodide.—Z. Roussin,[5] and W. Schmid found that **light** does not alter the dry iodide, but the moist iodide, particularly in air and sunlight, slowly forms lead carbonate, lead dioxide, and iodine. N. R. Dhar and A. C. Chatterji found rhythmic rings of lead iodide formed in silica gel are not affected by light. The action of **heat** has been examined by R. Brandes, A. Benrath, and M. Schtscherbakoff—*vide supra*. A. Jouniaux found that **hydrogen** does not reduce the iodide at a red heat. The reaction was studied by F. de Carli; and the equilibrium conditions $PbI_2+H_2 \rightleftharpoons Pb+2HI$, by K. Jellinek and R. Uloth. The constant p_{HI}/p_{H_2} is nearly $2·6 \times 10^{-2}$.

W. D. Bancroft[6] showed that lead iodide does not take up water of crystallization as indicated by J. M. Talmadge and previously by himself; and therefore the salt does not effloresce. No measurable rise of temp. could be detected by M. Berthelot when lead iodide was shaken with **water.** According to M. Denot, 100 c.c. of cold water dissolve 0·081 grm. of the salt, and boiling water, 0·515 grm., forming a colourless soln. J. B. Berthemot found 100 c.c. of water dissolve 0·535 grm. of the salt ; and J. L. Lassaigne, 0·17 grm. at 20° ; 0·20 at 27° ; and 0·39 at 100°. D. M. Lichty found for the solubility, S, in grams of salt per 100 grms. of water :

	0°	15°	25°	35°	45°	55°	65°	80°	95°	100°
S	0·0442	0·0613	0·0764	0·1042	0·1453	0·1755	0·2183	0·3023	0·3960	0·4360

M. de K. Thompson gave for the solubility 0·0423 grm.; and W. Böttger, 0·047 grm. per litre at 20·10°, and H. G. Denham said that the result is low because of the action of air on the soln. during the solubility determination. C. L. von Ende gave 1·58 milligram mols per litre at 25° ; and G. N. Lewis and T. B. Brighton, 1·64 milligram mols per litre at 25° ; and they gave for the **solubility product** $11·9 \times 10^{-9}$. M. L. Dundon found the solubility increased about 2 per cent. with particles 0·4μ diameter. J. B. Caventou found that the salt does not dissolve completely in water owing to the formation of a little oxyiodide, and in boiling water the smell of iodine is perceptible. P. F. G. Boullay said that the pure iodide can be obtained by crystallization from hot water, and J. White obtained no oxyiodide under these conditions, but M. Schtscherbakoff always found that some oxyiodide is formed. H. Braune and F. Koref said that lead iodide is soluble in a soln. of **sodium hydroxide,** and M. Schtscherbakoff observed no decomposition by dissolving the iodide in a 25 per cent. soln. of **potassium hydroxide.** V. Zotier examined the catalytic effect of lead iodide on **hydrogen dioxide.**

H. Moissan[7] showed that in the cold **fluorine** converts lead iodide into the fluoride. According to R. Brandes, **chlorine** transforms heated lead iodide into the chloride, and P. Hautefeuille observed that **hydrogen chloride** forms lead chloride when it acts on the heated iodide, while V. Thomas found boiling **hydrochloric acid** also produces lead chloride. P. F. G. Boullay, and R. H. Brett found lead iodide to be slightly soluble in cold and copiously soluble in hot soln. of **ammonium chloride,** forming, according to C. Völckel, H. Maisch, and V. Thomas, a complex chloroiodide. A. Mosnier, and E. Field found double salts are also formed with **potassium chloride ;** and V. Thomas showed that a hot soln. of **lead chloride** and iodide, on cooling,

deposits crystals of the chloride, then the iodide, and then a complex salt. B. Thorp said that lead iodide is soluble in **hydrobromic acid,** and V. Thomas found the iodide is very slowly attacked so that when the boiling soln. is cooled, crystals of a bromo-iodide are deposited. A. Mosnier found that **ammonium bromide** soln. form complex bromoiodides ; and A. Mosnier, and V. Thomas obtained complex bromoiodides by the solvent action of a soln. of **potassium bromide.** According to P. Fedotieff, a sat. aq. soln. of **iodine** dissolves 0·00216 mol of lead iodide per litre at 20°. V. Lenher found the salt to be very sparingly soluble in a dil. soln. of **hydriodic acid,** but readily soluble in a conc. soln. The action of hydriodic acid was also examined by F. Parmentier, and A. Ditte. E. Field, A. Mosnier, and A. Ditte showed that when treated with a soln. of **ammonium iodide,** complex salts are formed. A. Mosnier showed that **ethyl iodide** precipitates lead iodide from its aq. soln., and that lead iodide is soluble in a soln. of **triphenylammonium iodide.** According to M. Berthelot, a few drops of a soln. of a mol of hydriodic acid in 2 litres and an aq. soln. of potassium iodide precipitate lead iodide from a soln. containing 0·5 grm. per litre. J. B. Berthemot found that lead iodide is soluble in soln. of potassium, **sodium, barium, strontium, calcium, or magnesium iodide,** and A. Mosnier found that complex salts are formed with these and many other iodides. The effect of **potassium iodide** on soln. of lead iodide was studied by R. W. Balcom, A. Mosnier, A. A. Noyes and E. H. Woodworth, C. H. Herty, and A. Ditte. A. Bogorodsky obtained a complex salt with **lithium iodide.** F. D. Chattaway found that when lead iodide is treated with **nitrogen trihydrotriiodide,** $N_2H_3I_3$, ammonia, and lead hypoiodite are produced.

K. A. Hofmann and V. Wölfl [8] found that **ammonium sulphide** transforms lead iodide into a sulphoiodide. According to A. Michaelis and G. Koethe, **sulphur dioxide** acts on warm lead iodide, forming lead sulphite and hydrogen iodide ; and with **sodium sulphite,** lead sulphite and sodium iodide are formed. G. C. Wittstein found that a soln. of **ammonium sulphate** whitens lead iodide without dissolution ; A. Ditte, that a soln. of **magnesium sulphate** forms lead sulphate and magnesium iodide ; and A. Naumann, that **silver sulphate** forms lead sulphate and silver iodide. C. G. Stoffella found that the exothermic reaction with **zinc sulphate :** $PbI_2 + ZnSO_4 \rightleftharpoons ZnI_2 + PbSO_4$ is complete from left to right only in dil. equimolar soln. at 100° owing to the increase in the solubility of the lead iodide with temp. The reaction is incomplete in a sat. soln. at 100°, or in very dil. soln. at 15°. F. Field showed that lead iodide is very soluble in an aq. soln. of **sodium thiosulphate.**

According to G. C. Wittstein,[9] aq. **ammonia** slowly whitens lead iodide without dissolution, forming, according to M. Labouré, a white product which can be dried in air without decomposition, but which, when heated, decomposes into ammonia and lead iodide. E. C. Franklin and C. A. Kraus found lead iodide to be readily soluble in liquid ammonia ; K. Friedrichs said insoluble. C. A. Kraus and H. F. Kurtz studied the reduction of lead iodide by sodium in liquid ammonia. According to W. Biltz, lead iodide doubles its vol. under liquid ammonia at −75°, forming white **lead octamminoiodide,** $PbI_2.8NH_3$, which has a heat of formation of 7·8 Cals., and a dissociation press. of 6 mm. at −78·5° ; 64·8 mm. at −56·5° ; 100 mm. at −51·5° ; and 423 mm. at −34°. Between −78·5° and 0°, the octammine forms pale yellow **lead pentamminoiodide,** $PbI_2.5NH_3$, with a heat of dissociation of 9·7 Cals. ; and a dissociation press. of 9·8 mm. at −30·9° ; 100 mm. at −3° ; 122 mm. at 16·5° ; 387·6 mm. at 16·5° ; and 403 mm. at 17·1°. W. Biltz could not make **lead tetramminoiodide,** $PbI_2.4NH_3$, but F. Ephraim said that it appears as a white substance when ammonia gas acts on solid lead iodide at room temp. He gave 10·69 Cals. for the heat of dissociation, and a dissociation press. of 760 mm. at 32°. C. F. Rammelsberg made **lead diamminoiodide,** $PbI_2.2NH_3$, as a result of exposing lead iodide to the action of ammonia gas. F. Ephraim obtained it from the tetrammine ; and W. Biltz, from the octammine at 0°. C. F. Rammelsberg said that it loses all the combined ammonia when exposed to air ; under water it remains white, but decom-

poses into soluble ammonium iodide and lead oxide. F. Ephraim gave 12·75 Cals. for the heat of dissociation, and W. Biltz, 11·3 Cals. According to the latter, the vap. press. is 13·7 mm. at 16·5°; 100 mm. at 33°; 111·7 mm. at 34·45°; and 317 mm. at 55·9°; while F. Ephraim gave 760 mm. at 85°. F. Ephraim made **lead monamminoiodide,** $PbI_2.NH_3$, as a pale yellow powder, by heating the tetrammine, and W. Biltz, by heating the octammine to 60°. The former gave 13·81 Cals. for the heat of dissociation, and the latter 13·2 Cals. The dissociation press. found by W. Biltz were 11 mm. at 55·9°; 71 mm. at 80·2°; 100 mm. at 88°; and 302·2 mm. at 111°; while F. Ephraim gave 760 mm. at 112°. W. Biltz made **lead hemiamminoiodide,** $PbI_2.\frac{1}{2}NH_3$, by heating the monammine between 80° and 115°. The heat of dissociation is 14·4 Cals.; and the dissociation press. at 110·6° is 48·3 mm.; at 114·9°, 63·9 mm.; at 126°, 100 mm.; and at 156·6°, 361·5 mm. C. L. Clark studied the secondary valencies of these ammines.

E. C. Franklin [10] found that **potassium amide** reacts with lead iodide, forming a complex product, $Pb_2N_2H_3I.PbNH$. According to T. W. B. Welsh and H. J. Broderson, lead iodide is dissolved by anhydrous **hydrazine,** 0·02 grm. per c.c. —with decomposition. V. Thomas found that **nitrogen peroxide** decomposes lead iodide at ordinary temp. by an endothermal reaction (−10 Cals.), forming lead oxide, and evolving iodine. R. Benedikt and L. Gans found lead iodide to be easily soluble in dil. **nitric acid;** and C. L. von Ende found the solubility in $0·001N$-HNO_3 to be 38·87 millimols per litre of nitric acid at 25·2°; in $0·01N$-HNO_3, 39·06; in $0·051N$-HNO_3, 39·45; and in $0·04N$-KNO_3 plus $0·01N$-HNO_3, 39·45. G. C. Wittstein found a dil. soln. of **ammonium nitrate** slowly turns lead iodide white, without dissolution. F. W. O. de Coninck said that boiling soln. of **potassium or sodium nitrate** dissolves considerable quantities of lead iodide, and deposits it again as golden yellow plates on cooling. P. Fedotieff found that **copper nitrate** transforms lead iodide into lead nitrate, cuprous iodide, and iodine; the reaction is reversible. A. Naumann said that **silver nitrate** has no action; but C. Stürenberg showed that a boiling soln. of silver nitrate, incompletely saturated with lead iodide, furnishes the complex salt, $Pb(NO_3)_2.8AgNO_3.4AgI$, and with a more prolonged action, $Pb(NO_3)_2.2AgNO_3.2AgI$. According to A. A. Noyes and E. H. Woodworth, **lead nitrate** in small proportions reduces the solubility of lead iodide in accord with the ionic hypothesis.

A. Mosnier found that phosphorous iodide reacts with lead iodide, forming **lead phosphorous enneaiodide,** $3PbI_2.PI_3.12H_2O$, in yellow needles. It is decomposed by water and alcohol, and is dehydrated at 45°. The heat of formation is $(3PbI_2,PI_3)=4·7$ Cals.; $(3PbI_2,PI_3.12H_2O)=25$ Cals. for liquid water and 8 Cals. for solid water. The heat of soln. in 40 parts of water at 15° is 2·5 Cals. for the dodecahydrate, and 27·6 Cals. for the anhydrous salt. Lead iodide and arsenious iodide form **lead arsenious enneaiodide,** $3PbI_2.AsI_3.12H_2O$, in fine needles, and this behaves like the phosphorous compound. The heat of formation is $(3PbI_2,AsI_3)=27·1$ Cals., and $(3PbI_2,PI_3,12H_2O)=20·7$ Cals. for liquid water and 3·6 Cals. for solid water. The heat of soln. in 40 parts of water at 15° is −8·2 Cals. for the dodecahydrate and 12·5 Cals. for the anhydrous salt. Similarly with **lead antimonous enneaiodide,** $3PbI_2.SbI_3.12H_2O$. The heat of formation is $(3PbI_2,SbI_3)=21·4$ Cals., and $(3PbI_2,SbI_3,12H_2O)=29·1$ Cals. for liquid water and 12 Cals. for solid water. The heat of soln. is −8·5 Cals. for the dodecahydrate, and 20·6 Cals. for the anhydrous salt. Likewise with **lead bismuth enneaiodide,** $3PbI_2.BiI_3.12H_2O$, the heat of formation is $(3PbI_2,BiI_3)=13·8$ Cals., and $(3PbI_2,BiI_3,12H_2O)=33·8$ Cals. for liquid water, and 16·7 Cals. for solid water. The heat of soln. in 40 parts of water at 15° is −17·2 Cals. for the dodecahydrate, and 16·6 Cals. for the anhydrous salt.

As indicated above, lead iodide can be distilled unchanged in a current of **carbon dioxide,** but an aq. soln. of the iodide, when exposed to air, was found by H. G. Denham [11] to form lead carbonate. J. B. Berthemot said that when boiled with water and **sodium, barium, strontium, calcium,**

or **magnesium carbonate,** lead iodide yields lead carbonate and a soluble iodide ; the reaction is slowest with magnesium carbonate. C. F. Schlagdenhauffen studied what he called *la limite des réactions des carbonates alcalins.* A. Ditte found that **potassium hydrocarbonate** produces lead carbonate, and a complex salt $K_2PbI_4.4H_2O$ is formed. H. Arctowsky found that lead iodide is insoluble in **carbon disulphide ;** and A. P. N. Franchimont, insoluble in **benzene.** O. Henry said that lead iodide is sparingly soluble in **alcohol ;** and S. von Laszczynsky showed that **amyl alcohol** dissolves 0·2 grm. per litre at 133·5°. W. Eidmann, and A. Naumann said that lead iodide is insoluble in **acetone,** but S. von Laszczynsky found 0·2 grm. per litre is dissolved at 59°. A. Vogel found that when repeatedly boiled with **ether,** iodine is extracted and an oxyiodide is formed. O. Aschan reported that 100 grms. of formic acid dissolve 0·25 grm. of lead iodide at 19·8° ; and M. Denot said that, contrary to O. Henry, lead iodide is not more soluble in **acetic acid** than in water. D. Tommasi showed that lead iodide dissolves in a soln. of **potassium acetate,** forming the complex salt $KC_2H_3O_2.2PbI.C_2H_4O_2$; 100 c.c. of a conc. soln. of **sodium acetate** dissolve 2 grms. of lead iodide in the cold, and 4 grms. in the boiling liquid ; in the presence of 0·4 c.c. of acetic conc. acid, 12 grms. are dissolved, but greater proportions of the acid do not augment the solubility. 100 c.c. of a soln. of **lithium acetate** dissolve 18 grms. of lead iodide ; and 100 c.c. of **ammonium acetate,** 160 grms. A soln. of **cupric acetate** reacts by double decomposition—100 c.c. of a hot soln. of cupric acetate dissolving 12 grms. of lead iodide—some iodine escapes, and cuprous oxide is precipitated. 100 c.c. of a soln. of **barium acetate** dissolve 20 grms. of lead iodide ; **calcium acetate,** 23 grms. ; **magnesium acetate,** 10 grms. ; and **zinc acetate,** a trace. A boiling soln. of 10 grms. of **mercurous acetate** in 40 c.c. of water dissolves 7 grms. of lead iodide and precipitates red mercuric iodide. 100 c.c. of **aluminium acetate** dissolve a trace of lead iodide ; of **chromium acetate,** 20 grms.; of **uranium acetate,** a trace; **manganese acetate,** a quantity; **iron acetate,** 10 grms. ; and **cobalt acetate,** 5 grms. J. White noted that complex acetoiodides are formed with ammonium, potassium, and sodium acetates ; with a soln. of **lead acetate,** the oxyiodide, Pb(OH)I, is formed ; with alcoholic soln. of ammonium, potassium, and sodium acetates, and also in hot alcoholic acetic acid soln., unstable complex acetoiodides are formed. A. Naumann found lead iodide is sparingly soluble in **methyl acetate,** and insoluble in **ethyl acetate.** H. Braune and F. Koref found lead iodide is soluble in an amyl alcohol soln. of **sodium tartrate;** J. Spiller said that the iodide is not precipitated in the presence of **sodium citrate;** and G. C. Wittstein found that **ammonium succinate** colours lead iodide white, without dissolution. F. L. Shinn said that lead iodide is insoluble in **ethylamine,** probably forming a compound. H. Mandal, and S. von Laszczynsky said that at 13°, **aniline** dissolves 5 grms. of lead iodide per litre at 13° ; and 11 grms. at 184°. L. Pincussohn, and G. W. Heise found that lead iodide dissolves sparingly in **pyridine,** and complex salts are formed ; W. Goebbels, sparingly in **quinoline ;** A. Naumann, sparingly in **benzonitrile ;** J. H. Matthews, insoluble in **allyl sulphocyanide ;** and J. W. Retgers, nearly insoluble in **methylene iodide.** According to B. Köhnlein, the iodine of lead iodide is partially replaced by chlorine when the salt is treated with **isobutyl chloride ;** or, according to R. Brix, with **benzyl chloride.** M. Wildermann found the iodine partly replaced by bromine in the presence of **bromohydrocarbons** containing two or more halogen atoms, and two or more carbon atoms. B. Thorp said lead iodide dissolves in **thiocyanic acid** without forming a complex. W. Eisner found that soln. of lead acetate and potassium iodide which give a precipitate in aq. soln. fail to do so in the presence of **serum,** and form a colloidal soln. Similar results are obtained with lead acetate and sodium phosphate or carbonate in the presence of **bile, lecithin** soln., or serum. Previously precipitated lead iodide passes into colloidal soln. in the presence of excess of serum, and lead salts of low solubility in water, when present in a colloidal soln. in serum, are not precipitated by addition of potassium iodide. The rate of dialysis of lead salts in the presence of serum is increased by addition of potassium iodide, and the

latter salt, together with the chloride, inhibits the toxic action of lead on fermenting yeast. L. Kahlenberg and W. J. Trautmann studied the reduction of lead iodide when heated with powdered **silicon**. J. B. Berthemot found that when lead iodide is boiled with water in the presence of **iron**, lead and ferrous iodides are formed ; the decomposition occurs more readily with **zinc** in place of iron.

The higher iodides of lead.—According to M. Faraday,[12] when molten lead iodide is electrolyzed with carbon or platinum electrodes, the electrochemical eq. is only about two-thirds the value which would be furnished by the iodide PbI_2. He said :

I attribute this to the formation of a periodide at the positive electrode, which, dissolving in the mass of liquid iodide, came in contact with the lead evolved at the negative electrode, and dissolved part of it, becoming itself again protiodide. Such a periodide does exist ; and it is rarely that the iodide of lead formed by precipitation, and well-washed, can be fused without evolving much iodine, from the presence of this percompound ; nor does crystallization from its hot aq. soln. free it from this substance. Even when a little of the protiodide and iodine are merely rubbed together in a mortar, a portion of the periodide is formed. And although it is decomposed by being fused and heated to dull redness for a few minutes, and the whole reduced to the ordinary iodide, yet that is not at all opposed to the possibility, that a little of that which is formed in great excess of iodine at the *anode*, should be carried by the rapid currents in the liquid into contact with the *cathode*.

Related observations were made by G. Auerbach, and A. Helfenstein. V. Czepinsky also assumed that lead iodide which had been melted and cooled contained **lead tetraiodide,** PbI_4, or **plumbic iodide.** K. Elbs and R. Nübling could not prepare it like the corresponding chloride by the electrolysis of hydriodic acid of sp. gr. 1·42, between lead electrodes ; but when the anode liquid is treated with water, lead iodide is precipitated, and when treated with pyridine iodide, $C_5H_5N.HI$, a greyish-green precipitate approximating $(C_5H_5NH)_2PbI_6$ is formed. H. Friedrich obtained indications of the presence of lead tetraiodide in the products of the action of potassium iodide on lead tetrachloride. B. Piffard said that a dark-coloured precipitate of lead tetraiodide is produced when lead acetate is treated with a soln. of potassium iodide containing dissolved iodine, but E. Erlenmeyer said that the product is a mixture of lead dioxide and diiodide. A. Hutchinson and W. Pollard failed to make the tetraiodide by the action of hydriodic acid on lead tetracetate. C. F. Schlagdenhauffen treated a lead salt dissolved in a soln. of potassium iodide with sodium hypochlorite and obtained a blue precipitate in the presence of an excess of sodium carbonate, and a brown precipitate if an excess be not present. The product is probably an oxyiodide with adsorbed iodine. **Alkali iodoplumbates** have not been made. H. L. Wells reported a salt with the composition $K_3Pb_2I_8.4H_2O$, obtained by boiling a soln. of potassium iodide, lead iodide, and iodine. In arriving at this formula, H. L. Wells assumed that the material analyzed " was contaminated with 16·5 per cent. of potassium iodide, and that an excess of water was present." A. N. Meldrum prepared a similar product which was homogeneous under the microscope, and had the composition $K_9Pb_4I_{19}.10H_2O$. K. Elbs and R. Nübling obtained evidence of a *pyridine lead tetraiodide*, and of *quinoline lead tetraiodide*, $(C_9H_7NH)_2PbI_4$; and A. Classen and B. Zahorsky, of $(C_9H_7N)_2.HI.PbI_4$.

According to J. L. Lassaigne,[13] when a mixture of lead filings and hydriodic acid is exposed to air, white crystals are formed which dissolve when the acid is boiled, and are redeposited on cooling. A hot soln. of lead iodide in hydriodic acid deposits the same crystals on cooling. When the white crystals are kept in vacuo, or in dry air, hydrogen iodide is given off, and lead iodide remains ; a similar result is obtained when the crystals are heated. Cold water extracts the hydriodic acid from the crystals, with only a small quantity of lead iodide ; boiling water dissolves the salt completely, and on cooling deposits lead iodide, retaining the hydriodic acid in soln. The crystals are considered to be a **lead hydriodide** of an unknown composition. According to M. Berthelot, when lead iodide, water, and hydriodic acid are stirred together, yellow crystals of lead hydroiodide, $PbI_2.HI.5H_2O$, are formed.

They are decomposed by light, and by exposure to air ; by heat ; and by mixing with water.

Mixed salts.—H. Fonzes-Diacon,[14] and E. Field could not prepare a lead fluoiodide, but C. Sandonnini investigated the thermal diagram of mixtures of lead fluoride and iodide, and found it to be different from those obtained with the corresponding chloride and bromide. The results are shown in Fig. 99. There is a eutectic at 383° corresponding with 10 molar per cent. of fluoride ; the curve then rises to 432° and 20 molar per cent. of fluoride, corresponding with the existence of **lead fluoiodide,** PbFI, or $PbF_2.PbI_2$; thereafter the curve rises to 573° when there is a pause with 76·5 molar per cent. of fluoride, corresponding with **lead octofluodiiodide,** $PbI_2.4PbF_2$. The curve then rises to the m.p. of the fluoride.

F. Matthes [15] found that binary mixtures of lead chloride and iodide have only a limited miscibility when melted ; but solid soln. extend from 0 to 100 per cent. of lead chloride. The f.p. curve, Fig. 100, has a curved eutectic at 306° and 77 molar per cent. of the iodide. There is no sign of chemical combination ; nevertheless, V. Thomas, M. Labouré, and B. Dietzell claimed to have made **lead chloroiodide,** PbICl, by cooling a boiling soln. of lead iodide in hydrochloric acid ; V. Thomas, and E. Field, from a boiling soln. of lead iodide and ammonium chloride, or from a hot soln. of lead chloride in potassium iodide ; and A. Engelhardt, by cooling soln. of lead iodide in hot soln. of various metal chlorides—Na, Ba, Ca, Mn, Co, Ni, Zn, Sn, Al, Cr—C. H. Herty used boiling soln. of lead iodide in soln. of potassium or ammonium chloride. When this was dried at 100°, E. Field considered the product to be the *hemihydrate;* and H. Fonzes-Diacon supposed that with very slow cooling, sulphur-yellow monoclinic needles of the *dihydrate* are formed, and that when heated, the hydrates are dehydrated. The anhydrous salt furnishes sulphur-yellow prisms which are sensitive to light ; decomposed by water, attacked by nitrogen peroxide ; partially oxidized to the oxychloride, Pb_2OCl_2, with the expulsion of iodine in the cold, and all the iodine is expelled at the sublimation temp. ; not attacked by boiling hydrochloric acid ; and converted by bromine into PbClBr. A. B. Poggiale regarded the yellow needles obtained by cooling a hot soln. of lead iodide and ammonium chloride, or lead chloride and sodium iodide as *lead tetrachlorodiiodide,* $2PbCl_2.PbI_2$; and V. Thomas, the pale green crystals obtained by cooling a boiling soln. of lead chloride and ammonium or potassium iodide as *lead hexachlorodiiodide,* $3PbCl_2.PbI_2$, or Pb_2Cl_3I ; on the contrary, C. H. Herty regarded these salts as isomorphous mixtures of the component halides. S. Glasstone observed that the presence of sodium chloride increases the solubility of lead iodide ; and L. J. Burrage found that when concentrations are expressed in grams per 100 c.c. of soln. :

FIG. 99.—The Freezing-point Curve of Mixtures of Lead Fluoride and Iodide.

NaCl			0	0·29	0·59	1·16	2·34	5·86	11·70	29·80
PbI_2			0·758	0·778	0·859	0·951	1·10	1·41	1·64	1·79

at 25°, when the solid phase is lead iodide. If the conc. of the sodium chloride exceeds these limits, the solid phase contains chlorides.

F. Matthes found that binary mixtures of lead bromide and iodide have only a limited miscibility when melted ; the f.p. curve, Fig. 101, has a eutectic at 265° and 49 molar per cent. of lead iodide. C. H. Herty and T. R. Boggs consider that the products obtained by cooling aq. soln. of the component salts are only mixed crystals, and that there is no evidence of the formation of chemical individuals, in

spite of reports by B. Thorp of the formation of orange-coloured crystals of *lead bromoiodide*, PbBrI, as the first crop from soln. of lead iodide in hydrobromic acid ; pale yellow crystals of *lead tribromoiodide*, Pb_2Br_3I, as the second crop from the same soln. ; and white crystals of *lead dodecabromodiiodide*, $Pb_7Br_{12}I_2$, as the third crop. V. Thomas also reported crystals of the tribromoiodide to be formed by cooling a soln. of lead iodide in a hot sat. soln. of lead bromide, or of lead bromide in a hot soln. of potassium iodide. E. Field also reported greenish needles of *lead tetrabromodiiodide*, $Pb_3Br_4I_2$, to be obtained by cooling a boiling soln. of lead iodide and ammonium bromide.

B. Thorp obtained silky needles of presumably mixed crystals of *lead chloride, bromide, and iodide* from a hot aq. soln. of the three salts. F. Matthes studied the
FIGS. 100 and 101.—Freezing-point Curves of Binary Mixtures of Lead Iodide with Lead Chloride and Bromide.
FIG. 102.—Fusion Curves of Ternary Mixtures of Lead Chloride, Bromide, and Iodide.

f.p. curves of ternary mixtures of these three halides, and obtained no evidence of chemical combination, Fig. 102. The eutectic rises from 256° to 325° and then falls to 306°.

The lead oxyiodides.—The lead oxyiodides have not been examined in the light of the phase rule, and the reported salts are to be considered on probation. P. B. Durand,[16] M. Jammes, and E. Filhol noted that when iodine and water act on lead hydroxide, $3PbO.H_2O$, a blue or violet substance is produced which A. Ditte likened to a lake. This makes it probable that the iodine is adsorbed by the hydroxide. According to W. Gregory, when hot dil. soln. of potassium iodide and lead acetate are mixed, and cooled, small yellowish-green needles mixed with yellow crystals of lead iodide are produced. The latter were removed by hot water. The crystals were at first thought to be those of lead iodide, but later observations showed that they were **lead oxydiiodide**, Pb_2OI_2, or $PbO.PbI_2$. The salt was obtained by R. Brandes, and M. Denot by treating a soln. of potassium iodide with a large excess of lead acetate, leaving the precipitate in contact with the mother-liquor for some time, and boiling with water to extract free lead iodide. The same product was obtained by leaving lead iodide for several days in contact with a soln. of lead acetate, and agitating the mixture every now and then. R. Brandes also treated a soln. of potassium iodide with one of basic lead acetate. J. Wood and J. L. Borden treated lead iodide with conc. ammonia on a sand-bath for 10 hrs. M. Gröger obtained it by heating the periodide, $PbO.PbI_2.I_3$, at about 200°. A. Ditte, and D. Strömholm obtained the anhydrous salt by heating one of the hydrates. H. N. Holmes obtained Liesegang's rings by leaving silica gel containing potassium iodide in contact with a soln. of lead acetate. The yellow or greenish-yellow oxydiiodide, according to M. Denot, fuses between 200° and 300°, giving off white fumes mixed with the vapour of iodine, and leaves behind a glassy mass. G. André gave 1·6 Cals. for the heat of formation from the solid iodide and oxide. According to R. Brandes, and M. Denot, the oxyiodide is insoluble in boiling water ; chlorine transforms it into lead chloride ; it is not changed by a soln. of potassium iodide ; it is soluble in hot dil. acetic acid, and on cooling, the soln. deposits crystals of lead iodide.

According to A. Ditte, when lead hydroxide is treated with a soln. of potassium iodide, protected from air, crystals of **hemihydrated lead oxydiiodide,** $PbO.PbI_2.\frac{1}{2}H_2O$, are formed. If the reaction takes place in air, the complex iodide, $2KI.PbI_2.4H_2O$, is produced. The reaction in the former case is a balanced one, but the potassium hydroxide, simultaneously formed when an excess of lead hydroxide is used, produces a pentoxydiiodide, $5PbO.PbI_2.7H_2O$. A. Ditte also obtained the hemihydrated oxydiiodide by the action of an aq. soln. of potassium iodide on lead iodide in the absence of air. The colourless, transparent crystals lose their water when heated, and become golden yellow; at a higher temp., the crystals melt and give off the vap. of iodine. Acids first dissolve lead oxide, and later the iodide. A. de Schulten made **monohydrated lead oxydiiodide,** $PbO.PbI_2.H_2O$, or **lead hydroxyiodide,** $Pb(OH)I$, or *iodolaurionite*, by adding a hot soln. of 20 grms. of potassium iodide in 100 c.c. of water, to 400 grms. of lead acetate in a litre of water and 30–40 c.c. of acetic acid. The filtered liquid was heated on a water-bath for 5–8 hrs. On cooling, yellow crystals were formed. J. White obtained the same salt by decomposing the double salt of lead acetoiodide with acetate of ammonium, potassium or sodium by means of water. O. B. Kühn treated lead oxyacetate with potassium iodide; D. Strömholm treated lead iodide with ammonia; and M. Gröger boiled lead periodide, $PbO.PbI_2.I_3$, with water. The pale yellow crystals were found by A. de Schulten to be rhombic bipyramids with the axial ratios $a : b : c = 0.7476 : 1 : 0.9081$; and to resemble the corresponding hydroxychloride and hydroxybromide. The sp. gr. is 6.827 at 15°. W. Biltz examined the mol. vol. O. B. Kühn said the water is all expelled at 100°, while A. de Schulten said the water is driven off at a red heat when the compound melts and gives off iodine vapour. It is not attacked by water. M. Gröger said that the salt is sparingly soluble in cold water and in alcohol; boiling alcohol, and a soln. of potassium iodide extracts iodine; and an alcoholic soln. of lead acetate colours it brown, probably forming iodine and another oxyiodide.

According to M. Denot, when basic lead acetate—*acetate plombique*—is treated with an excess of potassium iodide, or when lead iodide is boiled with lead carbonate in water, **lead dioxydiiodide,** $2PbO.PbI_2$, is formed. O. B. Kühn obtained it by boiling lead oxide repeatedly with fresh quantities of a sat. soln. of lead iodide. D. Strömholm reported **monohydrated lead trioxydiiodide,** $3PbO.PbI_2.H_2O$, or $2PbO.Pb(OH)_2.PbI_2$, to be formed when lead hydroxide is mixed with twice the amount of potassium iodide soln. employed in making the hexoxydiiodide—*vide infra*—and shaken for a long time; and also by mixing lead hydroxyiodide with enough $0.5N$-NaOH to make the ratio $OH : 1 = 0.006N - : 0.074N$. The pale yellow, microscopic crystals become deep yellow when heated; and they are attacked by soda-lye. O. B. Kühn made **dihydrated lead trioxydiiodide,** $3PbO.PbI_2.2H_2O$, or $PbO.2Pb(OH)_2.PbI_2$, as a white precipitate by adding an excess of aq. ammonia to a boiling soln. of lead iodide; and J. Wood and J. L. Borden, by heating lead iodide with conc. aq. ammonia for 38 hrs. on a water-bath. D. Strömholm prepared dihydrated **lead enneaoxytetraiodide,** $9PbO.2PbI_2.2H_2O$, or $7PbO.2Pb(OH)_2.2PbI_2$, as a bright yellow voluminous mass, by mixing lead hydroxide with a little more potassium iodide soln. than is necessary for the formation of hexoxydiiodide, and then with sufficient potassium iodide to precipitate all the lead from the soln. A. Ditte reported **heptahydrated lead pentoxydiiodide,** $5PbO.PbI_2.7H_2O$, to be formed in white needle-like crystals by treating lead iodide with a hot conc. soln. of potassium hydroxide, and cooling. When treated with acids, lead iodide remains. When heated, the water is all expelled and yellow **lead pentoxydiiodide,** $5PbO.PbI_2$, remains. D. Strömholm could not make the hydrated salt. C. Langlois prepared the anhydrous salt by heating lead dioxydiperiodate, $2PbO.Pb(IO_4)_2.2H_2O$, in a tube. J. Wood and J. L. Borden obtained a hydrated form of this oxyiodide by heating lead iodide with conc. aq. ammonia on a water-bath for 68 hrs. M. Denot said that when melted it behaves like the oxydiiodide. D. Strömholm reported **dihydrated lead hexoxydiiodide,**

$6PbO.PbI_2.2H_2O$, or $4PbO.2Pb(OH)_2.PbI_2$, to be formed as a white voluminous mass of microscopic crystals, by allowing lead hydroxide to stand in contact with $0.5N$-KI until the soln. is free from iodine. It behaves like the corresponding chloride when heated.

C. F. Cross and S. Sugiura passed iodine vapour over heated lead dioxide, and repeated the treatment on the powdered product until its composition was not changed; the orange-yellow product had the composition *lead heptoxypentaiodide*, $Pb_{11}O_7I_8$. By using lead monoxide in place of the dioxide, *lead hexoxytetraiodide*, $Pb_9O_6I_4$, was formed. By passing a mixture of air and iodine vapour over lead monoxide, *lead octoxydiiodide*, $Pb_9O_8I_2$, was produced; when lead dioxide was used, yellow *lead decoxytetraiodide*, $Pb_{11}O_{10}I_4$, of sp. gr. 7.81, was formed.

M. Gröger described a compound with a composition $PbO.PbI_2.I_3$, as an amorphous precipitate, and this was confirmed by H. L. Wells, who showed that M. Gröger overlooked the presence of water, so that the product is **monohydrated lead oxypentaiodide**, $PbO.PbI_2.I_3.H_2O$. There is no evidence that the " excess iodine " is present as lead tetraiodide. H. L. Wells obtained it in brilliant black crystals, forming octahedra belonging to the tetragonal system, and with their faces much curved and distorted. The method of preparation is as follows :

Dissolve 10 grms. iodine in 100 c.c. absolute alcohol, then 50 grms. crystallized lead acetate in 150 c.c. of water, 3 c.c. glacial acetic acid, and 300 c.c. absolute alcohol. Mix the two soln., let stand 14–16 hrs. at the temp. of the room, filter to remove the small precipitate, then dil. with 1500 c.c. of boiling water. Let the whole stand until cold, when the compound sought will have crystallized out, mixed with iodine. Pour off the liquid and wash the crystals with cold alcohol in small quantities until the iodine is removed. Dry the product upon filter-paper, and then in the air at ordinary temp.

H. L. Wells used other methods of preparation—*e.g.* alcoholic soln. containing lead acetate and iodine, or potassium iodide. The presence of acetate was said to be indispensable because with lead nitrate the salt is not formed. The compound cannot be recrystallized from water, alcohol, or mixtures of the two liquids ; and M. Gröger suggested that it is formed by the decomposition of some complex compound by water. The crystals are stable in dry air, but when heated for a long time at $100°$, or for a short time at $200°$, the salt is decomposed, forming the yellow oxyiodide, $PbO.PbI_2$. The salt is scarcely acted upon by water, but it is slightly soluble in cold water ; with boiling water, lead hydroxyiodide is formed. The " excess iodine " is not dissolved out by cold alcohol, but is removed by a soln. of potassium iodide ; with boiling alcohol, dark yellow lead oxydiiodide is formed. Warm acetic acid decomposes it into lead acetate, lead iodide, and iodine ; it forms a brown liquid with a soln. of lead acetate, and is slowly decomposed.

B. Dietzell [17] reported a lead oxychloroiodide to be formed by the action of a small excess of lead acetate on a mixture of potassium iodide and chloride. The washed precipitate was dissolved in a little dil. acetic acid and evaporated, when greenish-yellow prisms of the oxychloroiodide of variable composition were deposited before the yellow lead iodide appeared. According to I. Domeyko, M. Schwartzemberg discovered an *oxychloroiodure de plomb*, forming crusts on the galena at a mine about 15 leagues from Paposo in the desert of Atacama ; it was also reported by G. F. H. Smith in samples from San Rafael mine, Bolivia ; by A. Frenzel, from Sierra Gorda, Peru ; etc. I. Domeyko called it *plombo oxichloroioduro* ; J. B. Dana, **schwartzembergite ;** and M. Adam, *plumboiodite*. Analyses were reported by I. Domeyko, and K. T. Liebe, and they correspond with $Pb_{10}Cl_6I_2O_{12}$; or, according to G. F. H. Smith and G. T. Prior, *lead hexoxydiiodatohexachloride*, $3Pb_3O_2Cl_2.Pb(IO_3)_2$, or, according to P. Groth, **lead dioxyiodochloride**, $2PbO.Pb(I,Cl)_2$. K. T. Liebe considers everything except lead oxide and iodide to be present as an impurity. The purer samples are honey-yellow, and others vary from straw-yellow to reddish-yellow. The rhombohedral crystals were found by G. F. H. Smith and G. T. Prior to be tetragonal, with the axial ratio $a : c = 1 : 0.430$, and not rhombohedral as stated by K. T. Liebe. E. Bertrand found the optical character

negative, and uniaxial. The crystals are flat, square pyramids with rounded faces, and are optically anomalous, showing a division into sectors with the optic axial angles $2V=16°$–$28°$. K. T. Liebe gave 6·2–6·3 for sp. gr. ; I. Domeyko gave 5·7–6·7, and for the hardness, $1\frac{1}{2}$–2. According to G. F. H. Smith and G. T. Prior, the refractive index is about 2·35 ; and when the mineral is heated with hydrochloric acid, chlorine is evolved ; and in the cold nitric acid soln. the iodine is present as iodate, not as iodide. A. C. Vournasos prepared *lead dibromodiiodide*, $K_2[PbI_2Br_2]$.

§ 28. The Complex Salts of Lead Iodide

P. F. G. Boullay [1] reported an ammonium iodoplumbite to be formed as a white precipitate when a soln. of lead nitrate is treated with an excess of ammonium iodide. The product was said to be decomposed by water. H. L. Wells and W. R. Johnston made a search for various ammonium salts, but were able to prepare only **ammonium triiodoplumbite**, $NH_4PbI_3.2H_2O$, in yellow, hair-like crystals, by dissolving 100 grms. of ammonium iodide and 10 grms. of lead iodide in sufficient

hot water to make 108 c.c., and cooling. They noticed that if lead iodide was deposited from a moderately conc., hot soln. of ammonium iodide, the lead iodide disappeared on cooling, and its place was taken by a compact, silky mass of crystals. C. H. Herty said that the process employed by E. Field for the 4 : 3-salt—*vide infra*—yielded this salt. J. White obtained this salt from the mother-liquor resulting from the preparation of ammonium acetoiodoplumbite, and he said that diffused daylight colours the yellow powder brownish-red, and greyish-brown owing to the liberation of iodine. This is the only complex iodide which N. Demassieux could find in her study of the ternary system : NH_4I–PbI_2–H_2O. E. Field reported **ammonium decaiodotriplumbite,** $(NH_4)_4Pb_3I_{10}$, to be formed by boiling a mixture of 30 grms. of ammonium iodide, one gram of lead iodide or chloride, and 75 c.c. of water, cooling the filtered soln., and drying the product at 100°. C. H. Herty found the 1 : 1 salt to be produced by this process. On the contrary, H. Fonzes-Diacon said that soln. of lead and ammonium iodides always furnish **hexahydrated ammonium decaiodotriplumbite,** $(NH_4)_4Pb_3I_{10}.6H_2O$, which, according to A. Mosnier, becomes anhydrous at 105°. The heat of formation for $(4NH_4I, 3PbI_2)$ is 3·75 Cals., and for the hydrated salt, 9·51 Cals. with liquid, and 0·93 Cal. with solid water. The white needle-like crystals of the hydrate have a yellow tinge, and, according to H. Fonzes-Diacon, they are monoclinic. The hydrated salt dissociates at 18°, and A. Mosnier gave for the vap. press., p mm. :

	19°	28·5°	46°	57°	72°	78°	85°	90°	98·5°
p	8	33	98	140	230	272	331	388	501

The salt is decomposed by water ; but H. Fonzes-Diacon said that if 62·7 grms. of ammonium iodide are present per litre, the complex salt is not decomposed—A. Mosnier said 168 grms. per litre at 10°, and 197 grms. per litre at 15° are needed to inhibit the decomposition. Soln. of ammonium halides were found by H. Fonzes-Diacon to replace the ammonium iodide with hot, but not with cold, soln. The solubility of the decaiodotriplumbite in soln. of ammonium iodide increases with conc. and temp. ; thus, A. Mosnier gave for the solubility, S, in grams per litre :

	10·5°	15°	16°	28°	38°
NH_4I	198	217·6	256	317·6	470·8
S	2·8	8·4	13·5	36·6	67·2

If oxy-salts are present, the decaiodotriplumbite is decomposed however much ammonium iodide be present. With ordinary or absolute ethyl alcohol, or methyl alcohol, lead iodide is precipitated as in the case of water. Expressing the solubility, S, in grams of salt per 1000 grms. of absolute alcohol :

	Methyl alcohol.			Ethyl alcohol.		
	15°	28°	38°	15°	28°	38°
NH_4I	39·16	55·8	82·9	38·8	55·4	82·14
S	0·84	1·4	2·10	0·70	1·26	1·96

The salt is not affected by pure and dried ether, but ordinary ether is coloured by the separation of lead iodide ; while ether which has been exposed to air, and therefore contains peroxides, is coloured reddish-yellow by the separation of iodine—lead oxyiodide is formed at the same time. A. Ditte claimed to have made **tetrahydrated ammonium tetraiodoplumbite,** $(NH_4)_2PbI_4.4H_2O$, by the action of a soln. of lead nitrate on one of potassium iodide, as in the case of the corresponding potassium salt. A. Mosnier prepared complex salts with tetramethylammonium, tetraethylammonium, and tetraphenylammonium iodides of the type $3PbI_2.4NH_4I$.

Both A. B. Poggiale, and C. Völckel described mixed double halides of lead and ammonium ; both products were obtained in silky needles. The former gave the composition $PbI_2.4NH_4Cl.2H_2O$, and the latter, $PbI_2.3NH_4Cl$. H. L. Wells and W. R. Johnston said that both used virtually the same mode of preparation, dissolving lead iodide in a soln. of ammonium chloride, and that both products are

probably the same, being more or less contaminated with ammonium chloride. They prepared what was regarded as the true compound in a similar manner, and found that it is really **dihydrated ammonium chlorodiiodoplumbite**, $NH_4PbClI_2.2H_2O$, with only a slight variation in the composition. Possibly it would be better to write the formula $NH_4Pb(Cl,I)_3.2H_2O$, for there is a doubt if the mixed halide complex salts are variable mixtures of two isomorphous halides, as H. L. Wells and H. L. Wheeler found to be the case with cæsium chloride and lead bromide, and C. H. Herty, with potassium iodide and lead bromide. On the other hand, H. L. Wells' $Cs_2HgCl_2I_2$ shows that such mixed salts can exist as chemical individuals. H. Fonzes-Diacon obtained the chlorodiiodoplumbite from the mother-liquid left after the preparation of $PbClI.\frac{1}{4}H_2O$; and by cooling a hot aq. soln. of ammonium chloride and ammonium decaiodotriplumbite. The crystals are described as pale yellow monoclinic needles. A mol of water is lost by exposing the salt for 2 or 3 days in air, and the second mol is lost at 100°. The salt dehydrated at 100°, is rehydrated by exposure to moist air. H. Fonzes-Diacon reported **ammonium bromodiiodoplumbite**, NH_4PbBrI_2, to be formed by cooling a hot soln. of lead iodide in a 100 per cent. soln. of ammonium bromide. The yellow plates belong to the tetragonal system, and are decomposed by exposure to light, and by water ; they are soluble in potash-lye, and in the strong acids. When a 30 per cent. soln. of ammonium bromide was employed, **dihydrated ammonium bromodiiodoplumbite**, $NH_4PbBrI_2.2H_2O$, was obtained in pale yellow needles, which can be easily dehydrated, and the dehydrated salt takes up water again in moist air.

O. Lehmann [2] observed the growth of crystals of a double iodide of lead and potassium by bringing together a drop of a conc. soln. of lead nitrate and of potassium iodide on a glass slip on the stage of a microscope. A. Ditte measured the solubility of lead iodide in soln. of potassium iodide of different conc., and at different temp. He said that when lead iodide is put into a soln. of potassium iodide, it dissolves at first slowly, afterwards more rapidly, until the soln. is sat. ; after a time, the liquid becomes filled with white needles which have only the slightest yellow tinge. These crystals have the composition **tetrahydrated potassium tetraiodoplumbite**, $PbI_2.2KI.4H_2O$; they are decomposed, with re-formation of lead iodide, both by addition of water, and by raising the temp. of the soln. ; alcohol produces the same effect. He examined the effect of (1) adding water to a great excess of the double iodide, so as to decompose only a part ; and (2) adding potassium iodide by degrees to a mixture of water and lead iodide until needles of the double salt begin to form. He thus found the weight of alkali iodide which at any given temp. is necessarily present, so as to prevent the decomposition of the double salt. These quantities are, per litre of liquid :

	5°	10°	14°	20°	28°	39°	59°	67°	85°
KI	140	160	175	204	251	300	503	560	738 grms.

The decomposition of the double iodide of lead and potassium follows the general law, namely, that at all temp. a liquid, in which the double salt is capable of existing without being decomposed, must contain a definite and minimum quantity of alkaline iodide. No reaction takes place when water, lead iodide, and potassium iodide are brought together ; if the proportion of the latter is less than that already indicated, a very little lead iodide only dissolves ; if the alkaline iodide is in sufficient quantity, the two iodides will combine until there remains in the liquor just sufficient alkaline iodide to prevent the decomposition of the double salt. Similar phenomena were observed when sodium or ammonium iodide was substituted for potassium iodide. A. Ditte also obtained the same salt by passing carbon dioxide into a soln. of potassium iodide in which freshly-precipitated lead carbonate or lead dioxide was suspended ; without the carbon dioxide, the double salt is not formed. The salt furnishes white silky needles, which, when heated, lose water, and become golden yellow. At a higher temp., the salt fuses and gives off iodine. Expressing

the conc. in grams per litre, the solubility, S, of the salt K_2PbI_4 in the presence of potassium iodide, is as follows :

	5°	10°	14°	20°	28°	39°	59°	67°	80°
KI	163	191	215·6	253·6	307	406·7	510	568	641
S	—	—	3·4	15·4	43·0	77·3	323	438	1276

The salt is converted into lead carbonate, etc., by the action of potassium hydro-carbonate ; and it is coloured yellow and dehydrated by absolute alcohol. According to M. Berthelot, **dihydrated potassium tetraiodoplumbite**, $K_2PbI_4.2H_2O$, is produced in warm soln. of lead iodide and potassium iodide. The heat of formation is given as 2·31 Cals. The anhydrous salt, **potassium tetraiodoplumbite**, K_2PbI_4, was obtained by A. Ditte by warming the tetrahydrate. F. P. H. Brooks made it by adding a gram of lead nitrate to 10 c.c. of a sat. soln. of potassium iodide, and after standing some time, washing the precipitate with 10 c.c. of a conc. ,soln. of potassium iodide in absolute alcohol. The white needles have a yellow tinge. They are decomposed by moist air and become yellow ; they are soluble in a conc. soln. of potassium iodide ; insoluble in alcohol, and sparingly soluble in chloroform. R. W. Balcom inferred from his observations of the solubility of lead iodide in soln. of potassium iodide that the complex salt K_2PbI_4, or the ion PbI''_4, is present in aq. soln. C. Immerwahr also examined the conductivity of these soln.

P. F. G. Boullay added a soln. of lead nitrate to an excess of a conc. aq. soln. of potassium iodide, and obtained pale yellow, silky needles, analyses of which agreed with *potassium heptaiodoplumbite*, $5KI.PbI_2$; when the mother-liquor was allowed to stand a few days, or mixed with alcohol, yellow prismatic crystals of what M. Berthelot considered to be *hexahydrated potassium decaiodoplumbite*, $4KI.3PbI_2.6H_2O$, were formed. C. H. Herty said they may be $K_3Pb_2I_7.4H_2O$, but more probably a mixture of potassium triiodoplumbite and iodide. J. B. Berthemot made the same salt by boiling lead iodide with a conc. soln. of potassium carbonate ; A. C. Becquerel, by separating soln. of potassium iodide and lead acetate by a porous partition and electrically connecting the soln. by a lead wire ; and E. Field boiled 60 grms. of potassium iodide, 2 grms. of lead iodide, and 150 c.c. of water, and cooled the filtered liquid—lead fluoride, chloride, or bromide can be used in place of lead iodide. A. Mosnier obtained it by a process analogous to that used for the ammonium salt. The pale yellow needles are stable in air ; they become anhydrous *potassium decaiodotriplumbite*, $K_4Pb_3I_{10}$, at 100° ; they dissolve readily in water with decomposition ; they dissolve in potash-lye, and in water acidified with nitric acid—more conc. nitric acid leads to the separation of iodine. M. Berthelot gave for the heat of formation $(4KI,3PbI_2) = -0·5$ Cal.

I. Remsen, H. L. Wells, and C. H. Herty were unable to establish the individuality of any salt other than **dihydrated potassium triiodoplumbite**, $KPbI_3.2H_2O$, when deposited from aq. soln. All the other salts which have been reported are considered to be mixtures of this salt with potassium iodide. This is the only complex iodide N. Demassieux could find in her study of the ternary system : $KI-PbI_2-H_2O$; so also with L. J. Burrage, who found that at 25° the mutual solubility of lead and potassium iodides expressed in grams per 1000 grms. of soln., at 23°, is :

KI	0	0·83	33·20	194·5	213·2	268·2	546·0	565·9	578·2	597·2
PbI_2	0·758	0·234	0·020	2·53	4·28	5·53	58·76	74·21	52·35	0
Solid phase		PbI_2			$KI.PbI_2.2H_2O$			KI		

According to C. H. Herty, *monohydrated potassium triiodoplumbite*, $KPbI_3.H_2O$, is known only in isomorphous mixture with potassium tribromoplumbite. The conditions of equilibrium were studied by F. A. H. Schreinemakers first on the assumption that the solid phase is, as first suggested by A. Ditte, $K_2PbI_4.2\frac{1}{2}H_2O$, and later with the assumption that this salt is really $KPbI_3.2H_2O$. Every one of the modes of preparation described by P. F. G. Boullay, M. Berthelot, J. B. Berthemot, W. Biltz. H. L. Wells, A. C. Becquerel, C. H. Herty, J. White, etc.,

furnish this salt contaminated with more or less potassium iodide. G. Campani obtained it by the action of an excess of a soln. of potassium iodide on lead sulphate at 130°–140°. C. H. Herty made it by the following process :

A hot soln. of 15 grms. of potassium iodide in 15 c.c. of water was added to a soln. of 4 grms. of lead nitrate in 15 c.c. of water. The soln. was stirred during the mixing. When cold, crystals of the dihydrate separated out. These were separated by suction filtration, and dried by press. between bibulous paper.

The white, silky needles are stable in air, and, according to H. L. Wells, and C. H. Herty, they lose a part of their water of crystallization when standing over sulphuric acid or quicklime in a desiccator. When heated, water begins to come off at 70° and the colour becomes yellow, and the vol. of the solid decreases ; at 110°, the salt loses all its water ; and at 310°, iodine begins to be evolved. Water decomposes the salt at all temp., potassium iodide is dissolved, and lead iodide precipitated, and F. A. H. Schreinemakers concluded that the double salt $PbI_2,KI,2H_2O$ has neither a proper m.p. nor a proper solubility. It can exist only in contact with solutions in which the ratio of potassium to lead is greater than the ratio K : Pb. At elevated temp., the double salt in contact with the soln. is decomposed into another double salt—possibly $3KI.PbI_2.\frac{1}{2}H_2O$—containing only half a mol. of water, the ratio of the two iodides being unknown. There is probably no temp. of transformation for either of these double salts into their components. J. M. Talmadge showed that while the conc. at ordinary temp. of a soln. from which the double salt $KPbI_3.2H_2O$ has separated is always attended by dissolution of the double salt, at 100°, the behaviour is reversed, for there is a continuous precipitation of the double salt on evaporation. According to P. F. G. Boullay, when heated with sulphuric acid, first lead iodide and then lead sulphate are formed. C. H. Herty found that a boiling soln. of sodium carbonate produces lead carbonate. Absolute alcohol decomposes the salt like water does. Cold alcohol, said P. F. G. Boullay, has no action on the crystals, but hot alcohol leaves the lead iodide undissolved, and deposits the double salt on cooling, some potassium iodide remaining in soln. W. Biltz found that the salt is soluble in acetone, and the addition of alcohol precipitates the double salt.

H. L. Wells', and A. N. Meldrum's observations respectively on the salts $K_3Pb_2I_7.4H_2O$, and $K_9Pb_4I_{17}.10H_2O$ have been previously discussed. C. H. Herty obtained mixed crystals of the isomorphous salts $KPbBr_3.H_2O$ and $KPbI_3.H_2O$ when the attempt was made to prepare *potassium bromoiodoplumbite*, $KPb(Br,I)_3.H_2O$, by crystallization from mixed soln. of the component salts. O. Lehmann made mixed crystals by treating a soln. of potassium iodide and bromide with lead nitrate ; and H. L. Wells also obtained isomorphous mixtures of the salts $K_3Pb_2Br_7.4H_2O$ and $K_3Pb_2I_7.4H_2O$ as $K_3Pb(Br,I)_7.4H_2O$, by crystallization from a mixed soln. of the component salts.

H. L. Wells obtained **dihydrated rubidium triiodoplumbite,** $RbPbI_3,2H_2O$, as the only complex iodide obtainable from hot soln. of lead and rubidium iodides under widely varying conditions. It forms slender, hair-like, pale yellow prisms, which lose water when exposed to air—the colour first becomes orange owing to the loss of one mol of water, and then pale yellow by the loss of the other mol. Dihydrated ammonium chlorodiiodoplumbite likewise changes from yellow to orange by the loss of a mol of water on exposure to air, but a second mol is not lost under these conditions. The air-dried salt is anhydrous **rubidium triiodoplumbite,** $RbPbI_3$. A. Mosnier reported tetrahydrated **rubidium tetraiodoplumbite,** $Rb_2PbI_4.4H_2O$, to be formed in pale yellow needles from hot soln. of the component iodides. The salt becomes anhydrous at 100° ; the heat of formation $(2RbI,PbI_2)=93·17$ Cals ; $(2RbI,PbI_2,4H_2O)=107·75$ Cals. with liquid water and 102·03 Cals. with solid water and the heat of soln. of the tetrahydrate, $-26·80$ Cals. H. L. Wells could not obtain this salt. H. L. Wells could obtain only **cæsium tri-iodoplumbite,** $CsPbI_3$, from hot soln. of the component salts under a wide range of

conditions. It furnishes yellow, slender, rectangular prisms which are slightly soluble in hot soln. of cæsium iodide.

A. Bogorodsky obtained **pentahydrated lithium triiodoplumbite**, $LiPbI_3.5H_2O$, by stirring lead iodide, in small portions at a time, into a soln. of lithium iodide, at 140°–150°, until yellow flakes began to separate. Water was added until the precipitate first formed was just permanent. The excess of water was evaporated, and the soln. evaporated until it became clear again. The above salt separates out in yellow needles, which should be pressed at a temp. above 72°, otherwise they may be contaminated with lithium iodide, $LiI.3H_2O$. At 95°, a mol of water is lost and the *tetrahydrate* is formed. The salt becomes anhydrous **lithium triiodoplumbite**, $LiPbI_3$, by long drying at 100°. The dried salt takes up a mol of water on exposure to air, and turns red ; the crystals thus formed become yellow at 88°. A. Mosnier reported yellow crystals of tetrahydrated **lithium tetraiodoplumbite**, $Li_2PbI_4.4H_2O$, to be formed by cooling boiling soln. of lead and lithium iodides. The salt is dehydrated by heat, and in moist air absorbs water and is decomposed. Water, alcohol, and ether act as on the corresponding sodium salt. The heats of formation are $(2LiI,PbI_2)=39.22$ Cals. ; $(2LiI,PbI_2,4H_2O)=74.74$ Cals. with liquid water and 69.02 Cals. with solid water ; the heat of soln. of the tetrahydrate is -14.02 Cals. in 40 parts of water at 15° ; and the heat of soln. of the anhydrous salt is 60.72 Cals.

A. C. Becquerel reported the formation of sodium iodoplumbite by the process which he employed for the potassium salt ; and P. F. G. Boullay, obtained evidence of the formation of a complex sodium salt analogous to the potassium salt. A. B. Poggiale, and C. H. Herty prepared **sodium triiodoplumbite**, $NaPbI_3$, by cooling a hot soln. of lead iodide in a sat. soln. of sodium iodide. The pale yellow needles (C. H. Herty), or plates (A. B. Poggiale) resemble the potassium salt ; they are deliquescent, and are decomposed by heat or by water with the separation of lead iodide. A. Mosnier considered A. B. Poggiale's product to have been Na_4PbI_6. A. Ditte reported **tetrahydrated sodium tetraiodoplumbite**, $Na_2PbI_4.4H_2O$, to be formed by cooling a soln. of lead iodide in an excess of a conc. soln. of sodium iodide ; A. Mosnier used a similar mode of preparation. C. H. Herty said that the product is contaminated with much sodium iodide. The crystals have a strong negative birefringence, and are probably triclinic. The surface of the crystals gradually becomes green on exposure to light. At 100°, the salt becomes anhydrous **sodium tetraiodoplumbite**, Na_2PbI_4, and in moist air, water is gradually absorbed, and finally passes into **hexahydrated sodium tetraiodoplumbite**, $Na_2PbI_4.6H_2O$, which is also obtained by cooling the mother-liquor from the tetrahydrate. The salts are decomposed by water and behave like ammonium and potassium iodoplumbites towards soln. of alkali iodide. Thus, expressing conc. in grams per 1000 grms. of water, the solubility, S, of the salt Na_2PbI_4 in the presence of sodium iodide is :

	8·5°	10·4°	15°	23°	28°	38°
NaI	210·10	226·88	273·55	410·29	459	535·47
S	5·94	20·64	34·15	55·11	66	92·73

The solubility in methyl and ethyl alcohols in grams per 1000 grms. of alcohol is :

	Methyl alcohol.			Ethyl alcohol.		
	15°	28°	38°	15°	28°	38°
NaI	15·77	22·71	36·5	15·01	22·45	36
S	0·58	0·99	1·81	0·49	0·90	1·48

Ether acts slowly on the salt. The heat of formation is $(2NaI,PbI_2)=76.35$ Cals. ; $(2NaI,PbI_2.4H_2O)=103.88$ Cals. with liquid water and 98.16 Cals. with solid water ; and $(2NaI,PbI_2,6H_2O)=106.63$ Cals. with liquid water, and 98.23 Cals. with solid water. The heat of soln. of the anhydrous salt is 76.95 Cals. ; of the tetrahydrate, -24.93 Cals. in 40 parts of water at 15° ; and of the hexahydrate, -27.68 Cals.

O. Ruff and E. Geisel prepared a white compound, **silver pentamminotetraiodoplumbite**, $Ag_2PbI_4.5NH_3$, by mixing soln. of lead and silver iodides in liquid ammonia. On exposure to air, it forms yellow **silver tetraiodoplumbite**, Ag_2PbI_4. A kind of alloy of silver and lead iodides corresponding, in composition, with **silver triiodoplumbite**, $AgPbI_3$, was obtained by G. F. Rodwell by fusing mixtures of the two salts. He found the vol. of the solid " alloy " at different temp. :

	0°	118°	128°	130°	131°	139°	150°	300°
Vol. .	1·000000	1·003610	1·002314	0·999716	0·994517	0·98412	0·984810	1·006500

The vol. of the solid alloy at 350° was 1·01370, and of the liquid " alloy " at 350°, 1·024370. The coeff. of cubical expansion, β, is :

	0°–118°	124°–128°	128°–130°	130°–131°	131°–133°	133°–139°	144°–350°
β .	+0·0₄306	−0·0₃3240	−0·0012990	−0·0017330	−0·003900	−0·0₃4329	+0·0₃1159

where the + refers to the results obtained on heating and − to those on cooling. T. Carnelley and L. T. O'Shea gave 350° for the m.p. M. Bellati and R. Romanese measured the sp. ht. G. F. Rodwell also made a number of other alloys. C. Tubandt and S. Eggert examined the conductivity of fused mixtures of lead and silver iodides, and also found the f.p. curves, Fig. 103. Crystallization occurs at 395° corresponding with silver hexaiodoplumbite, $4AgI.PbI_2$, or Ag_4PbI_6, and this compound forms mixed crystals with lead iodide with a minimum at 344°. Transition temp. occur at 144·6° and at 115°.

A. Mosnier obtained the iodides of the alkaline earths by cooling a soln. of lead iodide in a boiling soln. of the given iodide. In a few days, yellow, octahedral crystals of **calcium hexaiododiplumbite**, $CaPb_2I_6.7H_2O$, appear ; they belong to the cubic system, and become anhydrous at 100°. If exposed to light for some days under the mother-liquor, they appear brownish-red owing to the formation of calcium iodide, CaI_215H_2O. The salt is decomposed by water, and alcohol. Pure and dry ether has no action, but ordinary ether, or ether which has been exposed

FIG. 103. — Freezing - point Curves of Mixtures of Lead and Silver Iodides.

to air, decomposes the salt. The heat of formation is $(CaI_2,2PbI_2)=-10·99$ Cals. ; and $(CaI_2,2PbI_2,7H_2O)=11·3$ Cals. with liquid water and 1·3 Cals. with solid water. The heat of soln. of the anhydrous salt in 40 parts of water at 15° is 16·61 Cals., and of the heptahydrate, 5·3 Cals. **Strontium hexaiododiplumbite**, $SrPb_2I_6.7H_2O$, was obtained in a similar manner, and its properties were similar ; it also yields the anhydrous salt when warmed. The heat of formation is $(SrI_2,2PbI_2)=3·35$ Cals. ; and $(SrI_2,2PbI_2,7H_2O)=12·85$ Cals. with liquid water and 2·84 Cals. with solid water. The heat of soln. of the anhydrous salt in 40 parts of water at 15° is 17·55 Cals., and of the heptahydrate, 4·70 Cals. Likewise also with **barium hexaiododiplumbite**, $BaPb_2I_6.7H_2O$, which becomes anhydrous at 100°. The heat of formation is $(2PbI_2,BaI_2)=-16·70$ Cals. ; $(2PbI_2.BaI_2,7H_2O)=16·59$ Cals. with liquid water and 6·58 Cals. with solid water. The heat of soln. is 8·29 Cals. for one part of the heptahydrate in 40 parts of water at 15°, and 8·30 Cals. for the anhydrous salt. The actions of water, alcohol, and ether are like the case with the calcium salt. The solubility, S, of the barium salt in grams per 1000 grms. of solvent is as follows :
	Water.			Methyl alcohol.			Ethyl alcohol.		
	15°	28°	38°	15°	28°	38°	15°	28°	38°
BaI_2 .	68·9	94·5	141·2	35·6	48·8	73·4	33·9	56·8	72·6
S . .	5·04	21	44·8	2·8	11·2	24·3	2·5	11·2	22·4

A. Mosnier found that a soln. of lead iodide in a boiling soln. of beryllium

carbonate in conc. hydriodic acid furnishes yellow needles of **beryllium tetraiodo-plumbite**, $BePbI_4.3\frac{1}{2}H_2O$, which are decomposed by water. A. Mosnier found that a boiling conc. soln. of magnesium iodide sat. with lead iodide, and allowed to evaporate 4 days in vacuo over sulphuric acid, and a mixture of quicklime and potassium hydroxide furnished topaz-yellow crystals of **magnesium hexaiodo-plumbite**, Mg_2PbI_6. The heat of formation is $(2MgI_2,PbI_2)=8\cdot52$ Cals., and the heat of soln. in 40 parts of water at 15° is 110·52 Cals. The colour of the crystals does not change at 100°. The salt is decomposed by water and alcohol with the separation of lead iodide. Ether containing a peroxide decomposes the salt with the separation of iodine. R. Otto and D. Drewes prepared **hexadecahydrated magnesium hexaiodoplumbite**, $Mg_2PbI_6.16H_2O$. Magnesium carbonate was dissolved in aq. hydriodic acid and the soln. evaporated until a skin formed on the surface; then as much dry lead iodide was added as the liquid would take up. On filtering hot and allowing the filtrate to remain until cold, a copious deposit of rhombohedral crystals of the given salt was obtained. The honey-yellow salt loses its water of crystallization at 140° and becomes citron-yellow. Above 150°, it decomposes with separation of iodine. Like the corresponding chloride, it is exceedingly hygroscopic. In the air it quickly becomes a magnesium iodide lye, containing lead iodide in suspension. Water decomposes it into soluble magnesium iodide and insoluble lead iodide. Exposed to hydrogen sulphide, it immediately gives rise to lead sulphoiodide, which afterwards passes into lead sulphide. A. Mosnier made yellow, hygroscopic crystals of **zinc hexaiodoplumbite**, Zn_2PbI_6, by cooling in darkness a soln. of lead iodide in a boiling conc. soln. of zinc iodide. The heat of formation is 0·74 Cal., and the heat of soln. in 40 parts of water at 15°, 23·50 Cals. A. Mosnier likewise prepared **cadmium hexaiodoplumbite**, Cd_2PbI_6, in small white crystals which become brown when exposed to light. The heat of formation is 10·30 Cals., and the heat of soln. in 40 parts of water at 15°, is 8·30 Cals. Cold water, absolute alcohol, and ordinary ether colour these salts yellow; dried ether has no action. J. Preuss reported that *mercuric iodoplumbite* does not separate on cooling a hot soln. of lead iodide and mercuric nitrate, but on evaporation a white powder is produced; and A. Mosnier said that mercuric iodide does not form a soluble salt with lead iodide.

A. Mosnier prepared crystals of **decahydrated aluminium dodecaiodotriplumbite**, $Al_2Pb_3I_{12}.10H_2O$, by evaporating in vacuo a soln. of lead iodide in a hot conc. soln. of aluminium iodide. The salt becomes anhydrous at 100°. Its heat of formation $(2AlI_3,3PbI_2)=42$ Cals., $(2AlI_3,3PbI_2,10H_2O)=205$ Cals. with liquid water and 190·7 Cals. with solid water. The heat of soln. of the anhydrous salt in 40 parts of water at 15° is 220 Cals., and of the decahydrate, 15 Cals. The salt is decomposed by water. J. Barlot found that the electrical conductivity measurements of mixed soln. of lead and thallous iodides indicated the existence of **thallous triiodoplumbite**, $TlPbI_3$, which was prepared by crystallization from a boiling soln. of equimolar parts of the constituent salts. The yellow, hair-like crystals are decomposed by water into lead and thallous iodides. A. Mosnier prepared needle-like crystals of **stannous tetraiodoplumbite**, $SnPbI_2.8H_2O$, by cooling a filtered soln. of lead iodide in a boiling soln. of stannous iodide in fuming hydriodic acid. This salt becomes anhydrous at 100°. The heat of formation is $(SnI_2,PbI_2)=12\cdot1$ Cals., and $(SnI_2,PbI_2,8H_2O)=8\cdot8$ Cals.; the heat of soln. of the anhydrous salt in 40 parts of water at 15° is 12·7 Cals., and of the octohydrate, $-7\cdot5$ Cals. The salt is decomposed by water. A. Mosnier obtained greenish-yellow needles of **chromous hexaiodoplumbite**, $Cr_2PbI_6.3H_2O$, from a sat. soln. of lead iodide in a boiling conc. soln. of chromous chloride, and evaporating the liquid to a syrup. It forms the anhydrous salt at 100°. The salt is very hygroscopic and is decomposed by water. The heat of formation is $(2CrI_2,PbI_2)=9$ Cals., and $(2CrI_2,PbI_2,3H_2O)=22\cdot7$ Cals. with liquid water and 18·4 Cals. with solid water; the heat of soln. of the anhydrous salt in 40 parts of water at 15° is 20·4 Cals., and of the trihydrate, 2·3 Cals. By working in an analogous manner, A. Mosnier made brownish-red crystals of

manganous hexaiodoplumbite, $Mn_2PbI_6.3H_2O$. The salt is decomposed by water and alcohol, and it becomes anhydrous at 100°. The heat of formation is $(2MnI_2,PbI_2)=1\cdot5$ Cals. ; and $(2MnI_2,PbI_2,3H_2O)=48\cdot1$ Cals. The heat of soln. of the anhydrous salt in 40 parts of water at 15° is 43·9 Cals., and of the trihydrate, —8·5 Cals. By the same mode of preparation, A. Mosnier obtained crystals of **ferrous hexaiodoplumbite,** $Fe_2PbI_6.3H_2O$. The salt becomes anhydrous at 100°. The heat of formation is $(PbI_2,2FeI_2)=0\cdot3$ Cal. ; and $(PbI_2,2FeI_2.3H_2O)=57\cdot7$ Cals. with liquid water, and 52·8 Cals. with solid water. The heat of soln. of one part of salt in 40 parts of water at 15° is —10·2 Cals. for the trihydrate, and 46·9 Cals. for the anhydrous salt. He also obtained **cobaltous hexaiodoplumbite,** $Co_2PbI_6.3H_2O$, in greenish needles which are decomposed by water. The salt becomes anhydrous at 100°. The heat of formation is $(2CoI_2,PbI_2)=3\cdot9$ Cals., and $(PbI_2,2CoI_2,3H_2O)=52\cdot1$ Cals. with liquid water and 47·8 Cals. with solid water. The heat of soln. was —10·6 Cals. for one part of the trihydrate in 40 parts of water at 15° ; and 41·5 Cals. for the anhydrous salt. Likewise also with **nickelous hexaiodoplumbite,** $Ni_2PbI_6.3H_2O$, which furnishes greenish needles which are decomposed by water, and becomes yellow and anhydrous at 100°. The heat of formation is $(2NiI_2,PbI_2)=1\cdot4$ Cals. ; $(2NiI_2,PbI_2,3H_2O)=51\cdot3$ Cals. with liquid water and 47 Cals. with solid water. The heat of soln. of the anhydrous salt in 40 parts of water at 15° is 40·2 Cals., and of the trihydrate, —11·1 Cals.

§ 29. Lead Sulphide

K. Jellinek and J. Zakowsky [1] made estimates of the affinity of sulphur and lead. It was assumed by H. V. Collet-Descotils, and others, that lead subsulphides are

capable of existence because B. G. Bredberg obtained what appeared to be homogeneous products by fusing a mixture of galena and lead in the proportions required for *lead tetritasulphide*, or *lead quadrantosulphide*, Pb_4S ; and also for *lead hemisulphide*, or *lead subsulphide*, Pb_2S. J. Fournet also reported a similar product. P. Berthier claimed to have obtained the hemisulphide by igniting lead sulphate in a carbon crucible, and G. F. Rodwell, by heating the sulphate in a current of ammonia. A. Brand found steel-blue octahedral crystals in the Mechnernich lead furnaces containing lead sulphide said to be in isomorphous mixture with cuprous and ferrous sulphides, and he assumed that the lead is present as PbS, not as subsulphide. J. Percy could not verify J. Fournet's, P. Berthier's, and B. G. Bredberg's conclusions ; he said :

Lead and lead sulphide may be melted together in all proportions, and in external characters the products approximate to lead or lead sulphide according as one or other predominates. If, after fusion, cooling be rapidly effected, the mass ·may seem to be homogeneous throughout ; but if, on the contrary, cooling takes place slowly, the mass will be found to consist of soft, malleable, and comparatively pure lead at the bottom, and hard crystalline lead sulphide at the top. No distinct line of separation will be visible, and the passage from soft lead to hard sulphide is more or less gradual. . . . Experiments made on a small scale, in crucibles, are apt to lead to erroneous conclusions, as it is difficult to recognize the effect of liquation in a little button of metal.

A. Mourlot obtained no evidence of the existence of a subsulphide in his observations of the effect of the high temp. of the electric arc furnace on lead sulphide. K. Friedrich and A. Leroux measured the f.p. of mixtures of lead and galena. The precipitated sulphide did not give a homogeneous product when fused and examined microscopically. The curve fell from 1103°, the m.p. of galena, continuously without a break, Fig. 104. The eutectic horizontal is at 327°, and extends continuously throughout. The lead branch of the curve is so very short that it could not be explored. Micrographic examination showed the presence of only two constituents—the glistening white crystals of lead sulphide, and the duller crystals of lead. W. Guertler found a gap in the curve for the mixed crystals of lead and lead sulphide with between 5 and 10 per cent. of sulphur. The individuality of the alleged subsulphides therefore remains not proven.
FIG. 104.—Freezing Curve of Binary Mixtures of Lead and Lead Sulphide.

Native **lead sulphide,** PbS, is the well-known mineral **galena,** or the *galenite* of F. von Kobell.[2] According to X. Fischer, galena was used by the women of ancient Egypt for painting the eyes. In ancient times, oxidized ores found near the surface of the ground were largely worked for lead, and at the beginning of our era, Pliny, in his *Historia naturalis* (**33.** 31 ; **34.** 47), used the term " galena " for these oxidized products ; with the sulphide as an inferior variety. The term *molybdœna* was used about 350 B.C. by Aristotle, in his *De generatione animalium* (**2.** 2). Dioscorides, in his *De materia medica* (**5.** 50), about 400 years later, and a century later by Gahlen, in his *De succedaneis ;* and the terms *molybdœna* and *plumbago* were also used by Pliny for these oxidized lead products. The derivation of Pliny's word " galena " is not known. Some writers in the Middle Ages—*e.g.* G. Agricola, and C. Gesner—believed it to be of Spanish origin because Pliny obtained much of his information on this subject from Spain. G. Agricola, and C. Entzelt condemned the derivation of *galena* from Galicia in Spain. The derivation of the word from γαλήνη, a calm, or from γελέω or γελάω, I laugh or shine, is considered by J. W. Evans to be improbable, and he suggested that the term may be derived from an allied Aryan idiom akin to the English *cloam* and the Slavonic *glina*, meaning any yellowish earthy material.

C. Entzelt (1551) suggested that the term *molybdæna* should be used for lead ore free from silver, and *galena* for lead ore containing that metal. J. Mathesius (1571) used the terms *Glantz* and *galena* for argentiferous galena ; *Bleischweiff* and *plumbago* for an ore of sulphur and lead ; and *molybdena*, for litharge. J. C. Boulenger (1627) used the term *galena* for a graphite. O. Worm (1655) identified galena, *plumbago*, and *molybdæna* with lead sulphide ; J. Webster (1671), like C. Entzelt, used *galena* for the ore containing a sensible quantity of silver, and *plumbago* for the ore without that metal. During the seventeenth century, *lapis plumbarius*, *plumbago*, *galena*, and *molybdæna* were used in the sense of *graphite* as well as for the ores of lead, and soon afterwards the Swedish mineralogists restricted the term *galena* to the mineral which now bears that name. G. Agricola (1546) said that the term *Glantz* was applied by the miners to galena, and suggested that they had converted a foreign word into one with a similar sound already familiar to them. J. G. Wallerius (1747) applied the term *Blyglants* (Bleiglanz), *galena*, *plumbum sulphure et argento mineralisatum* to the mineral sulphide. J. B. L. Romé de l'Isle (1783), and A. G. Werner (1817) regarded *Bleischweiff* as a dense or compact variety of *Bleiglanz ;* the early writers like C. Berward (1684) understood it to be a granular or fibrous galena. Coarse-grained galena is sometimes called *potter's ore*, because it is used in glazing some varieties of pottery, and was mentioned by Falloppius in that connection in 1606. The antimoniferous galena from Argentiera, Tuscany, was called *targionite* by E. Bechi ; and the arsenical and antimoniferous galena from Pribram, *steinmannite*, by F. H. M. Zippe.

In his posthumous *Vollständiges Laboratorium Chymicum* (Hamburg, 1716), J. Kunckel denied the existence of sulphur in galena. The sample examined may or may not be what is now understood by that mineral. In 1778, R. Watson said that the Derbyshire smelters were not aware that the ore contained sulphur, but he proved that the ore contained both lead and sulphur. Early analyses were made by J. J. Berzelius,[3] T. Thomsen, L. A. Emmerling, R. Kirwan, J. F. Westrumb, J. L. Proust, L. N. Vauquelin, and J. Davy. Innumerable other analyses have since been made for industrial purposes. Reports have been made by F. Sandberger, C. F. Rammelsberg, J. R. Blum, C. von Hauer, J. U. Lerch, H. A. Miers, G. C. Hoffmann, J. Thiel, T. Landmann, O. Schilling, A. Brunlechner, E. Bechi, L. F. Navarro, H. Sjögren, L. H. Borgström, I. Domeyko, D. Forbes, L. Pflücker y Ryco, A. Raimondi, C. Rimatori, B. Kerl, O. Luedecke, F. E. Reuss, V. R. von Zepharovich, E. Manasse, E. Metzger, etc. Galena contains silver and occasionally selenium, vanadium, tellurium, copper, zinc, cadmium, arsenic, bismuth, and iron sulphides, sometimes native gold and silver, and platinum has even been reported by M. d'Argy in the galena from the Dépt. Charente, France.

Galena is the most important lead ore, and it is one of the most widely distributed metal sulphides. C. Hintze has reported the different occurrences of the mineral in some detail. It occurs in beds and veins in crystalline and non-crystalline rocks, It occurs associated with pyrite, marcasite, zinc-blende, chalcopyrite, sphalerite, etc. ; it occurs in quartz, calcite, barytes, fluorspar, etc. ; and it is common to find it with gold, and in veins of silver ore. It may also be associated with cerussite, anglesite, etc., which are usually the result of the alteration of the galena. It is generally assumed that galena has been formed from soln. J. S. Curtis assumed that the lead ores of Eureka, Nevada, were formed from soln. ascending by solfataric action, and A. Lacroix, F. Zambonini, O. de Fiore, and U. Paniche have discussed the occurrence of galena among the sublimates from Vesuvius, where it is supposed to have been formed by the action of hydrogen sulphide, derived from steam and sulphur, upon the vapour of lead chloride. According to S. F. Emmons, the deposits at Leadville, Colorado, were produced by descending soln. which had dissolved their minerals from neighbouring eruptive rocks. F. Posepny described stalactitic formations of galena called *Röhrenerze*, occurring near Raibl. Galena occurs as a pseudomorph after pyromorphite at Bernkastel on the Mosel, etc., and this was discussed by W. Haidinger, J. R. Blum, and A. Breithaupt. The latter

called it *sexangulites plumbeus*, or *plumbeine*. G. F. Becker and W. H. Melville described spring deposits formed by the pseudomorphous replacement of other minerals. W. Lindgren mentioned the replacement of calcite, dolomite, quartz, orthoclase, and rhodonite. The so-called *Tigererz*, described by A. Sigmund, is an argentiferous galena occurring in grains in the limestone near Türnitz, Austria. W. H. Hobbs has described secondary galena as a surface film on cerussite, which is supposed to have been formed by the action of hydrogen sulphide. The formation of lead in nature has also been discussed by P. Niggli, E. Dittler, W. Stelzner and A. Bergeat, F. Bernauer, K. A. Redlich, and G. Bischof.

In the first century of our era, Dioscorides, in his *De materia medica* (**5**. 48), described the preparation of lead sulphide, which he called μόλυβδος κεκαυμένος, which is rendered into Latin *plumbum ustum*. He said :

Strips of lead, beaten out as thin as possible, are placed in a new dish, and sprinkled over with sulphur ; more lead and sulphur are added, and again more until the dish is full. The mixture is then kindled, and stirred with a rod until it is completely reduced to ashes which are like lead well done.

Some modifications of this process are also described. Pliny, in his *Historia naturalis* (**34**. 50), written about the same time, described a similar process for making *plumbum ustum*. G. C. Winkelblech [4] described a similar process. He said that strips of lead, even tolerably thick, take fire in sulphur vapour, and burn with a vivid glow, depositing half-fused globules of lead sulphide. When sulphur is mixed with molten lead, the whole mass becomes red hot. When a mixture of equiatomic parts of sulphur and finely divided lead is placed in a glass tube and heated at one end, only so far as to induce combination, it does not continue to burn unless the tube and contents have been previously heated in boiling water. W. Heike described the preparation of the sulphide by this method. According to C. W. G. Fuchs, the product obtained by melting together lead and sulphur is a grey crystalline mass. A. Mourlot found that when amorphous lead sulphide is heated for a short time in the electric arc furnace, good crystals are produced. F. Stolba, and P. Tschirwinsky crystallized amorphous lead sulphide by heating it with chalk at a red heat ; W. Truthe, by fusing it with lead chloride ; and G. F. Rodwell, by heating it to 100° in a stream of hydrogen, carbon monoxide, or carbon dioxide. According to F. Rössler, lead sulphide crystallizes from lead in beautiful cubes, sometimes arranged in steps or needles. He melted 50 grms. of lead and one gram of sulphur under borax. The crystals were best separated from the matrix by electrolysis using a soln. of lead acetate, sodium acetate, and acetic acid in water, and a current density of 0·2–0·3 ampère. F. de Marigny obtained crystals of lead sulphide by fusing a mixture of lead or litharge, iron pyrites, and starch under borax. According to W. Spring, lead unites with sulphur at ordinary temp. under a press. of 6500 atm., and the yield of sulphide is greater, the more frequently the compression is repeated. The subject has been discussed by E. Jannettaz, C. Friedel, etc.—*vide* 1. 13, 18. L. Franck found that by rubbing flowers of sulphur on a clean lead surface, the blackening which occurs shows that lead sulphide is formed. H. C. Jenkins and E. A. Smith obtained lead sulphide by heating lead in contact with sulphur dioxide at about 300°—between 327° and 400° lead oxide and sulphate are formed. D. L. Hammick obtained lead sulphide by adding lead sulphate to molten lead ; and O. Boudouard, by reducing lead sulphate with carbon ; J. B. Senderens, by heating lead oxide with sulphur ; M. Berthelot, from lead oxide and hydrogen sulphide ; F. Fouqué and A. Michel-Lévy, from lead oxide, a lead salt, or amorphous lead sulphide at a red heat ; and L. Moser and E. Neusser, from lead oxide, hydroxide, sulphate, chloride, or carbonate at 300°–550°. E. Weinschenk obtained good crystals by heating a mixture of lead oxide, ammonium chloride, and sulphur ; R. Schneider, by melting together an intimate mixture of lead sulphide, potassium carbonate, and sulphur at a red heat, and extracting the cold mass with water ; and J. E. Reynolds, by melting

lead oxide mixed with an excess of potassium thiocyanate. T. Sidot obtained good crystals of lead sulphide by heating lead silicate in sulphur vapour, and E. Grieshammer observed the formation of the sulphide in lead-glasses, and P. Berthier in slags, containing sulphides. F. Schlagdenhauffen heated lead oxide in the vapour of carbon disulphide ; and J. Durocher heated lead chloride in a stream of hydrogen sulphide at a red heat—this reaction is supposed to imitate the natural process at Vesuvius—*vide supra*. K. Jellinek and J. Zabowsky studied the reaction at 500°–1100°. P. Richter found that when lead oxide is triturated with calcium sulphide, lead sulphide is formed slowly at ordinary temp., rapidly when warmed.

The occurrence of lead sulphide crystals in the masonry and flues of lead-smelting furnaces, and in furnace slags, has been observed by F. Sandberger, J. F. L. Haus-mann, C. W. G. Fuchs, A. Lacroix, R. Grund, A. Himmelbauer, H. A. Wheeler, E. Metzger, F. Ulrich, C. C. von Leonard, A. Sadebeck, B. von Cotta, F. O. Doeltz and C. A. Graumann, W. Heike, A. Brand, etc. M. Mayençon noted lead sulphide as a sublimate from a burning coal mine ; F. Gonnard found crystals in the flue of a flint-glass works near Lyon ; and A. Lacroix, in the products of a fire about the lead chambers of a sulphuric acid works. P. Spence observed a lead pipe, used for conveying ammoniacal-water from a gas-works, wholly converted into galena.

Lead sulphide has also been produced by numerous wet processes. The pre-cipitation of lead sulphide from soln. of lead salts by hydrogen sulphide has been discussed in connection with the analytical reactions of the metal. O. Ruff and B. Hirsch studied the fractional precipitation of lead as sulphide in the presence of salts of other metals—manganese, nickel, iron (ic and ous), chromium, aluminium, copper, silver, zinc, and cadmium. According to G. F. Rodwell, that precipitated from soln. of lead acetate is contaminated with a part of this salt ; and, according to F. M. Jäger and H. S. van Klooster, the precipitate from acetic acid soln. always contains less lead than is needed for the normal sulphide. O. Ruff and B. Hirsch studied the joint precipitation of lead and nickel sulphides. F. Muck said that the sulphide obtained from acetic acid soln. by hydrogen sulphide is always amorphous, while if the soln. contains sufficient nitric acid, the lead sulphide is deposited in microscopic cubes. F. Faktor precipitated lead sulphide from hot soln. of lead nitrate, mixed with ammonium chloride, by means of a hot conc. soln. of sodium thiosulphate ; and O. Hauser and E. Biesalsky precipitated the sulphide as a mirror on glass from soln. of lead salts by a mixture of thiourea and an aq. or alcoholic soln. of alkali hydroxide. J. E. Reynolds also precipitated the sulphide from lead salts by organic sulphur compounds—*e.g.* from hot soln. of lead tartrate in soda-lye by thiocarbamide. E. Weinschenk heated either a mixture of acetic acid and lead thiocyanate in a closed iron tube for 4–6 hrs. at 230°–250°, or a mixture of ammonium thiocyanate and lead nitrate in a sealed tube at 180°. Small tubes were used because violent explosions were liable to occur. J. B. Senderens obtained the sulphide by boiling a mixture of water, sulphur, and lead oxide, hydroxide, dioxide, carbonate, or acetate ; F. Muck, by allowing a stick of sulphur to stand for a long time in contact with a soln. of lead oxide in potash-lye ; and H. de Sénarmont, by heating in a sealed tube a mixture of amorphous lead sulphide and water sat. with hydrogen sulphide. C. Doelter allowed a mixture of lead chloride, sodium hydrocarbonate, and an aq. soln. of hydrogen sulphide to stand in a sealed tube at ordinary room temp. for five months, and obtained crystals of lead sulphide. H. N. Stokes found that when a mixture of pyrite or marcasite and an aq. soln. of lead chloride is heated in a sealed tube at 180°, crystals of lead sulphide are formed. A. Daubrée noticed that galena, mixed with anglesite and phosgenite, is formed by the action of the thermal water of Bourbonne-les-Bains on metallic lead. A. Breithaupt noted the blackening of white plumbiferous minerals near to specimens of sulphides developing hydrogen sulphide by weathering in the Freiberg museum. A. Gages suspended

a bag of lead sulphate in water sat. with carbon dioxide and containing some decomposing organic matter, and found that a crust of lead sulphide crystals was formed by the reduction of the sulphate. A. Russell found that the cavernous masses of lead mixed with charcoal taken up in 1846 from beneath the partly fused lead pump of a fire-ship wrecked in Falmouth harbour in 1780, contained small crystals of galena—as well as cotunnite, anglesite, and leadhillite—formed by the action of sea-water on the lead. A. C. Becquerel immersed mercuric sulphide in a soln. of magnesium chloride contained in a glass tube, and he left a lead-plate standing in the tube, which was kept closed, for six weeks. He found that crystals of lead sulphide were deposited on the sides of the tube. The lower part of the lead plate was brittle from the absorption of mercury ; and the liquor gave off sulphur dioxide when treated with a strong acid. R. Lorenz obtained lead sulphide by the electrolysis of a soln. of potassium nitrate using a cathode of cupric sulphide, and a lead anode ; and F. Peters, by the electrolysis of a soln. of sodium thiosulphate using a lead anode. P. P. Lebedeff could not prepare the sulphide by the electrolysis of a soln. of sodium hydrosulphide using an alternating current and lead electrodes.

According to M. Lucas,[5] if lead sulphide be slowly precipitated from dil. soln., free from other than the soluble lead salts, and also free from alkalies, a brown or grey soln. of **colloidal lead sulphide** is produced ; and, as T. Ewan pointed out, the colour of the sol obtained by adding sodium sulphide to an alkaline soln. of a lead salt depends on the nature and conc. of the other constituents. C. Winssinger prepared the soln. in which the sulphide was formed so dil. that it could be dialyzed before the sulphide became insoluble. R. Meneguzzi added hydrogen sulphide to a soln. of lead acetate containing as protective colloids peptone, white-of-egg, starch-paste, or sugar syrup ; J. Lefort and P. Thibault used gum arabic, and W. Leuze, sodium protalbinate ; E. W. Lewis and H. Waumsley prepared a deep brown opalescent soln. by leaving lead in contact with a soln. of caoutchouc in 90 per cent. carbon disulphide and benzene. The caoutchouc acts as a protective colloid ; and a soln. of nitrocellulose in acetone acts similarly. F. V. von Hahn prepared the colloidal sulphide by the cathodic disintegration of galena.

The physical properties of lead sulphide.—The lead sulphide precipitated by hydrogen sulphide is a brownish-black powder ; that prepared by fusing the elements is lead-grey with a crystalline granular fracture ; and native galena is also lead-grey with a bright metallic lustre. T. Ewan [6] noted that the depth of the colour of the precipitate is influenced by the nature and conc. of the soln. A. Lallemand said that in thin layers, the powder is bluish-grey. In very thin sections, L. Henry found the colour of galena to be brownish-yellow. In 1565, C. Gesner referred to the cubic form of the **crystals** of *Glantz ;* they belong to the cubic system. Galena commonly occurs in cubes or cubo-octahedra—less frequently in octahedra. It also occurs in skeleton crystals, reticulated and tabular. Massive galena (*Bleischweif*) may be cleavable or coarsely or finely granular, or even impalpably fine. It is occasionally fibrous or plumose. J. B. L. Romé de l'Isle said that *toutes les variétés qu'on y rencontre m'ont paru dériver du cube ou de l'octaèdre alumineforme.* The crystals were fully described by A. Sadebeck, in his memoir : *Krystallisation des Bleiglanzes ;* and observations were reported by R. J. Haüy, C. F. Naumann, E. Weiss, M. Bauer, A. Schrauff, P. W. Jeremejeff, P. Groth, A. Lacroix, G. Greim, O. Mügge, W. Cross, G. Cesaro, J. Mélon, H. Seifert, etc. J. W. Retgers studied its relations with other isomorphous sulphides, selenides, and tellurides ; H. G. Grimm, with sodium bromide ; L. Royer, the growth of alkali and silver halides on the cleavage faces ; and M. Volmer and A. Weber, the growth of nuclei in supersaturated soln. The **twinning** plane (111) has contact and penetration twins sometimes repeated ; the twinned crystals are sometimes tabular, parallel to (111). A. Sadebeck, V. von Zepharovich, and W. Cross showed that the twinning planes (441), (311), and (331) in polysynthetic twinned lamellæ sometimes give rise to striations on a cleavage surface ; while A. Schrauf and

E. S. Dana showed that in some cases, the striations are secondary, probably being due to press. since M. Bauer showed that gliding planes can be artificially produced in these directions by squeezing a crystal of the mineral. This subject was investigated by A. Johnsen, and O. Mügge. R. Brauns doubted the explanation. The cubic **cleavage** of galena is often perfect. In a few rare cases—*e.g.* galena from Habach, Monte Blanc, Wermland, and Nil-St.-Vincent—galena exhibits not the cubic cleavage, but a perfect octahedral cleavage. This phenomenon has been studied by H. Sjögren, V. von Zepharovich, G. Cesaro, and J. P. Cooke. The crystals exhibiting octahedral cleavage contain 1–2 per cent. of bismuth sulphide ; and they give a cubic cleavage after being heated without change in sp. gr. The change occurs without decrepitation ; this is not what would have been anticipated, because ordinary galena decrepitates when heated ; and sudden changes in crystalline structure are often attended by decrepitation. E. Weiss, E. Bauer, and W. Cross found the **percussion figures** on galena correspond with its holosymmetry. F. Becke, and G. Tammann and W. Krings studied the **corrosion figures** obtained with hydrochloric acid, and found them to be in harmony with the holosymmetry. H. Schneiderhöhn etched the crystals with nitric acid, and examined the structure of polished sections. F. N. Guild also worked on this subject, and R. Granigg examined thin sections of the mineral. J. E. Pogue described overgrowths of cubic galena with cubic crystals of pyrite from Alaska. According to W. H. and W. L. Bragg, the **X-radiogram** of the crystal of galena shows that it has the sodium chloride arrangement with the unit cube with $a=5\cdot80$ A. P. F. Kerr, and K. S. Ramsdell studied the subject. W. P. Davey discussed the arrangement of the electrons in the atoms to fit the simple cubic lattice of galena ; and estimated the size of the contained lead atoms.

In 1690, R. Boyle [7] gave 7·14 for the **specific gravity** of " tin-ore," presumably galena ; and in 1788, R. Watson found for galena 7·115–7·636. F. E. Neumann gave 7·658 ; A. Schrauf and E. S. Dana, 7·428–7·575 ; C. J. B. Karsten, 7·25–7·70 ; H. le Chatelier and F. Bogitsch, 7·590 ; J. U. Lerch, 7·252–7·324 ; F. Katzer, 7·562 ; P. Niggli, 5·57 ; G. Tschermak, 7·51 ; A. Breithaupt, 7·539 ; J. B. Hannay, 7·766 ; and P. Pilipenko, 7·226–7·502 at 14·3°. For artificial lead sulphide, R. Schneider gave 6·77 ; L. Playfair and J. P. Joule, 6·9238 at 4° ; C. J. B. Karsten, 7·5052 for precipitated and fused lead sulphide ; and A. Mourlot, 7·48 for the sulphide prepared in the electric arc furnace. F. A. Henglein studied the mol. vol. ; and A. Reis and L. Zimmermann, the relation between the **hardness** and the mol. vol. The hardness is about $2\frac{1}{2}$ and always under 3. The cleavage was found by G. Tammann and K. Dahl to disappear at $700°\pm40°$, so that galena can then be deformed without cracking. E. Bauer studied the **plasticity** of the crystals. W. Reinders found that when powdered galena is shaken with two liquids like water and carbon tetrachloride, benzene, or ether—the powder collects at the boundary surface ; but with water and paraffin oil or amyl alcohol, only a part of the powder collects at the boundary surface. P. Walden studied the diffusion of potassium chloride through a membrane of lead sulphide. E. Madelung and R. Fuchs gave $1\cdot81\times10^{-12}$ to $1\cdot89\times10^{-12}$ dynes per sq. cm. or $1\cdot92\times10^{-6}$ kgrm. per sq. cm. for the coeff. of cubical **compressibility** ; and P. A. Bridgman, $0\cdot80\times10^{-6}$ kgrm. per sq. cm., or for the volume compressibility $\delta V/V_0=18\cdot37\times10^{-7}p-6\cdot33\times10^{-12}p^2$ at 30°, and $18\cdot93\times10^{-7}p-7\cdot14\times10^{-12}p^2$ at 75° ; and for the linear compressibility, $\delta l/l_0=6\cdot122\times10^{-7}p-2\cdot48\times10^{-12}p^2$ at 30°, and $4\cdot126\times10^{-7}p-2\cdot78\times10^{-12}p^2$ at 75°.

J. P. Joule and L. Playfair [8] gave 0·000032 for the cubical coeff. of **thermal expansion** of powdered lead sulphide between 44° and 398°. H. Kopp gave 0·000068 for galena between 14° and 48° ; F. Pfaff, 0·000055782 between 0° and 100°, and for the linear coeff. he gave 0·000018594 between 0° and 100° ; while H. Fizeau found 0·00002014 at 40°. F. Streintz said that the **thermal conductivity** of the amorphous sulphide is low and that of the fused sulphide higher. H. V. Reg-

nault [9] measured the **specific heat** of galena and found 0·05086 between 13° and 99° ; H. Kopp, 0·0490 between 16° and 51° ; J. Joly, 0·0492–0·0522 ; G. Linder gave 0·04658 at 100° ; 0·04720 at 200° ; 0·04784 at 300° ; and 0·04811 at 350°. K. Bornemann and O. Hengstenberg gave 0·0500 from 0° to 100°, and 0·0540 from 0° to 600°. E. van Aubel said that Neumann's law is not applicable. E. D. Eastman and W. H. Rodebush gave for the **molecular heat**, C_p :

	−209·2°	−191·3°	−173°	−148·8°	−118°	−93°	−76·3°	−36°	90·7°
C_p	7·71	8·80	9·59	10·10	10·90	11·13	11·50	11·86	12·16

L. Rolla found that between 0° and 100°, the sp. ht. of crystalline and fused lead sulphide are approximately the same. F. Streintz gave 0·0529 for the fused sulphide between 15° and 100°, 0·0557 for a large crystal ; 0·061–0·0699 for crystalline powder ; for the pressed powder, 0·0600–0·065 ; and for the amorphous precipitate, 0·117. The increase of the sp. ht. corresponds with a decrease in the electrical conductivity, and irregularities between 100° and 110° indicate a possible transition point.

Galena usually decrepitates when heated, but, as indicated above, some varieties can be heated without decrepitation. K. Friedrich [10] found that at about 90° some gas may be evolved which reddens litmus. G. Tammann and K. Dahl found that 400° below the **melting point**, there are signs of softening, and the material becomes quite plastic, under press., at 700°±40°. G. F. Rodwell, and J. Percy noted that lead sulphide at a red heat melts to a thin liquid which rapidly filters through the ordinary kind of fireclay crucibles without corroding their substance. A. Brun gave 830° for the m.p. of galena ; A. Lodin, between 930° and 940° ; R. Cusack, 727° ; and W. Biltz, 1112°±2°. K. Friedrich gave 1120° for the m.p. of the pure sulphide ; D. Iitsuka, 1051° ; H. Freeman, 1130° ; W. Truthe, 1106° ; J. Guinchant, 1015° ; and W. Heike, 1106°. C. F. Rammelsberg showed that the composition of lead sulphide is not changed by melting. P. Berthier, in 1830, found that much of the flue-dust in lead furnaces contained lead sulphate produced by the oxidation of the readily volatile sulphide. According to J. Percy, the molten sulphide volatilizes sensibly, and this the more the higher the temp. The vap., if protected from oxidation, condenses in a crystalline form. W. Biltz said that artificially prepared lead sulphide sublimes at 950°. A. Lodin said that galena volatilizes without melting at 860°. The **volatilization** is promoted by currents of gas such as those proceeding from the combustion of fuel in metallurgical furnaces where it sometimes occurs as a sublimate—*vide supra*. C. Zengelis obtained evidence of the volatilization of lead sulphide at ordinary temp. P. Berthier found that when heated for an hour in a covered brasqued crucible, the sulphide lost 40 per cent. of its weight at 1060°, and 75 per cent. at 1450°. F. O. Doeltz and C. A. Graumann said that volatilization occurs at 860°, for the sulphide in a current of nitrogen lost 18 per cent. in weight at this temp. in an hour, and it volatilizes more readily than the oxide. H. C. Jenkins noted that lead sulphide near its m.p. readily evaporates in vacuo, and F. Damm and F. Krafft said that a sublimate is rapidly formed at 600°. L. Merz noted a thin film of sublimate in a cathode-vacuo at 565°, and a thick one at 620°. W. C. Roberts-Austen found that lead sulphide can be rapidly distilled in vacuo at 1200° ; and R. Schenck and A. Albers found the **vapour pressure** :

	850°	917°	940°	975°	980°	995°
Vap. press. .	2·0	4·0	6·0	11·9	13·0	17·0

Galena was found by H. E. Armstrong to volatilize rapidly in a current of air ; and H. C. Jenkins found that it volatilizes more rapidly in a stream of sulphur dioxide than in vacuo, and still more rapidly in a current of nitrogen ; J. B. Hannay, however, said that it volatilizes far more rapidly in a current of sulphur dioxide or water vapour than in nitrogen. W. C. Roberts-Austen found

no more rapid volatilization in sulphur dioxide than in other gases. He showed that 9 grms. of galena in 20 secs. at 1357° lost 38·2 per cent. in sulphur dioxide and 37·7 per cent. in nitrogen, while at 1434°, 50·2 per cent. was lost in sulphur dioxide, and 72·3 per cent. in nitrogen. F. O. Doeltz said that galena volatilizes unchanged in a current of carbon dioxide at 850°. According to H. V. Collet-Descotils, lead sulphide in volatilizing changes to a supersulphide which escapes, and a subsulphide which remains ; but this statement does not agree with the observations of E. Metzger, C. C. von Leonhard, and others, who found that the composition of the sublimed furnace product is ordinary sulphide and not a super-sulphide. A. Mourlot noted a partial dissociation of the lead sulphide in the electric arc-furnace. J. Guinchant gave 1085° for the **boiling point** of artificial lead sulphide. J. Joly gave 470° for the temp. of sublimation.

The **heat of formation** of lead sulphide was found by J. Thomsen [11] to be 20·4 to 18·42 Cals. ; M. Berthelot, 20·3 Cals. ; P. A. Favre and J. T. Silbermann, 22·35 Cals. ; and P. Gunther, 20·9 Cals. The free energy of the reaction was given by L. Rolla as 1610·66 cals. per gram eq. M. Berthelot gave for the thermal value of the reaction $Pb(C_2H_3O_2)_{solid}+NH_4HS$, 19·2 Cals. ; J. Thomsen, for $Pb(NO_3)_{2aq.}$ $+H_2S_{aq.}$, 11·43 Cals. ; and $(PbO,H_2S,Aq.)=29·2$ Cals. ; M. Berthelot, 26·6 Cals. ; and P. A. Favre and J. T. Silbermann, 22·36 Cals. W. Reinders gave $PbS+PbSO_4=2Pb+2SO_2-99·543$ Cals.

P. Drude [12] found the **index of refraction** for Na-light to be 4·300 when determined by reflection from a cleavage surface ; 2·96 when a polished surface is used ; and when the surface is thoroughly cleaned, 3·313. The corresponding values for the **absorption index** were respectively 0·400, 0·629, and 0·520. The **reflecting power** was measured by E. P. T. Tyndall, and J. Königsberger ; and the **spark spectrum** by A. de Gramont. The **reflecting power** of galena was found by W. W. Coblentz to be slightly greater in the visible than in the ultra-red, where it is constant at 31 per cent. to 14μ. B. Aulenkamp, and W. W. Coblentz and H. Kohler examined the **photo-electric sensitivity** of lead sulphide ; and G. Mie, the optical resonance with X-rays.

J. W. Hittorff,[13] F. Braun, C. Doelter, T. du Moncel, O. Weigel, J. Bernfeld, F. Beijerinck, and H. Buff found the **electrical resistance** decreases with rise of temp., and the decrease is more marked at low temp. than at higher ones. The **electrical conductivity** has been examined by F. Streintz and co-workers, M. J. Huizinga, K. Bädeker, W. Mönch, G. Cesaro, A. Wesely, P. Collet, M. Padoa, etc. According to J. Guinchant, the electrical resistance, R, at $\theta°$ between $-25°$ and 920° is $R=0·000298(1+0·00501\theta-0·0_5123\theta^2)$; and for lead sulphide which had been melted $0·0_3298$ ohms at 19°. E. van Aubel measured the resistance at the temp. of liquid air and found a minimum in the curve at $-189°$. O. Reichenheim gave 0·00243 ohm at 0°. F. Streintz measured the resistance of rods made by compressing the

powdered sulphide. J. Konigsberger and co-workers, G. von Hevesy, and C. Doelter showed that the con-ductivity is probably electronic. A. C. James found the electrical conductivity of lead sulphide changes abruptly at about 160°, corresponding with the passage from α-lead sulphide to β-lead sulphide. The results are illustrated by Fig. 105, where the dotted line indicates that the temp. is decreasing while the continuous line is taken on a rising temp. F. Streintz found that the conductivity of a crystal which has been heated and cooled is higher than its original value. This is due to the presence of some of the metastable β-form. The presence of 10 per cent. silver sulphide lowered the transition temp. to 133°. The passage of

FIG. 105.—Electrical Conductivity of Galena Crystals.

a direct current through galena is accompanied by the electrolytic formation of metallic threads ; this is increased by the presence of silver sulphide, and decreased by stannous sulphide. In 1906, H. H. C. Dunwoody discovered that some crystals

will rectify an alternating current, and, in the case of carborundum, attributed unilateral conductivity to the small area of contact permitting the passage of electrons more readily in one direction than another. Other hypotheses were proposed by W. H. Eccles, G. W. Pierce, C. Florisson, and J. Strachan; and A. C. James suggested that unilateral conductivity and rectification depend on the structure of the crystals and by the fact that in solid electrolytes, the current is carried entirely by one set of ions while the other forms a fixed framework. In rectification by galena crystals, the metal ions oscillate to and fro through fixed channels of sulphur ions giving alternately metallic and non-metallic contacts. The variation of rectifying properties at different points on the crystal surface is attributed to the possible movement of metal ions without collision in some planes of the crystal, but not in others. C. W. Heaps found that the resistance of galena increases with the strength of the magnetic field, and transversely more than longitudinally as with the metals. P. Collet employed galena as a detector for long-wave radiations. G. Gehlhoff and F. Neumier measured the relation of the thermal and electrical conductivities. H. S. Roberts and L. H. Adams, and E. T. Wherry studied the **rectifying action** of galena as a radio-detector. J. Stefan found the **thermoelectric force** of galena against copper to be positive; and A. Shrauf and ·E. S. Dana found some crystals positive, others negative. Observations were also made by F. Streintz, K. Bädeker, J. Stefan, and G. Gehlhoff and F. Neumier. W. Skey found that galena is negative towards iron pyrites when both are immersed in sea-water. R. C. Wells found the **electrode potential** of galena towards N-KCl to be 0·28–0·38 volt; N-H_2SO_4, 0·32 volt; N-NaOH, 0·11; N-Na_2S, —0·19 volt. G. Tammann measured the potential of galena against a normal hydrogen electrode. R. C. Wells showed that a cathode of galena is attacked by a soln. of sodium carbonate. G. Trümpler also measured the potential of the Pb | PbS electrode in soln. of sodium sulphide. He found that the **passivity** of galena is due to the hydrolysis of the surface and the deposition of a film of sulphur; this is removed in a few minutes by 2N-Na_2S. S. B. Christy found the potential towards N-KCy to be —0·28 volt when the normal electrode is —0·56 volt; with 0·1N-KCy, —0·48 volt; and with 0·01N-KCy, —0·52 volt. K. Fischbeck studied the **electrochemical reduction** of galena. P. Gaubert [14] found the octahedral faces of galena to be good **radio-detectors,** and the cubic faces poor ones; F. Trey studied the rectifying action of lead sulphide; and H. F. Vieweg, the frictional electricity. C. B. Thwing found the **dielectric constant** to be 17·92. F. Stutzer and co-workers found the **magnetic susceptibility** to be very small.

The chemical properties of lead sulphide.—According to D. S. Price,[15] when a thin layer of freshly prepared lead sulphide is exposed to **light,** oxidation occurs, and the colour becomes white; blue-light acts most quickly, yellow-light is weaker, violet-light is still weaker, and red-light does not act at all. J. F. Sacher showed that the presence of moisture favours the action because a film hermetically sealed and exposed to light for 3 years did not show the slightest bleaching action. The action of **heat** is indicated above.

According to H. V. Collet-Descotils,[16] and J. A. Arfvedson, **hydrogen** reduces lead sulphide at a bright red heat, forming lead and hydrogen sulphide; at a lower temp., reduction does not occur. According to J. E. Reynolds, reduction can be completed. In a rapid current of gas, some sulphide is volatilized and deposited on the cooler part of the tube. J. Percy said that hydrogen sulphide continues to be evolved at low redness. G. F. Rodwell showed that the amorphous sulphide becomes crystalline when heated to 100° in a current of hydrogen. The action of **air** or **oxygen** has been discussed in connection with the roasting of galena for the extraction of the metal. The cubic or (100)-faces of the crystals of galena are sometimes bluish while the octahedral or (111)-faces are brown; L. Leo said that this is because the (111)-faces are more rapidly attacked than the (100)-faces. P. B. Ganguly and N. R. Dhar [17] found colloidal lead sulphide is oxidized by air on exposure to sunlight, forming colloidal sulphur. J. B. Hannay's idea that *lead*

oxysulphide, PbS.PbO, can be obtained lacks confirmation. C. Lückow, and F. R. Steigelmann found that electrolytic oxygen converts lead sulphide into the dioxide; and C. F. Schonbein, and A. Lamy found that **ozone** converts the sulphide into sulphate (**1**. 14, 6); and A. Mailfert said that with the prolonged action of ozone, lead dioxide is formed, and sulphuric acid set free. V. Zotier examined the catalytic action of lead sulphide on hydrogen dioxide.

G. A. Kenngott [18] reported that powdered galena from Neudorf, Harz, gives a very faint alkaline reaction when moistened with **water.** C. Doelter said galena is slightly soluble in water, and O. Weigel showed that at 18°, a litre of water dissolves $3 \cdot 6 \times 10^{-6}$ mol of the precipitated sulphide; $1 \cdot 21 \times 10^{-6}$ mol of Freiberg galena, and $1 \cdot 21 \times 10^{-6}$ mol of artificial galena; G. von Hevesy and F. Paneth gave 3×10^{-4} grm. of lead sulphide at 25°; W. Biltz, $5 \cdot 5 \times 10^{-6}$ mol at 16°–18°; and J. Knox, $5 \cdot 1 \times 10^{-8}$ mol at 25° on the assumption that ionization is complete. Owing to other probable reactions than those assumed in measuring the solubility by conductivity methods, L. Bruner and J. Zawadsky consider that the results are unreliable. R. Flatt tried to connect the solubility with the electronic structure. K. Jellinek and J. Czerwinsky gave 3×10^{-13} for the solubility product; and they showed that a more soluble form of lead sulphide may exist. According to J. Percy, when molten galena is poured into cold water, the odour of hydrogen sulphide is perceptible, the granulated product is remarkably fusible, and a sensible quantity of black powder floats on the surface of the water; even when heated to low redness, and plunged into cold water, galena becomes exceedingly friable. According to H. V. Collet-Descotils, when galena is heated in a current of steam, part volatilizes without decomposition, and part decomposes, giving off hydrogen and sulphur dioxide, and forming a residue of lead sulphide mixed with the oxide, and metallic lead. H. V. Regnault said that galena heated in a current of steam gives off hydrogen sulphide, and becomes covered with a film of lead. It is assumed that the first products of the reaction are hydrogen sulphide and lead oxide; and that the latter reacts with the remaining sulphide, forming lead and sulphur dioxide, by which again a portion of the hydrogen sulphide is decomposed. H. L. Pattinson obtained a fused residue and a large quantity of hydrogen sulphide by this reaction. J. Böhm found that in a sealed tube with air-free water at 150°–200°, hydrogen sulphide is formed; the liquid becomes alkaline, and in some cases a red powder—possibly red-lead—is formed. H. L. Pattinson, W. J. Jordan, and J. Percy also reported experiments on the action of steam on galena. A. Gautier said that at a bright red heat, galena is decomposed into its elements by water vapour, $3PbS + 2H_2O = 3Pb + 2H_2S + SO_2$, followed by $2H_2S + SO_2 = 2H_2O + 3S$. A small quantity of sulphur dioxide is evolved, and free sulphur mixed with a little lead sulphate collects in the cool part of the tube. The sulphate is probably formed by the reaction: $PbS + 2SO_2 = PbSO_4 + 2S$. J. B. Hannay's statement that *hydrated lead sulphide*, PbS.H$_2$O, is formed when galena is heated in water vapour has not been confirmed. J. Lemberg observed but a slight change when galena is boiled with a soln. of **potassium hydroxide.** For the action of the fused alkali hydroxides, *vide infra*, alkali carbonates. J. Lemberg made observations on the action of soln. of bromine in alkali-lye, of alcoholic soln. of hydriodic acid, and of soln. of silver salts.

L. E. Rivot [19] and co-workers showed that **chlorine** in the presence of water or alkali-lye furnishes lead dioxide. According to H. Rose, chlorine does not decompose galena at ordinary temp., but when heated, lead chloride and volatile sulphur chloride are formed—the yield of lead chloride, according to L. R. von Fellenberg, being 94·68 per cent. E. Schäfer found that the yield is quantitative and rapid at the m.p. of lead chloride, and more rapid and complete than the corresponding reaction with **bromine.** J. Lemberg said that bromine in alkaline soln. forms a yellowish-brown mixture of lead dioxide and oxybromide which is converted by alcoholic hydriodic acid into yellow lead iodide. According to E. Filhol and J. Mellin, **iodine** reacts vigorously on dry, powdered, artificial lead sulphide; the

decomposition is also rapid in the presence of water or other solvents for iodine ; the reaction is slow in the cold, rapid when heated ; lead sulphate was not produced. V. Lenher found that galena is insoluble in **hydrofluoric acid ;** A. Lacroix that a mixture of **hydrogen chloride** and steam transforms it into lead chloride. Galena is decomposed slowly by conc. **hydrochloric acid,** when hydrogen sulphide is evolved, and lead chloride is formed. F. Becke studied the corrosion figures made by this acid. **Aqua regia** readily forms lead sulphate and chloride. W. C. Moore said that it oxidizes more rapidly than does nitric acid—lead chloride being less ionized than the nitrate. E. A. Atkinson found that **hydrogen bromide** does not remove lead from galena at 100°, but antimony is carried off. V. Lenher found galena to be readily soluble in **hydrobromic acid,** and also in **hydriodic acid.** W. Hampe, and R. Benedikt found that hydriodic acid of sp. gr. 1·7 quickly decomposes galena, a more dil. acid requires warming. R. H. Brett said that galena is insoluble in a soln. of **ammonium chloride.** J. Percy heated a mixture of ammonium chloride and galena in a crucible until fusion occurred ; some lead chloride was formed. H. Houben found that galena dissolves with difficulty in molten **sodium chloride,** even at a high temp. J. Percy found that when a mixture of sodium chloride and galena is roasted in air, sodium sulphate, lead chloride, sulphate, and oxide are formed ; if the temp. is too high, some sulphur dioxide may be given off. C. P. Townsend reduced lead sulphide by bringing the sulphide in contact with a cathode in a fused electrolyte of sodium chloride in which the lead sulphide is almost insoluble ; the alkaline earth chlorides can be similarly employed. According to A. Levallois, the **chlorides of silver, gold, magnesium, zinc, mercury** (ic), **aluminium, tin** (ous and ic), **antimony** (ous), **iron** (ous), and **platinum** act by double decomposition on galena in the presence of water in a sealed tube at 160°. If the zinc chloride is in great excess, a sulphochloride is formed, and similarly with iron, tin, antimony, etc. Mercuric chloride also gives a colourless sulphochloride which is blackened by light. At a higher temp., silver and mercuric chlorides form lead chloride and silver or mercuric sulphide. G. Viard passed a current of carbon dioxide carrying the vapour of zinc or cadmium chloride over galena, and found that a balanced reaction occurs, e.g. $ZnCl_2 + PbS \rightleftharpoons ZnS + PbCl_2$. In the wet way, also, a balanced reaction may occur, and E. F. Anthon showed that finely divided galena will precipitate silver or copper sulphide from soln. of the respective salts. According to F. Raschig, when a soln. of cuprous chloride in sodium chloride is boiled with galena, cuprous sulphide and lead chloride are formed. When boiled with a dil. soln. of cupric chloride, cupric sulphide and lead·chloride are produced. E. Schürmann found that a soln. of ferrous chloride does not act on galena, but a soln. of stannous chloride decomposes it completely. W. Skey noted that platinic chloride soln. is slowly reduced by galena, and gold is precipitated from a soln. of auric chloride. H. Eckenroth found that an aq. soln. of **lead chloride** dissolves galena. L. E. Rivot and co-workers showed that **alkali hypochlorites,** *in statu nascendi,* oxidized galena to lead dioxide. According to R. S. Dean, when galena is treated with **iodic acid,** in the presence of hydrochloric acid, the lead furnishes lead chloride, one-third of the sulphur forms sulphuric acid, and two-thirds separate as sulphur.

According to H. de Sénarmont,[20] galena is somewhat soluble in an aq. soln. of **hydrogen sulphide** when heated in a sealed tube. L. Bruner and J. Zawadsky gave for the solubility product, $[Pb\cdot\cdot][S'']=3\cdot4\times10^{-28}$; J. Knox, $2\cdot6\times10^{-15}$; L. Rolla, $6\cdot7\times10^{-30}$; and G. Trümpler, 5×10^{-29}. The latter found that at 25°, a litre dissolves $5\cdot1\times10^{-8}$ gram-ion ; and L. Bruner and J. Zawadsky, $3\cdot1\times10^{-5}$ gram-ion. G. von Hevesy and F. Paneth found that a litre of a sat. aq. soln. of hydrogen sulphide dissolves $1\cdot5\times10^{-4}$ gram of lead sulphide. C. Doelter noted that galena is soluble in soln. of **sodium sulphide,** and I. Bernfeld reported that a litre of N-NaSH dissolves $2\cdot9\times10^{-5}$ gram-ion at 25°—this value was not accepted by G. Bodländer, and L. Bruner and J. Zawadsky because of the abnormal behaviour of the electrode of lead sulphide. P. P. Lebedeff said that a litre of N-NaSH sat. with both

lead and hydrogen sulphides contains at atm. press. and room temp., $2·58 \times 10^{-21}$ gram-ion. V. Stanek showed that no change occurs with **ammonium sulphide** in 8 hrs. at 200°. E. F. Smith found that galena at 250° is decomposed by **sulphur monochloride,** S_2Cl_2, vapour ; H. Feigel, by a soln. of sulphur mono-chloride in benzene ; and H. B. North and C. B. Conover, that galena in a sealed tube with **thionyl chloride** at 150°–175° furnishes lead chloride, sulphur dioxide and monochloride. According to A. Guerot, **sulphur dioxide** reacts with heated galena, forming a little lead thiosulphate, much lead sulphate, and sulphur, and hydrogen sulphide is evolved. H. Reinsch said that sulphur dioxide does not attack galena unless air be present, when lead sulphate is formed. J. B. Hannay's statement that *lead sulphitosulphide,* $PbS.SO_2$, is formed when galena is heated in a current of sulphur dioxide lacks confirmation. Galena is not decomposed by **sulphurous acid.** M. Berthelot showed that lead sulphide is decomposed by conc. **sulphuric acid,** hydrogen sulphide and sulphur dioxide being successively evolved ; with 60 per cent. acid, no sulphur dioxide was detected. F. Rosenkränzer measured the rate of soln. of galena in dil. sulphuric acid—0·0125–1·25 per cent.—and it was found to be proportional to the conc. of the acid, and the surface-area of the particles. The effect of temp. is independent of the size of the particles. The fact that rapid shaking is without effect on the velocity, shows that the velocity of the dissolution is not merely a diffusion velocity, and that a chemical process—possibly a gradual hydrolysis of the sulphide—precedes the dissolution. E. Jannettaz found that when **potassium hydrosulphate** and galena are triturated together, hydrogen sulphide is evolved. J. Percy heated a mixture of galena and **sodium sulphate,** and found a partial reduction to the metal, sulphur dioxide was evolved, and sodium sulphide formed. E. G. Zies and co-workers found that a 1·25 per cent. soln. of **copper sulphate** forms with galena, cupric sulphide, and with an excess of copper sulphate soln., cuprous sulphide. S. Meunier found that after galena has stood some years in contact with a soln. of copper sulphate, lead sulphate and brochantite are formed. J. Lemberg found that when galena is treated with an acidic soln. of **silver sulphate** at 60°, it acquires a dark steel-blue film of silver ; a similar deposit is formed at ordinary temp.—*vide supra* for the action of powdered galena. A. D. Carmichael said that galena reacts with **calcium sulphate** at 400°, forming lead sulphate and calcium sulphide ; on the other hand, F. O. Doeltz found that between 400° and 1100° in a current of carbon dioxide or nitrogen, there is very little action ; if a current of air be employed, the effect is analogous to that produced by roasting galena. J. Hanus, and S. H. Emmens found that when galena is boiled with a soln. of **ferric sulphate,** it is slowly converted into lead sulphate with the separation of sulphur and the formation of ferrous sulphate ; according to E. Jannettaz, acid soln. of **ferrous sulphate** also attack galena. E. Waller showed that galena is soluble in a soln. of **sodium thiosulphate ;** and T. Rosenbladt, insoluble in a soln. of **potassium thiocarbonate..**

E. C. Franklin [21] said that galena is insoluble in liquid **ammonia.** Cold dil. **nitric acid** decomposes galena, forming lead nitrate, nitric oxide, and sulphur ; fuming nitric acid oxidizes both elements, forming lead sulphate with the evolution of nitrous fumes. R. H. Brett said that galena is insoluble in a soln. of **ammonium nitrate.** C. A. M. Balling showed that freshly precipitated lead sulphide reacts with a soln. of **silver nitrate,** forming silver sulphide ; for the action of powdered galena, *vide supra.* J. Fournet [22] found that when **arsenic sulphide,** or realgar, is fused with lead, arsenic is volatilized and lead sulphide is formed : $2Pb + AsS_2 = 2PbS + As$; and J. Percy added : " It is therefore reasonable to conclude that when lead sulphide is heated with **arsenic,** it will not suffer the least reduction." P. Berthier stated that when galena is heated with **antimony,** lead antimoniosulphides are formed ; J. Fournet found after fusion, one part resembled galena, the other part antimony, and there was no line of demarcation between the two. J. Percy con-cluded that lead sulphide is not reduced by antimony. E. Schurmann found that soln. of **thallous nitrate** and of **cobalt nitrate** do not act on galena ; and that, in

general, lead sulphide is more stable towards salt soln. than the sulphides of zinc, nickel, cobalt, iron, arsenic, thallium, and manganese, and less stable than many other sulphides.

J. Fournet said that when galena is heated white-hot in a **carbon** crucible, carbon disulphide and lead subsulphides (*q.v.*) are formed. On the other hand, J. Percy described what he called a simple and pretty experiment to show the sublimation of galena :

Put some galena at the bottom of a plumbago crucible, fill up with fragments of charcoal, and lute on the cover. Heat the crucible strongly, and leave it to cool gradually in the furnace. Beautiful crystals of lead sulphide will be found deposited on the charcoal. Care must be taken not to heat the crucible to too high temp. or too long, in which case no sulphide may remain.

This means that carbon, at these temp., is without action on galena. H. C. Geel-muyden found that **calcium carbide** readily reduces galena, forming calcium sulphide, and lead. L. R. von Fellenberg said that **carbon monoxide** has only *une action très faible*, forming a little carbon disulphide. G. F. Rodwell also observed very little action when carbon monoxide or **carbon dioxide** is passed over heated galena. H. Reinsch also observed no effect with carbon dioxide, but A. Lodin said the oxidation of galena by this gas begins at about 800°. J. Lemberg found that a sat. soln. of **potassium cyanide** and potassium hydroxide dissolves galena. A soln. of cadmium acetate decomposes galena when heated under press. in a sealed tube. According to J. Percy, fused potassium cyanide reduces much of the galena, forming potassium thiocyanate and lead ; and H. Rose observed that with several re-meltings with cyanide the whole of the lead may be obtained in the metallic state. A. Levol reduced 84–84·5 per cent. of the lead in galena by heating a mixture of **potassium ferrocyanide** and that mineral. J. Percy made a number of experiments on this subject. H. C. Bolton showed that a conc. soln. of **citric acid** decomposes galena in the cold, and if potassium iodide be present, crystals of lead iodide are formed. J. Johnston, and E. Jordis and E. Schweizer observed that **carbon disulphide** dissolves sulphur from some samples of galena. L. Rosenthaler found that **mannite, glucose,** and **tartaric acid** are not adsorbed by precipitated lead sulphide, but appreciable quantities of **caffeine, amygdaline, codeine,** and **salicine** are adsorbed. A. J. Carlson and A. Woelfel found that lead sulphide is not very soluble in **gastric juice.** L. Oliver said that no miner of galena has died of plumbism in England for many years, and J. Rambousek and C. Biondi added that plumbism is practically unknown among the miners of galena ore in Bohemia, but cases have been observed among the galena miners of Sardinia.

According to P. Berthier, when galena is heated with **sodium carbonate,** there is only a partial reduction of the sulphide, and a grey fusible slag is formed containing sodium sulphate and sulphide, and lead sulphide. He showed that when galena with half its weight of sodium carbonate is heated in a retort, about 53 per cent. of lead is obtained, and he inferred that in vacuo, only 49 per cent. of lead would be reduced. He assumed that some air left in the retort contributed to the reduction, and that the reaction in the absence of air can be symbolized : $4PbS+4Na_2CO_3 =Na_2SO_4+3Na_2S+4Pb+4CO_2$. If air has access during the operation, even the whole of the lead may be reduced, but the actual results vary with the mode of operation. The sodium sulphide is at the same time oxidized to sulphate. If potassium nitrate be added to the mixture, the result is the same as when the oxygen of the air has access. Similar results were obtained with **potassium carbonate,** or with **sodium or potassium hydroxide** used as flux. The reducing action was promoted by the presence of carbon which acts by preventing the formation of alkali sulphate so that less alkali carbonate is available for the reduction than is indicated in the given equation. H. Becquerel found that a soln. of **sodium hydrocarbonate** transforms galena into crystalline lead carbonate. P. Berthier showed that when galena mixed with **calcium oxide** is heated in a

brasqued crucible, reduced lead and a slag are formed ; the slag consists of calcium and lead sulphides, and an excess of galena. W. J. Jordan [23] found that galena embedded in calcium hydroxide, in a luted crucible at the temp. of molten pig-iron, yields not a trace of reduced lead, nor was there any sign of the formation of calcium sulphide. ` If a small proportion of carbon is present, a small proportion of the galena is reduced to lead. W. Menzel also made observations on this subject. L. E. Rivot found that an intimate mixture of galena and lime at a red heat, with free access of air, furnishes calcium sulphate. P. Berthier found that **barium oxide,** with and without carbon, furnishes results analogous to those obtained with calcium oxide. W. Biltz also studied the desulphurization of lead sulphide with barium oxide ; and with **cadmium oxide** the reaction : $PbS+CdO=PbO+CdS$ begins at 440°. P. Berthier found that when galena is heated with **manganese dioxide,** sulphur dioxide is evolved, and lead, and manganese sulphide are formed : $PbS_2+MnO_2=Pb+MnS+SO_2$; he also stated that galena reduces **ferric oxide** to a lower degree of oxidation and that sulphur dioxide is evolved, but the lead appears to be reoxidized by another portion of the ferric oxide. W. J. Jordan did not get the least trace of lead by heating a mixture of hæmatite and galena, but in the presence of carbon, the galena reacts by reducing the iron oxide and the iron reacts by reducing the galena to metallic lead. The peculiar actions of **lead oxide,** and of **lead sulphate** on galena have been previously discussed ; according to H. C. Jenkins, there are no grounds to justify the assumption that a complex *lead sulphatosulphide* has been formed. L. Kahlenberg and W. J. Trautmann studied the reduction of lead sulphide when heated with powdered **silicon.** J. Percy represented the reaction between **ferrous silicate** and galena by the equation : $2Fe_3SiO_5+5PbS=2Fe_2SiO_4+2PbFeS_2+SO_2+3Pb$. J. Percy found that **lead silicates** are partially decomposed by galena. E. Grieshammer showed that molten **glass** readily dissolves galena from which, on cooling, it separates in cubic crystals. E. Dittler showed that a colloidal soln. of **molybdic acid** is coagulated by a trace of lead sulphide ; soln. of molybdic acid attack galena very slowly.

Galena is reduced by **iron,** forming lead and iron sulphide. Iron is used as a reducing agent in assaying galena, and in the smelting of lead. Cast-iron is considered to be better than wrought-iron. Observations on this subject were reported by B. Kerl, J. Fournet, and J. Percy. The reaction was represented : $3PbS+3Fe=2Pb+PbS.Fe_2S.FeS$. J. Fournet found that when galena and **tin** are fused in a crucible, the mixture separates into two layers—the lower layer being an alloy of lead and tin, and the upper layer, a double sulphide of tin and lead. J. Percy also reported experiments on this subject. P. Berthier, and C. J. B. Karsten found that galena is reduced when heated with **copper.** J. Percy, and W. Guertler reported that the regulus which is formed is a double sulphide of copper and lead. J. Fournet reported that galena does not react with **zinc** at a red heat. J. Percy showed that galena is reduced by zinc furnishing " a hard, dull, black, porous mass in which lead sulphide and globules of lead are entangled." N. Parravano and P. Agostini found that **aluminium** readily reduces galena. According to F. M. Perkin, when a mixture of galena and **calcium** is inflamed lead and a complex calcium lead sulphide are formed. F. M. Perkin and L. Pratt showed that a mixture of galena and **calcium hydride** gives a similar product. H. G. Grimm studied the mixed crystals of lead sulphide and **sodium bromide.** J. L. Smith examined the action of alkali salts on lead sulphate. G. Tammann studied the reaction between **cadmium oxide** and lead sulphide.

The higher sulphides of lead.—L. Playfair and J. P. Joule [24] referred to a *lead sesquisulphide*, Pb_2S_3, of sp. gr. 6·335, but the existence of this compound has not been confirmed. The mineral was named by W. Haidinger *johnstonite*—after J. F. W. Johnston who studied the *supersulphuretted lead* obtained by W. Phillips from Dufton, Westmoreland. The mineral resembles galena, but it contains a higher proportion of sulphur than the Pb : S of galena. In some cases 14 per cent. excess has been reported. Examples have been reported by W. Haidinger, A. Raimondi,

F. Roemer, and A. Förster. C. F. Rammelsberg, R. P. Greg and W. G. Lettsom, and others are of the opinion that the so-called johnstonite is a mixture of galena and sulphur produced by the decomposition of a portion of the mass. A. Hutchinson and W. Pollard tried in vain to prepare *lead disulphide*, PbS_2, by the action of hydrogen sulphide on solid or dissolved lead tetracetate ; but H. Reinsch, and K. A. Hofmann and V. Wölfl consider that the sulphohalides which they prepared contained the group PbS_2 in combination with the lead halide. J. J. Berzelius also supposed that a polysulphide, probably **lead pentasulphide,** PbS_5, could exist as a reddish-brown precipitate when potassium pentasulphide is added to a soln. of a lead salt, but it breaks down very quickly into a brown mixture of lead sulphide and sulphur. F. Bodroux prepared the pentasulphide by adding a soln. of calcium polysulphide to an excess of a dil. soln. of lead nitrate cooled to 0°, washing the precipitate successively with water, alcohol, and carbon disulphide ; and drying at a low temp. over sulphuric acid. The purple-red product is stable only below 10°, above that temp. it decomposes into the monosulphide and sulphur. It is insoluble in soln. of the alkali sulphides ; cold nitric acid decomposes it rapidly with the separation of sulphur, and the formation of lead nitrate.

The lead sulphohalides.—V. Lenher's attempts [25] to make *lead sulphofluoride* analogous to the sulphochloride were not successful, because of the low solubility of lead fluoride in water, in soln. of the alkali fluorides, and in hydrofluoric acid. W. Truthe observed no sign of the formation of a compound in the f.p. curve of mixtures of lead sulphide and chloride, Fig. 106. The simple V-curve has a eutectic at 441° with 22 per cent. of lead sulphide. L. Hünefeld noticed that when hydrogen sulphide water is added to an aq. soln. of lead chloride, the precipitate first produced is yellowish-red, and then red when it contains about $3PbS.2PbCl_2$. The addition of an excess of hydrogen sulphide changes the precipitate into black lead sulphide, and the same change occurs when the red precipitate is boiled with water which extracts lead chloride. H. Reinsch added that when hydrogen sulphide is passed into a soln. containing 0·5 part of lead acetate in 100 parts of water mixed with 10 parts of hydrochloric acid of sp. gr. 1·168, a carmine-red precipitate of lead sulphochloride is formed ; and if the soln. contains 1 part of lead acetate, 112 parts of water, and 14 parts of hydrochloric acid, a yellow precipitate is formed. When boiled with water these precipitates furnish a soln. of lead chloride and a precipitate of black lead monosulphide. If instead of using 14 parts of hydrochloric acid, 14 parts of a mixture of hydrochloric and nitric acids be used in the proportion of 2 : 1, prepared two days previously, there is first produced a yellowish-red and then a vermilion-red granular precipitate. If the hydrogen sulphide treatment be continued, the red precipitate becomes brown and finally black. When the vermilion-red precipitate is boiled with water, it gives a soln. of lead chloride, and a brownish-red flocculent powder which, when heated in a glass tube, gives off sulphur, and hydrogen sulphide, and fuses to dark brown lead sulphide. Hence it was assumed that the vermilion-red precipitate is a compound of lead chloride and polysulphide. V. Lenher obtained the red sulphochloride (i) by digesting the freshly precipitated lead sulphide with a soln. of lead chloride, and (ii) by treating galena with conc. hydrochloric acid until hydrogen sulphide is steadily evolved, and then adding water. White lead chloride is first precipitated, then the red sulphochloride, which is converted by an excess of water into black lead sulphide.

F. Parmentier said that the red precipitate obtained by passing hydrogen sulphide into a soln. of lead chloride in dil. hydrochloric acid is **lead sulphodichloride,** Pb_2SCl_2. This is decomposed by water, acids, and alkali-lye. The alkali-lye first blackens the red sulphochloride, and afterwards changes it to a white, flocculent mass. N. Tarugi claimed to have made **lead trisulphodichloride,** $3PbS.PbCl_2$, by

FIG. 106.—Freezing-point Curve of Mixtures of Lead Sulphide and Chloride.

the action of thioacetic acid on a very dil. soln. of lead chloride. The red precipitate becomes brown lead sulphide when treated with hot water. K. A. Hofmann and V. Wölfl found that by treating an excess of a cold soln. of lead chloride with very dil. ammonium polysulphide, red-coloured **lead hexasulphodichloride,** $Pb_4S_6Cl_2$, is produced ; and it is assumed that the compound is not to be regarded as $4PbS.S_2Cl_2$, but rather as $3PbS_2.PbCl_2$, that is, $Cl.Pb.S.S.Pb.S.S.Pb.S.S.Pb.Cl$. The same compound was made by mixing one part of a cold sat. soln. of lead chloride (1 : 100) and 1·5 parts of a soln. of 4 grms. of sodium thiosulphate in 100 c.c. of water in a vessel cooled with ice, and exposed to sunlight. In a few hours, the red precipitate is separated by filtration, washed with ice-cold water, then with alcohol, and finally with ether, and dried in vacuo over sulphuric acid. If the experiment be made in darkness, or in diffused daylight, black lead sulphide is formed. The red sulphochloride decomposes above 0°, and in darkness into black lead sulphide.

F. Parmentier reported **lead sulphodibromide,** Pb_2SBr_2, to be formed by the action of hydrogen sulphide on a dil. soln. of lead bromide in conc. hydrobromic acid, as in the case of the corresponding chloride. V. Lenher also made it by digesting galena with conc. hydrobromic acid until hydrogen sulphide is being steadily evolved, and treating the product with a large proportion of water. The brick-red product resembles the sulphodichloride, but is rather more stable. V. Lenher tried to make lead sulphoiodides, analogous to the sulphochloride, but on account of the low solubility of lead iodide in dil. hydriodic acid, the results were fruitless. Lead iodide dissolves readily in conc. hydriodic acid, but the action of hydrogen sulphide on this soln., furnishes neither the sulphide nor the iodosulphide. If, however, an aq. soln. of hydrogen sulphide be added to the hydriodic acid soln. of lead iodide, yellow lead iodide is first deposited, and with a further addition of more hydrogen sulphide, the yellow iodide changes into brick-red **lead sulphocto-iodide,** $PbS.4PbI_2$, or Pb_5SI_8. This is separated by suction, washed sucessively with a conc. soln. of potassium iodide, cold water, carbon disulphide, and absolute alcohol, and then dried by a current of cold air. The same compound is produced when an aq. soln. of hydrogen sulphide acts on a soln. of lead iodide and potassium iodide. The same compound was produced by treating freshly precipitated lead sulphide with conc. hydriodic acid, and diluting the soln. with much water as in the case of the sulphobromide. He then assumed that " whatever the method of preparation, the red sulphoiodide has always the same composition." This brick-red sulphide is yellower than either the sulphochloride or the sulphobromide. It is slowly decomposed by the prolonged action of light ; and rapidly by heat, acids, or alkali-lye. An excess of hydrogen sulphide water changes it to brown and finally black lead sulphide. A soln. of sodium carbonate furnishes lead sulphide and carbonate, and sodium iodide. F. Parmentier said that he made *lead sulphodiiodide,* Pb_2SI_2, by the action of hydrogen sulphide on a soln. of lead iodide in hydriodic acid ; the product was stated to be impure because of the low solubility of lead iodide in the acid, and the difficulty in completely removing free iodine. K. A. Hofmann and V. Wölfl employed methods analogous to those used for lead hexasulphodichloride, and obtained **lead tetrasulphodiiodide,** $Pb_3S_4I_2$, or $2PbS_2.PbI_2$, that is $I.Pb.S.S.Pb.S.S.Pb.I$, the copper-red, microcrystalline powder consisting of dendrites and plates. It is said to be more stable than the hexasulphodichloride. At 100°, it forms a black mass of minute, prismatic crystals. When strongly heated, lead iodide and sulphur sublime, leaving behind scaly crystals of lead sulphide resembling graphite.

J. Sterba-Böhm and M. Auerspergrova [26] were not successful in their attempt to make **lead disulphide,** PbS_2, by the action of hydrogen sulphide on lead dioxide. With the gaseous sulphide a product was obtained containing some combined and some free sulphur. It was thought that the following reactions occur : (i) $PbO_2 + H_2S = PbO + S + H_2O$; and (ii) $PbO_2 + 2H_2S = PbS + S + 2H_2O$. The first predominates where liquid hydrogen sulphide is used at ordinary atm. press. ; and the second predominates at 100°—*vide* the action of hydrogen sulphide on lead

dioxide. An aq. soln. of potassium sulphide reacts very slowly on lead dioxide, forming lead sulphide. Gaseous hydrogen sulphide gives lead sulphide with a soln. of lead tetrachloride in methyl alcohol.

Complex salts with lead sulphide.—P. Niggli and K. Faesy.[27] studied the complex lead sulphide minerals. According to P. Berthier, when a mixture of lead and sodium sulphates is heated to whiteness in a charcoal crucible, there are formed lead, and an impure *sodium lead sulphide* approximating $2Na_2S.3PbS$, or $Na_2S.PbS$—*sodium thioplumbite*. The shining, lead-grey, brittle mass has a close fracture, and when digested with water furnishes a soln. of sodium sulphide and lead sulphide probably mixed with excess lead. H. Freeman gave 650° for the m.p. of $Na_2S.PbS$. C. Immerwahr measured the potential of lead towards a 0·05N-soln. of sodium hydrosulphide with lead sulphide in suspension. A number of complex **cuprous lead sulphides** have been reported occurring either as minerals, or in furnace products. K. Friedrich measured the f.p. curves of mixtures of cuprous and lead sulphides, and found no evidence of the existence of any compound. The curve is of the V-type with a eutectic at 541°, and 51 per cent. of cuprous sulphide. W. Guertler and K. L. Meissner studied portions of the ternary systems Cu–Pb–S ; Pb–Cu–Cu_2S ; Pb–Cu_2S–PbS ; and Cu_2S–PbS–S. A fused mixture of $9Cu_2S.2PbS$ was found by J. Fournet to have the same texture as galena ; and a mixture, $3Cu_2S.2PbS$, gave, after fusion, a black radiated mass resembling cuprous sulphide. C. J. B. Karsten also reported that when copper is fused with an excess of galena, an alloy of copper and lead, and a compound of lead and copper sulphide, are formed. A. Breithaupt applied the term **cuproplumbite,** and M. Adam, *plumbocuprite,* to a massive mineral approximating $Cu_2S.2PbS$; and F. P. Dunnington applied the term to a mineral approximating $5Cu_2S.PbS$. J. A. Antipoff reported minerals with the same composition. F. Field applied the term *alisonite*—after R. E. Alison—to a deep blue mineral approximating $3Cu_2S.PbS$. F. Ulrich, and A. Schertel described similar minerals. F. A. Genth found a furnace product from Argo, Colorado, with the 3 : 1 composition. W. H. Newhouse observed the formation of a similar mineral by the action on galena of the weathered products of some copper ores. A. Lodin, and P. Groth described a related mineral with the composition $2Cu_2S.PbS$. A. Brand obtained mixed crystals $Cu_2S.PbS$ along with some ferrous sulphide as a furnace product ; and B. von Cotta, one with the composition $9Cu_2O.5PbS$. J. Fournet heated to whiteness a mixture of lead and silver sulphides in a carbon crucible, and obtained besides metallic silver, a product resembling galena—probably not *silver lead sulphide*. W. Guertler and E. Lüder studied the ternary system Pb–Ag–S, and the quaternary system Pb–Cu–Ag–S. K. Friedrich found no evidence of any compound on the f.p. curve. The curve is the simple V-type, with a eutectic at about 630° and 77 per cent. of silver sulphide, Fig. 108. The transformation of silver sulphide
FIG. 107.—Freezing-point Curve of Mix-
tures of Lead and Cuprous Sulphides.
FIG. 108.—Freezing-point Curves of Mix-
tures of Lead and Silver Sulphides.

occurs at about 175°. J. S. Maclaurin passed sulphur vapour into a molten alloy of silver and gold to saturation, but it is not clear if a complex *gold lead sulphide* was formed—probably not.

P. Berthier heated to whiteness a mixture of lead sulphide and barium sulphate in a carbon crucible, and obtained what he regarded as a *barium lead sulphide*. Much lead sulphide volatilized during the operation. The crystalline product is decomposed by water, forming a soln. of barium sulphide, and a mass of lead sulphide. J. Fournet also fused mixtures of lead and barium sulphide without definite results. According to W. Menzel, and O. W. Brown, it is possible that a *calcium lead sulphide* is formed as a furnace product when galena is heated with calcium oxide and carbon ; or when mixtures of the two sulphides are heated. F. M. Perkin and L. Pratt said it is produced as a slag when galena and calcium or calcium hydride are heated. Several analyses show the existence of zinciferous galena—*e.g.* according to A. Liversidge,[28] a mineral at Broken Hill has 15 per cent. of zinc ; and H. A. Miers and co-workers found one corresponding with $ZnS.4PbS$ in octahedral crystals from Bingham, Utah. K. Friedrich made an incomplete study of the system with lead and zinc sulphides. There is no evidence of the formation of *zinc lead sulphides* as chemical individuals, Fig. 109. I. Domeyko referred to a *galena blendosa* from Ingahaas, Huasco, which was called by J. D. Dana, *huascolite*. It is a

FIG. 109.—Freezing-point Curves of Mixtures of Lead and Zinc Sulphides.

bluish-grey massive mineral, and was analyzed by D. Forbes. Its composition approximates $Zn_3Pb_2S_4$. A. Raimondi, and C. F. Rammelsberg represented a sample from Dos de Mayo, Peru, called *pavonado blanco* or *chumbe blanco*, by Zn_7PbS_6 ; L. Pflücker y Ryco, the steel-grey crystals from Tuctu, Peru, by $ZnS.PbS$; I. Domeyko, a sample from Morochocha, Peru, by $(Zn,Fe)S.PbS$; and C. R. C. Tichborne regarded a sample from Kilmacoo, Wicklow, Ireland, which was called *kilmacooite*, as an argentiferous galenic blende. G. A. Kenngott regarded huascolite, etc., as intimate mixtures of galena and blende—*vide* the sulphostannates. J. B. Hannay called a mineral from Ballarat, Victoria, *youngite*—after J. Young. Its composition approximated $24ZnS.5MnS.5PbS.2FeS$. Its homogeneity is doubtful.

G. Canneri and L. Fernandes [29] measured the f.p. curves of the binary system *lead and thallous sulphides*. They found that thallous sulphide and lead sulphide, completely miscible in the liquid state, are only partly so in the solid state, conjugate solid soln. containing respectively 3 and 75 per cent. of lead sulphide separating at 290°. This system possesses a eutectic mixture, containing 40 per cent. of lead sulphide, m.p. 290°, Fig. 110. Lead sulphide precipitated from slightly acid soln. containing thallium contains up to 4 per cent. of thallous sulphide. The results indicate the probable occurrence of thallium in arsenic minerals as thiosalts in solid soln. in the corresponding lead salts, whilst in galena the thallium occurs as sulphide in isomorphous mixture with lead sulphide.

§ 30. Lead Sulphates

H. G. Denham [1] prepared **lead subsulphate,** Pb_2SO_4, by passing the vapour of methyl sulphate over lead hemioxide, at 280° ; and C. Féry said that this substance is produced at the cathode during the normal discharge of a lead accumulator. The dark iron-grey powder, said C. Féry, is a feeble conductor of electricity, and is readily oxidized to the normal sulphate. H. G. Denham found that when heated to 120° above the m.p. of lead it does not alter its appearance, and no lead is separated ; this is not likely to be the case if the alleged subsulphate were a mixture of finely divided lead and normal lead sulphate. The subsulphate is more soluble in alcohol than the normal sulphate ; it is decomposed by water ; and by acids, forming lead and normal lead sulphate.

Normal **lead sulphate,** $PbSO_4$, was first reported in 1779 by A. G. Monnet [2] as a mineral product of the decomposition of galena ; he called it *vitriol de plomb ;* and T. Bergman, in 1782, described it as *plumbum acido vitriolico mineralisatum.* W. Withering noted that an " immense quantity " of " lead mineralized by vitriolic acid " exists in the Island of Anglesey, and F. S. Beudant applied to it the name **anglesite**—A. Breithaupt, *sardinian ;* and G. S. O. Lasius, *Bleiglas.* J. L. Proust made observations on *vitriol de plomb* from Andalusia. Analyses of anglesite or of lead sulphate have been reported by M. H. Klaproth, J. J. Berzelius, P. Berthier, C. F. Bucholz, J. S. Stas, E. A. Smith, S. T. Tyson and G. J. Brush, W. J. Jordan, F. Stromeyer, etc.

The mineral commonly occurs in cavities in galena, or on the surface of that ore. The mineral has been found at Leadhills and Wanlockhead, in Scotland ; Cumberland, Derbyshire, and Cornwall, in England ; the Harz, Silesia, in Germany ; Felsöbanya, in Hungary ; Nerchinsk, in Siberia ; Schwarzenbach and Mies, in Carinthia ; Monteponi, in Sardinia ; Linares, in Spain ; Sierra Mojada, in Mexico ; Phenixville, Pennsylvania ; Missouri lead mines ; Castle Dome district, Arizona ; Rossie, New York ; Southampton, Massachusetts ; Walton gold mine, Virginia, etc. Large quantities have been imported in England from Australia. In some cases, fine, transparent, prismatic crystals are found, *e.g.* at the mines on Parys, Island of Anglesey ; and, added J. Percy :

At those interesting and picturesque copper mines and quarries, decomposition of copper and iron pyrites by weathering action is perpetually in operation on a large scale ; and as galena, chiefly in admixture with blende, is found there, the formation of anglesite as a secondary product is easily conceivable.

In confirmation, J. Hanus, and S. H. Emmons found galena is attacked by soln. of ferric sulphate ; and E. Jannettaz, by acid soln. of ferrous sulphate such as are generated by the oxidation of pyrite or marcasite. The association of galena with

pyrites is therefore favourable to the formation of anglesite. In some cases, the native sulphate formed from galena is still cleavable in the direction of the cubic faces of the parent crystals. According to A. Lacroix and co-workers, anglesite occurs as a recent formation in the lead slags of Laurion, Greece ; and in the lead tubes of the Roman thermal springs of Bourbonne-les-Bains. A. Russell found anglesite on the cavernous masses of lead mixed with charcoal, taken up in 1846 below the partly fused lead pump of a fireship sunk in Falmouth Harbour in 1780. A. Scacchi, and F. Zambonini observed anglesite in the ejecta of Vesuvius. J. F. L. Hausmann found anglesite as a furnace product, but F. O. Doeltz and C. A. Graumann observed non-crystalline lead sulphate in the flues of lead furnaces. L. Michel detected anglesite in cavities in some old lead slags of Poullasuen, Finistère. F. Kuhlmann observed the formation of anglesite in the lead chamber of a sulphuric acid works.

According to H. C. Jenkins and E. A. Smith,[3] lead sulphate is produced when sulphur dioxide is passed over molten lead. If the temp. is near that of molten lead, a considerable proportion of sulphur trioxide is present in the effluent gases, but by working well above the m.p. of lead, but below 400°, the proportion of sulphur trioxide is small. Lead sulphide is formed at the same time. They suggest that the reactions involved are : (i) $Pb+3SO_2=PbS+2SO_3$, followed by $Pb+2SO_3=PbSO_4+SO_2$. Lead sulphate is formed when sulphuric acid and lead are heated together. P. A. Mackay said that lead is rapidly dissolved at 150° by the fuming acid ; and when once the reaction has begun, complete conversion into lead sulphate occurs without further application of heat, or at least a temp. not exceeding 100°. If the lead be first coated with an electronegative metal—e.g. mercury or copper—or if such metals be added to the acid during the operation, the working temp. is reduced to 50°–100° with a violent exothermal reaction. The lead sulphate is precipitated by diluting the soln. O. Schott showed that the amorphous sulphate can be crystallized by fusion with sodium, calcium, or lead chloride ; and F. Guthrie, by fusion with potassium nitrate. P. Gaubert obtained the lead sulphate in crystals by evaporating to dryness a soln. of the amorphous sulphate in boiling sulphuric acid. L. Bourgeois heated the amorphous sulphate with dil. hydrochloric acid (1 : 2) in a sealed tube at 150° ; or for a short time at 100° with conc. sulphuric acid. A. H. Eyles and co-workers made the sulphate by passing the dust of molten lead mixed with an oxidizing agent into dil. sulphuric acid. According to J. A. Wilkinson, when molten lead is treated with conc. sulphuric acid, persulphuric acid, or ammonium persulphate, a bluish-white luminescence appears as the mass is solidifying. This can best be seen by stirring the mass with a glass rod, and as it solidifies, a bluish-white streak will follow the rod. Lead sulphate is slowly formed when lead is placed in contact with dil. sulphuric acid exposed to air, and lead is also attacked with the formation of lead sulphate by aq. soln. of other sulphates (vide lead). If sulphuric acid be left in contact with lead oxide or its salts, or with one of the higher oxides of lead, lead sulphate is formed. H. Rose said that at ordinary temp. lead oxide does not absorb the vap. of anhydrous sulphuric acid. J. B. Senderens made the sulphate by boiling lead oxide, hydroxide, dioxide, carbonate, or acetate, or red-lead, with sulphur and water ; D. L. Hammick passed sulphur dioxide over lead oxide ; and F. O. Doeltz and C. A. Graumann treated lead oxide with sulphur trioxide at 900°. Red-lead, or lead dioxide reacts with sulphur dioxide at ordinary temp., forming lead sulphate ; sulphurous acid, or hot conc. sulphuric acid, may also be employed. H. B. North and A. M. Hagemann noted its formation when lead dioxide and thionyl chloride are heated in a sealed tube at 150°.

Lead sulphate is formed during the roasting of lead sulphide, and hence the presence of the sulphate in the flue-dust of smelting furnaces. This subject was investigated by F. Dempwolff—vide supra. C. von Ernst found that the presence of calcium oxide favoured the formation of the sulphate. J. Gitsham and H. R. Evershed oxidized the vapour of lead sulphide volatilized in an electric arc

furnace. E. Jannettaz noted that lead sulphate is formed by the trituration of a mixture of galena and potassium hydrosulphate. A. C. Becquerel obtained crystals of lead sulphate by allowing a mixed soln. of copper sulphate and sodium chloride to stand in contact with galena for a few years. G. Piolti, by the prolonged immersion of galena in a soln. of potassium nitrate, and also by the immersion of iron pyrites in a soln. of lead nitrate for 16½ years, obtained slender needles of anglesite on the pyrites. Lead sulphate is precipitated as an amorphous powder when dil. sulphuric acid, or an aq. soln. of a soluble sulphate, is added to an aq. soln. of a salt of lead—e.g. nitrate or acetate. A. Findlay said the precipitation is slower than is the case with lead iodide. L. L. de Koninck ignited the precipitate after washing it with a 0·7 per cent. soln. of ammonium sulphate. J. W. Mellor has discussed the contamination of the precipitated sulphate with adsorbed salts. J. A. Wilkinson observed no luminescence when a sat. soln. of lead sulphate is treated with conc. sulphuric acid, or a boiling sat. soln. of sodium sulphate. C. Winkler, and K. A. Hofmann heated lead nitrate with sulphuric acid to 400°–420°, and found some free acid still remained. J. Milbauer and K. Kohn dropped sulphuric acid into a boiling nitric acid soln. of lead diammoniate, and obtained rhombic crystals of lead sulphate. A. Drevermann found lead sulphate crystals are produced in the preparation of lead chromate if the potassium chromate used for the precipitation contains some sulphate. F. Auerbach and H. Pick treated a suspension of lead carbonate in a soln. of sodium sulphate with carbon dioxide, best under press., and obtained lead sulphate. A. Macé obtained crystallized lead sulphate by adding a soln. of ferrous sulphate very slowly to one of lead nitrate ; and an analogous process was used by C. E. Guignet, A. de Schulten, E. Frémy, and E. Masing, where a soluble sulphate was allowed to diffuse very slowly into one of a lead salt. N. S. Manross obtained crystals of anglesite by fusing lead chloride with sodium sulphate ; and also by hanging a strip of lead in a soln. of potassium sulphate. F. Zambonini made crystals of the sulphate by the action of vapours of lead chloride and sulphur trioxide. J. Gitsham and H. R. Evershed passed the powdered sulphide through the arc of an electric furnace. C. G. Schlüderberg obtained the amorphous sulphate by the electrolysis of sulphuric acid with a lead anode—with an alternating current an electrodic luminescence occurred, but not with a direct current. The phenomenon was also studied by J. A. Wilkinson.

J. Hausmann observed that rhythmic precipitation of lead sulphate is produced by diffusion in gelatine. E. Hatschek found that the spaces between the strata consist of aggregates—partly sheaf-like bundles, and partly spherical aggregates, while the strata themselves consist almost exclusively of individual crystals. W. P. Dreaper found that when lead sulphate is formed by diffusion of a 5 per cent. soln. of potassium sulphate and a 2 per cent. soln. of lead acetate in a capillary tube, the stratification occurs. In about 2 months, the colloidal precipitate begins to crystallize. E. H. Büchner and J. Kalff obtained **colloidal lead sulphate** by dropping a dil. soln. of a lead salt into one of a soluble sulphate, but they could not obtain a clear gel. H. Schiff treated an alcoholic soln. of lead acetate with sulphuric acid, and obtained a starch-like mass of sulphate. P. P. von Weimarn also studied the precipitation of colloidal lead sulphate. W. Leuse treated a mixed soln. of sodium protalbinate, lead acetate, and sodium hydroxide with a soln. of sodium sulphate. The lead sulphate is not precipitated. When dialyzed in water, a brown sol is obtained which becomes opalescent and milky in about 12 hrs.

The physical properties of lead sulphate.—Lead sulphate prepared by precipitation is a white powder ; and it can be obtained in colourless or white crystals. Anglesite was found by Z. Toborffy [4] in colourless crystals ; it may also occur in white crystals tinged more or less grey, blue, violet, yellow, or green. J. G. Bornemann said that the green colour is due to the presence of a copper salt ; F. Millosevich, ferrous sulphate. The **crystals** of anglesite are sometimes tabular but more often prismatic ; or pyramidal of various types. The mineral also occurs massive, granular or compact ; sometimes stalactitic ; and sometimes nodular, enclosing

a nucleus of galena with a concentric structure made up of layers of a different colour. The crystals were described by R. J. Haüy, N. von Kokscharoff, N. S. Manross, E. V. Shannon, L. Bourgeois, A. Pelloux, V. von Zepharovich, A. Schrauf, Q. Sella, V. Goldschmidt, R. Helmhacker, A. F. Rogers, E. H. Kraus and A. B. Peck, F. Hessenberg, F. Millosevich, H. Dauber, A. de Schulten, A. Franzenau, E. Repossi, Z. Toborffy, O. C. Farrington and E. W. Tillotson, P. Hermann, J. Milbauer and K. Kohn, A. Drevermann, etc. A. Breithaupt's sardinian was said to be monoclinic; but F. M. Jäger and H. C. Germs regard this as doubtful. Artificially prepared, and natural crystals of anglesite are rhombic bipyramids which, according to V. von Lang, have the axial ratios $a : b : c = 0.7852 : 1 : 1.2894$. R. Kolb measured the change in the crystal angles with variations of temp. The crystals of anglesite are isomorphous with those of barytes, celestine, and aragonite. A. Fock observed mixed crystals were formed with barium sulphate. P. Gaubert made observations on this subject. T. V. Barker obtained growths of crystals of potassium perchlorate and permanganate on crystals of anglesite. As indicated above, pseudomorphs after galena are not uncommon; R. S. Dale reported pseudomorphs after cubic alum. The (001) and (110) **cleavages** of anglesite are distinct. The faces (110) and (100) are often striated vertically; and the (102)-face, horizontally. The **optical character** is positive. A. des Cloizeaux found the **optic axial angles** $2H = 89° 44'$ to $90° 59'$; $2V = 66° 45'$ to $66° 47'$—with the red ray, $2V = 66° 40'$, and with the yellow ray, $2V = 60° 50'$. W. Ramsay made observations on this subject. A. Arzruni gave for the D-ray, $2V = 75° 24'$ at $20°$; $77° 40'$ at $50°$; $82° 44'$ at $100°$; and $89° 17'$ at $200°$. F. M. Jäger and H. Haga, R. W. James and W. A. Wood, and H. Mark discussed the **X-radiograms** of these crystals. O. Lehmann studied the growth of the crystals under the microscope. According to G. Tammann and Q. A. Mansuri, the crystallization of the powder begins at $310°–316°$. R. Schenck and W. Rassbach found that there is an enantiomorphous **transition point** at $850°$, showing that the crystals are dimorphous. The crystals of α-anglesite are rhombic, and those of β-anglesite (above the transition temp.), monoclinic. J. B. J. D. Boussingault gave $856°$ for the transition temp.; A. Hare, $866°$; and H. C. Germs, and F. M. Jäger and H. C. Germs, $864° ± 1°$. The last-named say that the heat of the transformation is considerable.

The **specific gravity** of lead sulphate was given by C. J. B. Karsten[5] as 6.1691; E. Filhol gave 6.30; A. Gorgeu, 6.16; O. Pettersson, 5.97 at 16.8°, and 5.96 at 17.1°; H. G. F. Schröder, 6.329 for the native sulphate, and 6.212 for precipitated; J. L. Smith, 6.35; F. Field, 6.20; E. H. Kraus and A. B. Peck, 6.35; A. de Schulten, 6.393 at 15°; R. Popper, 6.380; and P. Niggli, 6.393, and for the eq. vol., 47.4. F. A. Henglein, and A. Balandin studied the mol. vol. G. Tammann and Q. A. Mansuri observed evidence of the coalescence of particles by crystallization at $310°–316°$. The **hardness** is 2.75–3.0. F. Paneth made observations on the surface area of granules of lead sulphate. E. Madelung and R. Fuchs gave for the **compressibility** coeff. of anglesite, $1.87 × 10^{-12}$ dynes per sq. cm. H. V. Regnault[6] gave 0.08723 for the **specific heat** of artificial and calcined lead sulphate between 18° and 99°; H. Kopp gave 0.0827 for anglesite between 19° and 49°, and F. E. Neumann, 0.0827 between room-temp. and 100°.

J. Percy showed that lead sulphate is permanent at a low red-heat, provided reducing agents are absent. F. Guthrie said that the compound melts at a white heat. P. Berthier, and J. B. J. D. Boussingault stated that at a white heat the sulphate softens and becomes enamel-like with the evolution of a little sulphur dioxide. J. Percy showed that at bright redness in a fireclay crucible, a crystalline basic sulphate is formed; the reaction with the silica of the crucible interferes with the result. P. Berthier, indeed, showed that all the sulphur trioxide can be expelled by calcining the sulphate with silica or clay. O. L. Erdmann also found that the sulphate becomes coloured and loses in weight if calcined in an open or in a loosely covered crucible;

J. L. Gay Lussac made analogous observations; and J. B. J. D. Boussingault added that all the sulphur trioxide can be removed at a white heat in an open crucible. W. Grahmann, F. M. Jäger and H. C. Germs, and F. O. Doeltz and C. A. Graumann showed that the sulphate decomposes between 900° and 1000°; H. C. Hofman and W. Wanjukoff showed that in an open tube, in dry air, decomposition begins at 637°, and is marked at 705° when the residue has the composition $5PbO.5SO_3$; at 952°–962°, $2PbO.SO_3$. M. Bodenstein and W. Pohl said that the decomposition is marked at 700°; and with the purified sulphate, W. Mostowitch observed no change at 800° in a current of dry air, but decomposition begins above 800° and a mixture of lead oxide and sulphate is formed. The mixture $PbO.PbSO_4$ melts between 900° and 1000°. F. M. Jäger and H. C. Germs said that an accurate determination of the **melting point** is not possible because the salt begins to dissociate near this temp. By extrapolation, they obtained 1170° for the m.p. W. Ramsay and N. Eumorfopoulos gave 937° for the m.p., but this is too low; W. Grahmann gave 1080°; G. Calcagni and D. Marotta, 1000°–1010°; and R. Schenck and W. Rassbach, over 1100°. R. Lorenz and W. Herz estimate the m.p. to be 1170°. W. Grahmann said that the **heat of crystallization** is small; and F. M. Jäger and H. C. Germs, the **heat of fusion** is small. M. Berthelot [7] gave for the **heat of formation**, $(Pb,S,2O_2)=214$ Cals.; while J. Thomsen gave 216·2 Cals.; and for $(Pb,O,H_2SO_4)=75·55$ Cals.; and $(Pb,O_2,SO_2)=145·1$ Cals. P. Günther calculated $(Pb,S,2O_2)=218·8$ Cals. M. Berthelot gave $(PbO,SO_3)=605$ Cals., and for the **heat of neutralization** of PbO by H_2SO_4, 19·9 Cals.; and for lead hydroxide, A. Guntz gave 21·4 Cals. The heat of formation by the substitution of lead for magnesium in magnesium sulphate is, according to J. Thomsen, 6·17562 Cals.; and W. E. Henderson and G. Stegeman gave for the replacement of the mercury in mercurous sulphate by lead, 41·785 Cals.; and for the free energy of the reaction, 41·2 Cals. A. Hare gave 4·06 Cals. per mol. for the heat of transformation.

A. des Cloizeaux [8] gave for the **indices of refraction** of anglesite with the red ray, $a=1·8740$, $\beta=1·8795$, and $\gamma=1·8924$; and for the yellow ray, $a=1·8770$, $\beta=1·8830$, and $\gamma=1·8970$. A. Arzruni found:

			C-ray (20°)	F-ray (20°)	20°	50°	100°	200°
						D-ray		
a	.	.	1·86981	1·89549	1·87709	1·87636	1·87529	1·87260
β	.	.	1·87502	1·90097	1·88226	1·88166	1·88080	1·89134
γ	.	.	1·88630	1·91263	1·89365	1·87260	1·87833	1·88754

H. C. Sorby gave 1·882 for the mean refractive index of anglesite. For temp. ranging from 16·1° to 19·3°, A. Ehringhaus and H. Rose obtained the following values for the indices of refraction and the birefringence with light of different wavelengths:

λ	.	.	690·7	623·9	589·3	546·1	491·6	404·7
a	.	.	1·86719	1·87346	1·87739	1·88383	1·89480	1·92434
β	.	.	1·87228	1·87862	1·88266	1·88914	1·90020	1·93001
γ	.	.	1·88351	1·88998	1·89435	1·90078	1·91202	1·94252
$\beta-a$	.	.	0·00509	0·00516	0·00527	0·00531	0·00540	0·00567
$\gamma-\beta$	.	.	0·01123	0·01136	0·01169	0·01164	0·01182	0·01251
$\gamma-a$	.	.	0·01632	0·01652	0·01696	0·01695	0·01722	0·01818

The **birefringence** is positive. At ordinary temp., $\gamma-a$ and $\gamma-\beta$ decrease with increasing wave-length, while $\beta-a$ is not affected; and with rise of temp., $\gamma-a$ and $\gamma-\beta$ decrease, while $\beta-a$ increases. The **dispersion** $G-B$ was found by R. Kolb to increase with rise of temp. The **reflecting power** was measured by T. Liebisch and H. Rubens; and C. Schaefer and M. Schubert gave for the percentage reflecting power for rays of wave-length λ:

λ	.	.	22	33	39	52	63	83	94	310μ
a	.	.	8·84	5·87	5·20	53·0	74·5	69·5	70·1	54·5
β	.	.	9·54	6·12	3·00	32·2	58·0	53·5	82·6	56·8

W. W. Coblentz found that there is a large band in the **ultra-red reflection spectrum** of anglesite at intervals $4\cdot55\mu$ and $9\cdot1\mu$, and this is characteristic of the SO_4-radicle; the **ultra-red transmission spectrum** has complex bands at $4\cdot55\mu$ and $6\cdot4\mu$, and deeper ones at 5μ and $6\cdot7\mu$. There are slight bands at $1\cdot9\mu$ and $3\cdot2\mu$. J. A. Wilkinson found that lead sulphate exhibits a blue **fluorescence** in cathode rays, and the colour becomes greyish-brown owing to decomposition.

G. Cesaro[9] found that anglesite has but a small **electrical conductivity.** F. Kohlrausch measured the sp. electrical conductivity of the sat. aq. soln. and found :

	$-0\cdot26°$	$1°$	$3\cdot48°$	$17\cdot01°$	$17\cdot08°$	$33\cdot23°$
Sp. Cond. .	$0\cdot0_41629$	$0\cdot0_41717$	$0\cdot0_41957$	$0\cdot0_43181$	$0\cdot0_43188$	$0\cdot0_4485$

W. Böttger, and M. Pleissner also made observations on this subject. H. G. Denham found that the resistance of a sat. aq. soln. at 25° is 3030 ohms when that of water is 27,000 ohms. M. Pleissner estimated that the **degree of ionization** of the aq. soln. is 80 per cent. at 18°, and that a millimol of the salt per litre has $0\cdot027$ millimol $PbSO_4$; $0\cdot099SO_4''$-ions ; $0\cdot062Pb\cdots$-ions ; $0\cdot037PbOH\cdot$-ions ; and $0\cdot037H\cdot$-ions. The presence of sulphuric acid lowers the hydrolysis, and increases the ionization. W. Böttger estimated a 92 per cent. ionization at 25°. A. Klein found the **electromotive force** of the cell $Pb \mid PbCl_2 \mid 0\cdot01N\text{-KCl} \mid 0\cdot01N\text{-K}_2SO_4 \mid PbSO_4 \mid Pb$ to be $0\cdot0529$ volt at $23\cdot1°$, while the free energy is $2418\cdot7$ cals. and the thermal value -2480 cals. ; if the chlorides be replaced by the bromides, these values are changed to $0\cdot0465$ volt, $2095\cdot6$ and -6040 cals. respectively ; and with iodides in place of chlorides $0\cdot0084$ volt, $281\cdot6$ and -11810 cals. C. B. Thwing gave $15\cdot80$ for the **dielectric constant ;** and W. Schmidt, 28 for $\lambda = 25$ cms. H. Joachim found the dielectric constants for $\lambda = 300\mu$ to be for a, 44, and for β, 50. B. N. Chuckubutti obtained Nobili's rings with a brass plate as cathode with a soln. of lead sulphate. The rings consist of granular particles of lead or oxide—$500\mu\mu$ in diameter near the centre, and $275\mu\mu$ near the periphery. The colours are due to the diffraction of light by these granules. L. Ebert studied the dielectric polarization of lead salts.

The chemical properties of lead sulphate.—J. A. Arfvedson[10] showed that when lead sulphate is heated in a stream of **hydrogen,** water, sulphur dioxide, and, lastly, hydrogen sulphide are evolved, while lead and lead sulphide remain. According to G. F. Rodwell, the complete reaction at a red heat can be represented : $2PbSO_4 + 7H_2 = 2Pb + SO_2 + H_2S + 6H_2O$. H. Mennicke found that the sulphate is easily reduced to spongy lead by cathodic hydrogen or by hydrogen from zinc and dil. hydrochloric acid. P. A. Bolley fixed a thick layer of lead sulphate between two zinc plates and left the combination immersed in a soln. of sodium chloride for 9–10 days. A mass of spongy lead was formed. C. Luckow found that anodic **oxygen** from the electrolysis of soln. of sodium or magnesium sulphate transforms lead sulphate into lead dioxide.

According to M. Willenz,[11] the lead sulphate prepared in a dry way is insoluble in **water ;** according to P. Kremers, water dissolves $0\cdot077$ grm. of lead sulphate per litre at ordinary temp. ; C. R. Fresenius found $0\cdot043$ grm. at 11° ; and G. F. Rodwell, $0\cdot031$ grm. at 15°. According to H. C. Dibbits, M. Pleissner, W. Böttger, K. Beck and P. Stegmüller, and F. Kohlrausch, the solubility, S, of lead sulphate in water in grams per litre is :

	0°	5°	10°	15°	20°	25°	30°	35°	40°
S .	$0\cdot028$	$0\cdot031$	$0\cdot035$	$0\cdot038$	$0\cdot041$	$0\cdot045$	$0\cdot049$	$0\cdot052$	$0\cdot056$

J. Sehnal, M. Barre, and L. L. de Koninck also made measurements of the solubility of lead sulphate in water ; the former found $0\cdot082$ grm. per litre at 18°, and claimed that the same result is obtained at 100°. S. Mitchell gave $0\cdot032$ grm. for 1000 c.c. of water. W. A. Roth measured the speed of soln. R. Flatt tried to connect the solubility with the electronic structure. W. A. Köhler and J. H. Mathews found the **heat of wetting** lead sulphate with water sat. with

the same salt is less than 0·09 cal. per 529,000 sq. cms. J. Sehnal showed that the salt in aq. soln. suffers **hydrolysis,** forming lead hydroxide and free sulphuric acid ; the presence of sulphuric acid hinders the hydrolysis and lowers the solubility. G. Carrara and G. P. Vespignani also noted the hydrolysis of lead sulphate. F. Dolezalek estimated that the aq. soln. is from 5 to 15 per cent. hydrolyzed ; M. Pleissner estimated 17 per cent. hydrolysis at 0°, and about 30 per cent. at 18°. H. Rose said that lead sulphate is soluble in aq. soln. of **potassium or sodium hydroxide,** especially if the soln. be warm. V. Kohlschütter and H. Rösti found that, at ordinary temp., 10N-NaOH dissolves lead sulphate with the separation of yellow rhombic crystals of lead monoxide, but with 2N- to 5N-soln. no separation occurs. M. C. Boswell and J. V. Dickson said that with the molten alkali hydroxide, hydrogen is developed. F. Rolle, and M. Tipp found that lead sulphate is decomposed by a soln. of **calcium hydroxide.** V. Zotier examined the catalytic effect of lead sulphate on **hydrogen dioxide.**

According to A. Ditte,[12] **hydrofluoric acid,** containing 27–54 grms. per litre, does not decompose lead sulphate after 24 hrs.' action between 15° and 100° ; it is sparingly soluble in an aq. soln. of potassium fluoride ; there is a balanced reaction : $PbSO_4 + 2KF \rightleftharpoons PbF_2 + K_2SO_4$, which is complicated by the formation of the complex salt $K_2Pb(SO_4)_2$. C. Hensgen found that dry **hydrogen chloride** attacks lead sulphate between 250° and 300°, liberating sulphuric acid ; and A. Colson said that two solid phases are present when the press. of the hydrogen chloride is 180 mm. at 0° ; 281 mm. at 10° ; and 354 mm. at 14·5°. F. Ephraim prepared lead chlorosulphate, $PbSO_4.2HCl$, with a dissociation press. of 713 mm. at 32°. H. V. Collet-Descotils said that lead sulphate is slightly soluble in hot **hydrochloric acid,** and on cooling, the soln. deposits a little lead chloride, leaving an eq. amount of sulphuric acid in soln. If the hydrochloric acid soln. is evaporated, but not boiled, A. Hayes said that the lead chloride is decomposed. C. R. Fresenius found lead sulphate to be soluble in hot acid. A. L. Young and G. F. Dixon found that a gram of lead sulphate with 4·035 grms. of hydrochloric acid, containing 1·251 grms. HCl, furnishes, on evaporation, 0·8 per cent. of lead chloride. G. F. Rodwell found that 100 grms. of an acid of sp. gr. 1·0515 dissolved 0·14665 grm. of lead sulphate ; sp. gr. 1·080, 0·35495 grm. ; 1·107, 0·946525 grm. ; 1·135, 2·113800 grms.; and 1·157, 2·854000 grms. of salt. The decimals are all out of perspective and give a distorted idea of the accuracy of the conclusions. A. Ditte studied the equilibrium conditions of the reaction. He said that when less than 7 grms. of HCl are present per litre, the acid dissolves only a trace of lead sulphate at ordinary temp. ; with a more conc. acid, some lead chloride goes into soln., and this the more the higher the temp. The system attains equilibrium in less than 24 hrs. If a denotes the initial percentage conc. of the HCl, and y the final percentage conc. of the sulphuric acid, then, for equilibrium, the free hydrochloric acid, x per cent., will be $x = 0.912ay$. K. Beck and P. Stegmüller gave for the solubility in mgrm. Pb per 100 c.c. of hydrochloric acid of different conc.

	H_2O	0·1N-HCl	0·2N-HCl	0·3N-HCl	0·4N-HCl
At 18°	2·60	19·00	35·70	55·37	75·27
At 25°	3·00	22·18	42·88	65·15	84·04
At 37°	3·80	28·04	54·50	84·04	111·90

According to A. Vogel, lead sulphate is slightly decomposed by a cold soln. of **ammonium chloride,** and to a greater extent on boiling, and completely when rapidly boiled with fresh quantities of the salt—the products are ammonium sulphate which remains in soln. and lead chloride which is precipitated on cooling. G. C. Wittstein noted the solubility of lead sulphate in ammonium chloride soln. R. H. Brett said that the cold soln. of lead sulphate in ammonium chloride gives a precipitate with a large excess of ammonia. A. Ditte showed that the reaction is a balanced one, so that if a sufficient excess of ammonium chloride be present, the decomposition of the sulphate is complete. The reaction is complicated by

the formation of a complex salt, $(NH_4)_2Pb(SO_4)_2$. A. Ditte showed that the behaviour of a soln. of **potassium chloride** resembles that of ammonium chloride. L. F. Bley found that lead sulphate is slightly decomposed by a soln. of **sodium chloride**; but M. Mayer and A. Fehlmann found that hot conc. soln. readily decompose the sulphate. A. C. Becquerel said that 0·66 grm. of lead sulphate is contained in a litre of sat. soln. at room temp. F. N. Flynn also made observations on this subject. F. Matthey reported that about half the quantity of lead sulphate is decomposed by an eq. amount of sodium chloride, and after repeated treatment more and more sulphate is decomposed. F. Field showed that when lead sulphate is digested with a cold sat. soln. of sodium chloride, lead chloride is deposited after a few hours. A. Ditte found that a soln. of sodium chloride acts less energetically than hydrochloric acid; and that the equilibrium conditions are simpler than with potassium chloride since there is no complex salt formed. A soln. with 300 grms. of sodium chloride per litre at 15° has for equilibrium, 266·66 grms. of NaCl, and 40·91 grms. Na_2SO_4; at 48°, respectively 282·40 and 21·49 grms.; and at 100°, 289·60 and 12·75 grms. respectively. K. Beck and P. Stegmüller found that at 18°, the solubility, in mgrm. Pb per 100 c.c. of the soln. of sodium chloride is, at 18°:

	H_2O	0·1N-NaCl	0·2N-NaCl	0·3N-NaCl	0·4N-NaCl
Pb	2·60	11·19	18·73	26·51	33·76

P. Berthier showed that when a mixture of lead sulphate and sodium or potassium chloride is fused, vapours of lead chloride are disengaged, and a compact, grey, translucent mass with a scaly fracture is obtained. F. Marguéritte obtained a similar result and noted the formation of alkali sulphate; and showed that a soln. of lead chloride in water in the presence of calcium sulphate is converted into lead sulphate; and if the lead sulphate be heated with an alkali chloride, alkali sulphate and lead chloride are produced. This was suggested as a means of producing alkali sulphate from gypsum without the use of sulphuric acid— J. Nicklès showed that the reactions are incomplete. O. Schott found that lead sulphate is soluble in molten sodium chloride, and, on cooling, crystallizes out in acicular six-sided crystals; the salt dissolves more readily in molten **calcium chloride** from which both lead chloride and sulphate crystallize on cooling. F. N. Flynn noted that lead sulphate is soluble in an aq. soln. of calcium chloride. According to P. Berthier, when lead sulphate is fused with **barium chloride,** lead chloride is evaporated and a white mass with a granular fracture is formed. F. N. Flynn found that lead sulphate dissolves in a conc. soln. of **magnesium chloride,** and H. Hof and co-workers added that on cooling the boiling sat. soln., the complex salt, Mg_2PbCl_6, and magnesium sulphate are formed. M. de Jong said that an acid soln. of **stannous chloride** freely dissolves lead sulphate, converting it into the chloride, but A. van Raalte claimed that the effect is due solely to the hydrochloric acid present. A. Ditte said that lead sulphate is not perceptibly soluble in a boiling soln. of **lead chloride.** P. Berthier found that a mixture of lead sulphate and chloride readily fuses with effervescence, forming when cold, a transparent enamel. O. Schott obtained microscopic, rhombic crystals, of lead sulphate from a soln. of that salt in molten lead chloride. C. R. Fresenius found lead sulphate to be soluble in a soln. of **ferric chloride.** A. Ditte found that lead sulphate behaves towards soln. of **potassium chlorate** similarly to what it does towards a soln. of potassium chloride. The reaction is a balanced one, and for equilibrium, a soln. of 312 grms. of the chlorate in a litre of water in contact with an excess of lead sulphate, holds 1·34 grms. of potassium sulphate at 15°; and 2·39 grms. at 100°; while a soln. of 100 or 200 grms. of the chlorate per litre furnishes very little potassium sulphate or lead chlorate.

A. Ditte noted the solvent action of **hydrobromic acid** on lead sulphate, and the result resembles that with hydrochloric acid; a soln. of **potassium bromide** also behaved like one of potassium chloride. A soln. of 300 grms. of the bromide

per litre in contact with an excess of lead sulphate furnishes, when in equilibrium, 1·53 grms. of potassium sulphate at 13°, and 2·16 grms. at 100°. He also noticed that with **zinc bromide** there is a balanced reaction : $ZnBr_2+PbSO_4\rightleftharpoons PbBr_2$ $+ZnSO_4$, which progresses from left to right with rise of temp. A. Ditte also noted that the action of hydriodic acid on lead sulphate is similar to that of hydrochloric acid ; and that a soln. of potassium iodide behaves like a soln. of potassium chloride. A 5 per cent. soln. of potassium iodide in contact with an excess of lead sulphate furnishes 1·531 grms. of potassium sulphate at 13° ; and a 15 per cent. soln., 1·64 grms. of potassium sulphate at 15°, and 1·01 grms. at 100°. G. Campani found that with an excess of potassium iodide, either lead iodide or the complex salt, $K_2Pb(SO_4)_2$, is formed. A. Ditte also investigated the action of **magnesium iodide :** $PbSO_4+MgI_2\rightleftharpoons PbI_2+MgSO_4$.

E. Filhol and J. B. Senderens [13] showed that when boiled with **sulphur** and water, lead sulphate is slowly decomposed ; the supernatant liquor is not acid, probably owing to the formation of lead hydrosulphate. According to F. Utz, lead sulphate is coloured yellow and brown much more slowly by **hydrogen sulphide** than is white-lead. J. F. Sacher found that when dry hydrogen sulphide is passed into absolute alcohol holding lead sulphate in suspension, and water is dropped slowly into the liquid, the white sulphate becomes yellow, brown, and finally black. F. O. Doeltz showed that when lead sulphate is triturated with **sodium or calcium sulphide,** the mass becomes dark grey ; and, according to F. O. Doeltz, when the mixture is heated, black lead sulphide appears. The work of J. Percy, A. Lodin, W. Reinders and co-workers, H. C. Jenkins and E. A. Smith, and R. Schenck and co-workers on the action of **lead sulphide** on lead sulphate has been previously discussed. H. Schulze showed that at ordinary temp. dry lead sulphate absorbs **sulphur trioxide,** forming what might be lead pyrosulphate, $Pb_2S_2O_7$; and, according to H. Ditz and F. Kanhäuser, the same complex may be present in a soln. of lead sulphate in fuming sulphuric acid. The solubility of lead sulphate in dil. **sulphuric acid** was found by C. R. Fresenius to be 0·0025 part per 100 parts of acid, but it is more soluble in conc. sulphuric acid from which it is partly precipitated by the addition of water, and completely by the addition of alcohol. He said that lead sulphate is more soluble in water than barium sulphate, and less soluble than strontium sulphate. C. Schultz said 100 parts of conc. sulphuric acid dissolve 6 parts of lead sulphate, while H. Struve said 0·13 part ; A. C. Cumming, that $7·4N·H_2SO_4$ at 25° dissolves approximately 6×10^{-5} mol per litre ; and T. Garside, that 100 parts of the boiling acid dissolve 1·5 parts of lead sulphate, and on cooling a few crystals are deposited, while 1·15 parts are retained in soln. ; J. H. Gladstone and W. Hibbert, that 29 per cent. sulphuric acid, sp. gr. 1·22, dissolves 0·012 grm. of lead sulphate per litre ; and J. Kolb, that at ordinary temp. 100 grms. of an acid of sp. gr. 1·841 dissolves 0·039 grm. lead sulphate ; sp. gr. 1·793, 0·011 grm. ; and sp. gr. 1·540, 0·003 grm. A. Marshall added that the value for the acid of sp. gr. 1·841 is too low because 98 per cent. H_2SO_4 dissolves 0·09 per cent. $PbSO_4$, and the 94 per cent. acid, 0·06 per cent. $PbSO_4$. A. E. Dawkins gave 0·71–1·05 mgrm. of sulphate per 100 c.c. of 0·1–20 per cent. sulphuric acid at 30°. The presence of sulphur dioxide or of nitrous oxides was found by J. Kolb to increase the solvent action of sulphuric acid, while it is increased by nitric acid. A trace of sulphuric acid has a marked effect in reducing the solubility of lead sulphate in water ; thus, expressing the conc. in grams per litre at 18°, M. Pleissner gave :

| H_2SO_4 | . | . | . | 0 | 0·0049 | 0·0098 | 0·0245 | 0·0490 | 0·4904 |
| $PbSO_4$ | . | . | . | 0·0382 | 0·0333 | 0·0306 | 0·0194 | 0·0130 | 0·0052 |

and J. Sehnal, at 20°, gave rather different values—

| H_2SO_4 | . | . | . | 0 | 0·0098 | 0·0196 | 0·0980 | 0·4900 | 0·9800 |
| $PbSO_4$ | . | . | . | 0·082 | 0·051 | 0·025 | 0·013 | 0·006 | 0·000 |

A. Hayes said that lead sulphate is more soluble in commercial sulphuric acid

than in a more conc. acid. H. Struve found that 100 grms. of fuming sulphuric acid dissolve 4·19 grms. of lead sulphate, and H. Ditz and F. Kanhäuser gave for 100 grms. of the conc. and fuming acids, at 17°–18·5° :

H_2SO_4 per cent.	98·11	98·94	100·01	101·13 (5 per cent. SO_3)	105·05 (15 per cent. SO_3)
$PbSO_4$ grams .	0·54	1·34	4·21	3·54	8·23

The resulting curve resembles that obtained for the electrical resistance of sulphuric acid. As indicated above, it was assumed that the soln. contained a complex—possibly PbS_2O_7. C. Schultz obtained **lead hydrosulphate,** $Pb(HSO_4)_2.H_2O$, by passing moist air over the crystals of lead sulphate obtained by cooling a boiling, sat. soln. of lead sulphate in conc. sulphuric acid. A. D. Donk studied the ternary system, $PbSO_4$–H_2SO_4–H_2O, between 0° and 200°, but obtained no evidence of a solid phase $PbSO_4$–H_2SO_4—*vide* $Ba(HSO_4)_2.2H_2O$. Expressing concentrations in grams of salt per 100 grms. of sat. soln., A.D.Donk found at 0° the results indicated in Table XI, and plotted in Fig. 111. At temp. between 50° and 200°, the only solid

TABLE XI.—SOLUBILITY OF LEAD SULPHATE IN SULPHURIC ACID AT 0°.

phase present was lead sulphate. This subject was discussed by J. Kendall and A. W. Davidson. A. Hayes found that the cold soln. of lead sulphate in conc.
FIG. 111.—Equilibrium in the Ternary System : $PbSO_4$–H_2SO_4–H_2O at 0°.

sulphuric acid is rendered turbid and precipitated by hydrochloric acid, but the precipitate re-dissolves on heating ; and A. du Pasquier showed that hydrogen sulphide does not precipitate lead sulphide from a soln. of the sulphate in conc. sulphuric acid, but, when the acid is diluted with water, lead sulphate is precipitated and the soln. then exhibits the usual reaction with hydrogen sulphide. J. Löwenthal, and P. A. Bolley made some observations on this subject. H. Rose found lead sulphate to be soluble in a soln. of **ammonium sulphate.** P. Berthier showed that mixtures of lead sulphate and **alkali sulphates** are very fusible. J. N. Brönsted, A. Ditte, and G. Calcagni and D. Marotta, found that lead sulphate forms double salts with ammonium sulphate and **potassium sulphate,** but not with **sodium sulphate** (*q.v.*). P. Berthier said that lead sulphate does not yield fusible products with **calcium, strontium, or barium sulphate.** F. Zambonini found lead sulphate and **didymium sulphate,** $Di_2(SO_4)_3$, are immiscible when crystallized from warm conc. sulphuric acid. J. Löwe showed that an aq. soln. of **sodium thiosulphate** dissolves lead sulphate owing to the formation of a double salt ; when the soln. is exposed to air, lead sulphide is produced in small quantity,

but on boiling a large quantity is precipitated; and when acids are added, lead sulphate and free sulphur are formed. This was confirmed by J. Percy; but K. Fischer and K. Thiele said the conc. of the lead in the soln. of sodium thiosulphate is so small that the electrolysis of the soln. does not give a coherent precipitate. S. E. Goldschmidt also found lead sulphate to be soluble in a soln. of calcium thiosulphate.

According to E. C. Franklin and C. A. Kraus,[14] lead sulphate is insoluble in liquid ammonia. G. F. Rodwell's observations on the action of the dry gas at a red heat agreed with the assumption that the reaction can be represented by the (probably wrong) equation: $7PbSO_4 + 20NH_3 \rightarrow 3PbS + 2Pb_2S + 22H_2O + 8N_2 + 2(NH_4)_2SO_4$; W. R. Hodgkinson and C. C. Trench found that the decomposition is not complete at a red heat, and only a little lead sulphide is formed. G. C. Wittstein showed that lead sulphate dissolves completely in warm aq. ammonia. and, on cooling, a basic salt is deposited. A. Vogel made some observations on this subject. According to A. Ditte, when conc. aq. ammonia is added to lead sulphate, there is a brisk reaction, and the mixture solidifies, all smell of ammonia disappearing if sufficient lead sulphate be present. With dil. soln., the ammonia forms ammonium sulphate and lead oxide, the latter combining with the excess of lead sulphate to form a basic sulphate, $PbO.PbSO_4$; and the complex salt, ammonium sulphatoplumbite, is formed. V. Kohlschütter and H. Rösti showed that, at ordinary temp., $2N$- to $12N$-soln. of ammonia do not attack lead sulphate. Lead sulphate dissolves in nitric acid, and this the more, in proportion as the temp. or the conc. of the acid is augmented. According to G. Bischof, 100 grms. of nitric acid of sp. gr. 1·144 at 12·5° dissolve 0·58 grm. of lead sulphate; water does not render the soln. turbid, but the salt is precipitated by sulphuric acid or ammonium carbonate. H. W. F. Wackenroder, however, showed that the sulphate dissolves slowly in dil. nitric acid, and added that the salt is not precipitated by hydrochloric or phosphoric acid, not at all or very slightly by alkali sulphates; and it is precipitated by tartaric acid or dil. sulphuric acid—the more conc. the nitric acid, the greater the proportion of sulphuric acid required for the precipitation; the precipitate forms only slowly, and if the quantity of nitric acid be not too great, it may be complete. When the nitric acid soln. is evaporated, F. von Kobell found that needle-like crystals of the sulphate, and octahedral crystals of the nitrate, are formed. According to G. F. Rodwell, nitric acid with 60 per cent. N_2O_5 transforms lead sulphate almost completely into lead nitrate in 3 or 4 days; but A. Ditte said that in no case of the action of nitric acid on lead sulphate was he able to verify this result. A. Ditte said that the solubility of the sulphate varies with the temp. and conc. of the acid. With an acid containing 445 grms. of N_2O_5 per litre, the quantity of lead sulphate dissolved increases with temp., but with more conc. soln., the action of heat is reversed, for the quantity of lead sulphate dissolved decreases with rise of temp.; with fuming nitric acid, containing 800 grms. N_2O_5 per litre, not a trace of lead sulphate was dissolved at 50°. G. F. Rodwell showed that the solubility, S per 100 grms. of the acid, is for an acid of sp. gr. 1·079, 0·33 grm.; 1·123, 0·58 grm.; 1·250, 0·78 grm.; 1·420, 1·01 grms. K. Beck and P. Stegmüller found the solubility, S, in mgrm. of Pb per 100 c.c. of soln. at 18°:

	H_2O	$0·1N$-HNO_3	$0·2N$-HNO_3	$0·3N$-HNO_3	$0·4N$-HNO_3
S	2·60	10·48	17·48	23·41	29·84

According to J. Kolb, the presence of nitric acid increases the solvent action of sulphuric acid for 0·044 grm. of lead sulphate is dissolved by a mixture of 100 grms. of sulphuric acid, sp. gr. 1·841, and 5 grms. of nitric acid, sp. gr. 1·352; 0·014 grm. lead sulphate by 100 grms. sulphuric acid, sp. gr. 1·749, and 5 grms. of nitric acid, sp. gr. 1·352; and only a trace of lead sulphate by 100 grms. of sulphuric acid, sp. gr. 1·512, and 5 grms. of nitric acid, sp. gr. 1·352. He added that the presence of nitrogen oxides does not increase the solvent action of sulphuric acid. According

to G. Bischof, 100 grms. of a soln. of **ammonium nitrate** of sp. gr. 1·29 dissolve 0·103 grm. of lead sulphate ; the soln. is rendered turbid by potassium sulphate, but not by sulphuric acid. C. Marie reported that in the presence of nitric acid, 15 grms. of ammonium nitrate are necessary for the soln. of 0·3 grm. of lead sulphate. A. Ditte reported that very little lead sulphate is dissolved by cold or hot soln. of **sodium or potassium nitrate,** and no chemical action was observed. F. Guthrie found that lead sulphate dissolves in molten potassium nitrate, and the soln., on cooling, deposits crystals of lead sulphate. L. J. Thénard said that a nitric acid soln. of **barium nitrate** produces lead nitrate. M. G. Mellon found lead sulphate to be somewhat soluble in a soln. of **copper nitrate.**

P. Berthier [15] made some observations on the action of **carbon** on lead sulphate, and J. L. Gay Lussac ascertained that if an excess of carbon is present, the lead sulphate is reduced to sulphide at *rouge sombre*, and the gas evolved is free from sulphur dioxide : $PbSO_4 + 2C = 2CO_2 + PbS$; but if less carbon than is needed for this reaction is employed, a mixture of lead sulphide and unconverted sulphate will be produced. In either case, if the temp. be raised to *cérise clair*, metallic lead, $PbS + PbSO_4 = 2Pb + 2SO_2$, or lead oxide, $PbS + 3PbSO_4 = 4PbO + 4SO_2$, will be formed according to the proportion of carbon present—*vide supra*, the action of calcium fluoride. The reduction of lead sulphate by carbon was found by W. Mostowitch to begin at 550° ; the reduction is energetic at 630°. The reactions are symbolized : $PbSO_4 + 4C = PbS + 4CO$; and $PbS + PbSO_4 = 2Pb + 2SO_2$— *vide infra*. According to G. F. Rodwell, if **carbon monoxide** be passed over heated lead sulphate, lead is produced, and carbon and sulphur dioxides are evolved ; he assumed that the first action can be symbolized : $2PbSO_4 + 6CO = Pb + PbS + SO_2 + 6CO_2$. W. Mostowitch found that the reduction begins at about 600°, and is energetic at 630° when the carbon monoxide is more active than carbon alone. At 630°, 74·4 per cent. of lead sulphate is reduced by carbon monoxide, and 36·98 per cent. by carbon : $PbSO_4 + 4CO = PbS + 4CO_2$; the lead sulphide and sulphate react : $PbSO_4 + PbS = 2Pb + 2SO_2$, and $3PbSO_4 + PbS = 4PbO + 4SO_2$; and the lead oxide is reduced by the carbon monoxide : $PbO + CO = CO_2 + Pb$. The products of the decomposition thus contain lead, and lead sulphide and sulphate in quantities varying with the temp. and time of reduction. A. Ditte showed that an aq. soln. of **carbon dioxide** under atm. press. does not attack lead sulphate cold or hot ; but L. Michel, G. Seligmann, P. von Jeremejeff, and others have noted the transformation of anglesite into cerussite under natural conditions. G. C. Wittstein found that an aq. soln. of normal **ammonium carbonate** converts lead sulphate into lead carbonate ; and A. Ditte reported that with an excess of lead sulphate, the carbonate disappears entirely from the soln. and with twice the theoretical quantity of lead sulphate, only a part forms the complex salt, $(NH_4)_2Pb(SO_4)_2$, and a part forms lead-hillite, $PbSO_4.3PbCO_3$. J. Lemberg noted that a soln. of commercial ammonium carbonate also transforms the sulphate to carbonate. J. Percy, and O. Schott reported that when lead sulphate is decomposed by **sodium or potassium carbonate,** at a red-heat, the alkali sulphate and lead monoxide are formed. According to A. Ditte, an aq. soln. of potassium carbonate acts like one of ammonium carbonate ; and a soln. of sodium carbonate produces only lead carbonate and sodium sulphate, not the double salt of sodium and lead sulphates. The **alkali hydrocarbonates** act similarly. F. Auerbach and H. Pick found that lead sulphate in contact with $0·1N-Na_2CO_3$ forms white-lead, and sodium hydrocarbonate and sulphate are produced in the molar ratio 1 : 3 ; with an excess of lead sulphate, a basic lead carbonate is precipitated until the soda-content of the soln. begins to increase, when normal lead carbonate is produced and the complex salt dissolved. There is a balanced reaction : $PbSO_4 + 2NaHCO_3 \rightleftharpoons PbCO_3 + Na_2SO_4 + CO_2 + H_2O$.

Much attention has been devoted to the action of soln. of the acetates on lead sulphate. G. Bischof found that 100 grms. of a soln. of **ammonium acetate**, sp. gr. 1·36, dissolve 2·13 grms. of lead sulphate, forming a soln. which gives a precipitate

with sulphuric acid or potassium sulphate. J. Mercer also noted the solubility of lead sulphate in soln. of ammonium acetate. Expressing conc. in grams per litre, J. W. Marden found at 25° : •

$CH_3.COONH_4$	.	.	.	0	7·96	15·91	31·70	53·4	106·8	213·7
$PbSO_4$	.	.	.	0·041	0·636	1·37	3·04	5·6	16·8	38·9

J. C. Long found at 100° :

$CH_3.COONH_4$	.	.	.	280	300	320	350	370	400	450
$PbSO_4$	.	.	.	71·2	83·6	98·8	102·6	105·8	107·8	111·0

and A. A. Noyes and W. H. Whitcomb, at 25°, for soln. with 0, 7·98, 15·96, and 31·92 grms. of ammonium acetate per litre, respectively 0·041, 0·636, 1·38, and 3·02 grms. of lead sulphate per litre. They attribute the increase in the solubility with increasing conc. of the ammonium acetate to the formation, by metathesis, of non-ionized mols. of lead acetate, $(CH_3.COO)_2Pb$. J. J. Fox found that the equilibrium $PbSO_4+2NH_4C_2H_3O_2 \rightleftharpoons (NH_4)_2SO_4+Pb(C_2H_3O_2)_2$ is complicated by the formation of the complex salt, $(NH_4)_2Pb(SO_4)_2$. C. Blomberg's observations on the f.p., and electrical conductivity of the soln., led him to conclude that the increased solubility is due to the formation of either complex or basic salts. J. J. Fox made some observations on this subject. F. H. Storer found that a conc. aq. soln. of ammonium acetate mixed with alcohol exerted no solvent action on lead sulphate ; a similar result was obtained in the presence of sulphuric acid ; but with ammonium sulphate in place of sulphuric acid, much lead sulphate is dissolved. J. J. Fox examined the equilibrium : $PbSO_4+2KC_2H_3O_2 \rightleftharpoons K_2SO_4+Pb(C_2H_3O_2)_2$, and found that soln. of lead sulphate in those of **potassium acetate** contain lead and potassium acetates only. The results are plotted in Fig. 112. The solid phase consists of lead potassium sulphate, which is practically insoluble as such in the acetate, no lead acetate being present in the solid phase. The formation of the salt $PbK_2(SO_4)_2$ on mixing soln. of lead acetate and potassium sulphate may be accounted for by the preliminary formation of complex acetates, such as $PbK_2(C_2H_3O_2)_4$. This would then react with more potassium sulphate to give inso· luble $PbK_2(SO_4)_2$. J. Mercer noted the solubility of lead sulphate in soln. of this salt as well as in **sodium acetate.** H. C. Dibbits showed that a soln. containing 100 grms. of water, a few drops of acetic acid, and 2·05 grms. of anhydrous sodium acetate dissolved 0·054 grm. of lead sulphate ; with 8·2 grms. of the acetate, 0·90 grm. lead sulphate ; and with 41·0 grms. of the acetate 11·20 grms. of lead sulphate. The temp. had very little

Fig. 112.—The Solubility of Lead Sulphate in Soln. of Potassium and Sodium Acetates.

effect on the result, and the soln. gave a precipitate with sulphuric acid, and other reagents ordinarily employed to precipitate lead salts from aq. soln. J. J. Fox found that the equilibrium : $PbSO_4+2NaC_2H_3O_2 \rightleftharpoons Na_2SO_4+Pb(C_2H_3O_2)_2$, is not disturbed by the formation of a double salt ; and his results for the solubility of lead sulphate in soln. of sodium acetate are plotted in Fig. 112. F. H. Storer said that a dil. alcoholic soln. of sodium acetate, mixed with normal sulphuric acid, with ammonium sulphate or with lead acetate seemed to have no solvent action on lead sulphate. L. Krafft, and H. C. Dibbits studied the solvent action of soln. of **barium acetate** on lead sulphate ; J. Mercer, W. Städel, and H. C. Dibbits found that 100 grms. of a dil. soln. of **calcium acetate** dissolve 45·45 grms. of lead sulphate. J. Mercer noted the solubility of lead sulphate in soln. of **magnesium acetate.** H. C. Dibbits found lead sulphate to be soluble in a soln. of **copper acetate,** but not in one of **silver acetate ;** soluble in soln. of **zinc, manganese, and nickel acetates,** but not in a soln. of **mercury acetate ;** and E. Lenssen, J. Mercer, and
J. L. Mayer showed lead sulphate is soluble in soln. of **aluminium acetate** but not if an excess of alkali or aluminium sulphate is present. J. L. Smith, and K. Stammer found lead sulphate to be insoluble in soln. of normal **lead acetate,** but the latter found it to be soluble in basic lead acetate. F. H. Storer said that lead sulphate is not soluble in dil. alcoholic soln. of **ammonium or sodium oxalate** in the presence of sulphuric acid or ammonium sulphate. F. Wöhler, and G. C. Wittstein said that lead sulphate is soluble in an aq. soln. of **ammonium succinate,** but F. H. Storer added not in a dil. alcoholic soln. in the presence of sulphuric acid, or ammonium sulphate. J. L. Smith said that lead sulphate is soluble in a soln. of **ammonium tartrate ;** C. Reichard added that lead sulphate is insoluble in **potassium and sodium tartrates,** but is soluble in their double tartrates with ammonium. Ammonia itself does not dissolve the compound, but if added to a soln. of sodium tartrate containing lead sulphate in suspension soln. takes place. The soln. of lead sulphate in neutral **ammonium tartrate** seems to contain part of the lead as a basic salt, for on adding a small quantity of potassium dichromate, the precipitate formed at first consists of the orange-red basic lead chromate. F. H. Storer added that a dil. alcoholic soln. of potassium tartrate containing a little sulphuric acid does not dissolve lead sulphate. According to H. C. Bolton, a cold conc. soln. of **citric acid** dissolves anglesite ; J. L. Smith said the sulphate is soluble in an aq. soln. of **ammonium citrate,** but, added F. H. Storer, not if alcohol and sulphuric acid or ammonium citrate be present. A soln. of **ammonium dicitrate,** or of **potassium tricitrate,** dissolves lead sulphate in the presence of alcohol and sulphuric acid. H. W. F. Wackenroder said that the best solvents among the ammonium salts are the nitrate, citrate, and tartrate ; the two latter should be made alkaline with ammonia. H. G. Denham found the resistance of a sat. soln. of lead sulphate in **alcohol** to be 93,000 ohms at 25°. F. H. Storer found that 59 per cent. alcohol alone, or mixed with **ethylsulphuric acid,** or with **sugar,** does not dissolve lead sulphate after three months' action. A. Naumann found lead sulphate to be insoluble in **acetone,** in **methyl acetate,** and in **ethyl acetate ;** and H. Mandal, sparingly soluble in **aniline.** A. Conduché said that **chloroform** at 350° forms lead chloride. J. Percy, and H. Rose showed that when lead sulphate is fused with about five times its weight of **potassium cyanide,** the whole of the lead is reduced to the metallic state, and the process can be used for quantitative analysis. A. Ditte found that when lead sulphate is added to a soln. of potassium cyanide, lead cyanide is formed, and as the potassium sulphate accumulates in the system, the double sulphate is formed. J. Aub said that a litre of blood **serum** at 25° dissolves 0·0437 grm. of lead sulphate. J. Marc studied the **adsorption** of organic colouring agents of lead sulphate.

A. Ditte [16] showed that aq. soln. of **boric acid** and of **potassium or sodium borate** have no action on lead sulphate either in the cold or at boiling heat. J. Percy found that a mixture of borax and lead sulphate can be readily fused ; and if clay crucibles are used, some of the sulphate may be decomposed with the evolution of sulphur dioxide. E. Vigouroux observed lead sulphate is reduced by **silicon,** and L. Kahlenberg and W. J. Trautmann represented the reaction with powdered silicon at an elevated temp. by $PbSO_4 + 2Si = PbS + 2SiO_2$; $2PbS + 3O_2 = 2PbO + 2SO_2$; $PbO + SiO_2 = PbSiO_3$; and $3PbO + Si = 2Pb + PbSiO_3$. P. Berthier found that lead sulphate is decomposed by **silica** at a red heat, forming lead silicate. The time required for the reaction is no longer than with mixtures of lead oxide and silica. W. Mostowitch said that silica does not alter the temp. or progress of decomposition below 950° ; silica begins to act on lead sulphate at 975°. The progress of the decomposition depends on the nature of the silicate formed—di- and tri-silicates retard the decomposition by surrounding the sulphate with a viscous silicate. P. Berthier also found that **clay** acts similarly, and suggested that lead sulphate might be used in place of galena, or other lead compounds, in the glazing of pottery, or in place of red-lead in making flint-glass. S. Hilpert said that the reaction begins at about 720°, and progresses rapidly above 750°, as indicated in

Fig. 113. J. Percy, and M. Tipp showed that when lead sulphate is mixed with **calcium oxide,** and heated to redness, calcium sulphate and lead oxide are formed. G. Tammann studied the action of the oxides of the alkaline earths, lead oxide, and of the **alkali carbonates** on lead sulphate. W. Reinders found that the attack with **magnesium oxide** begins at about 800°. P. Berthier noted that a mixture of lead sulphate with 10 per cent. of **lead oxide** at a white heat becomes *aussi liquid que de la litharge,* and *sous-sulfates* are formed—*vide infra,* oxysulphates. O. Proske found that **ferrous oxide** at 800° favours the decomposition of lead sulphate; **ferric oxide** at 900° has not a marked influence, but the action is vigorous at 1200°. S. Hilpert compared the behaviour of ferric oxide with that of silica. J. Milbauer and K. Kohn found that, when heated, **potassium chromate** quickly transforms lead sulphate into the chromate, and they also studied the reverse reaction.

FIG. 113.—Speed of the Reaction between Lead Sulphate and Silica.

J. A. Wilkinson observed that in the reduction of lead sulphate by **sodium** no luminescence occurs. P. Berthier, and J. Percy represented the reaction which occurs when **lead** is heated with its sulphate by $PbSO_4+Pb=2PbO+SO_2$. The reaction has been further studied by H. C. Jenkins and E. A. Smith, W. Reinders, A. Lodin, J. B. Hannay, etc.—*vide supra,* the extraction of lead. J. Percy found that when a mixture of lead sulphate and **iron** is heated, lead and scoriaceous slag are formed. G. Tammann also studied the action of iron on the sulphate. B. N. Chuckubutti obtained Nobili's rings with a brass cathode in a lead sulphate soln.

P. Louyet [17] obtained an indefinite product, possibly *lead fluosulphate,* by the action of conc. sulphuric acid on lead fluoride. F. Matthey reported that when lead sulphate is repeatedly treated with a soln. of sodium chloride, there remains a mixture of undecomposed lead sulphate and *lead chlorosulphate.* S. Zinno treated the product of the action of iodine on an aq. soln. of sulphur dioxide and sodium sulphite—$Na_2SO_4.I_2$, with lead acetate and obtained a white precipitate supposed to be *lead iodosulphate,* $PbSO_4.I_2$. A. Michaelis and G. Köthe said the white precipitate is a mixture of lead sulphite and iodine which with more iodine furnishes yellow lead iodide.

The basic lead sulphates—lead oxysulphates.—As indicated above, P. Berthier [18] fused mixtures of lead oxide and sulphate and obtained what were regarded as basic lead sulphates. The fusion curve of mixtures of lead oxide and sulphate was investigated by R. Schenck and W. Rassbach, W. Reinders, F. M. Jäger and H. C. Germs, etc. The results of R. Schenck and W. Rassbach are summarized in Fig. 114. Owing to the decomposition of lead sulphate, the curve with the higher proportions of lead sulphate was not explored above 950°. The remainder of the curve shows two distinct maxima, one at 966°, corresponding with $PbO.PbSO_4$; and one at 951°, corresponding with $2PbO.PbSO_4$. A third compound, $3PbO.PbSO_4$, does not show a maximum because it decomposes before this can be reached, and, above 880°, furnishes the compound $2PbO.PbSO_4$ and melt. There is a eutectic at 820°, and 87 per cent. PbO between PbO and $3PbO.PbSO_4$; one at 940° and 55·3 per cent. PbO between $2PbO.PbSO_4$ and

FIG. 114.—Freezing-point Curves of Mixtures of Lead Oxide and Sulphate.

$PbO.PbSO_4$; and one at 950° and 30 per cent. PbO between $PbO.PbSO_4$ and $PbSO_4$. There is a horizontal at 845° corresponding with the transition point of
lead sulphate (q.v.), and a second one at 450° between 42 and 85 per cent. of PbO, not shown in the diagram, corresponding with a rearrangement of the compound $2PbO.PbSO_4$. The break is shown on a rising and a falling temp. so that the change is reversible. The nature of this change is not known ; it may be due to the formation of a different modification of $2PbO.PbSO_4$, or it may be due to a chemical reaction : $2(2PbO.PbSO_4) \rightleftharpoons PbO.PbSO_4 + 3PbO.PbSO_4$. S. Ganelin made basic sulphates by grinding lead sulphate and magnesia with water ; and G. Lunge and C. H. M. Lyte, from lead nitrate, sodium sulphate, and hydroxide. Other modes of preparation are indicated below.

The so-called *sublimed white-lead* is a mixture containing lead sulphate 75–80 per cent. ; lead oxide, 14–20 per cent. ; and zinc oxide, 5–6 per cent. It may be a mixture of basic sulphates, and is used as a painter's pigment, largely in the manufacture of mixed paints. Its use was developed by G. T. Lewis and E. O. Bartlett, and it was made by a process resembling that used for making zinc oxide, namely, by subliming the ore in an oxidizing fire, and collecting the condensed product in cloth filters or bags. The composition is naturally dependent on the character of the galena or lead ore employed as raw material ; on the amount of air which comes in contact with the ore ; on the temp. of the furnace ; etc. The process of manufacture has been the subject of numerous patents. The manufacture of this and other varieties, and the properties have been described by C. D. Holley, H. O. Hofman, C. Schnabel, F. C. Breyer and co-workers, J. A. Schaeffer, E. E. Banes, J. B. Hannay and co-workers, W. J. M. Jackson, W. Bell and co-workers, S. B. Wilson, E. C. C. Baly, A. Macdonald, L. F. Hughes, P. F. Nursey, B. S. White, etc. The so-called *non-poisonous white-lead* which has been on the market is a basic sulphate—72·74 per cent. PbO ; 24·90, SO_3 ; and 2·36, CO_2. It was shown by H. Kionka, and K. B. Lehmann to be just as poisonous as other varieties.

The conditions of equilibrium of **lead trioxysulphate,** $4PbO.SO_3$, or $3PbO.PbSO_4$, or $Pb_4O_3SO_4$, have been indicated in connection with Fig. 114. The salt was prepared by R. Schenck and W. Rassbach, E. Jänecke, F. M. Jäger and H. C. Germs, and W. Reinders. It decomposes above 880° before its m.p. is attained. D. Strömholm reported **hydrated lead trioxysulphate,** $3PbO.PbSO_4.H_2O$, or *lead hydroxydioxy-sulphate,* $2PbO.Pb(OH)_2.PbSO_4$, to be formed when lead hydroxide is mixed with a soln. of ammonium sulphate—potassium sulphate does not do so well. M. Pleissner made it by shaking an intimate mixture of lead hydroxide, $PbO.\frac{1}{3}H_2O$, lead sulphate, and water at 18° for three days. The white mass of small crystals has a solubility of 26·2 mgrms. per litre at 18° ; the sp. conductivity of the soln. being $9·3 \times 10^{-6}$ mho. The conditions of equilibrium of **lead dioxysulphate,** $3PbO.SO_3$, or $2PbO.PbSO_4$, or $Pb_3O_2SO_4$, by R. Schenck and W. Rassbach, are indicated in Fig. 114. The subject was also studied by E. Jänecke. W. Reinders made the dioxysulphate by heating a mixture of finely divided lead and lead oxysulphate in an evacuated tube at 700° ; the reaction was symbolized $4Pb_2OSO_4 + Pb$ $= 3Pb_3O_2SO_4 + SO_2$. The salt melts at 951°, and has a transition point at 450°. F. M. Jäger and H. C. Germs made the salt, and gave 961° for the m.p. The conditions of equilibrium for **lead oxysulphate,** $PbO.PbSO_4$, are indicated in Fig. 114 ; and the subject was also studied by E. Jänecke. According to F. M. Lyte the basic sulphates can be converted into other basic salts by treatment with soluble carbonates, phosphates, or chlorides ; and, according to W. E. B. Blenkinsop and F. M. Lyte, with soluble borates, silicates, or oxalates.

H. J. Brooke described a rare mineral from Leadhills, Lanarkshire, which he called *sulphatocarbonate of lead,* and it was represented by the formula $PbSO_4.PbCO_3$. F. S. Beudant called it **lanarkite,** and A. Breithaupt, *dioxylite.* Specimens have also been reported from Siberia ; Tanne, Harz ; and Biberweier, Tyrol. Analyses by F. Pisani, W. Flight, and N. Collie show that its composition corresponds with **lead oxysulphate,** $2PbO.SO_3$, or $PbO.PbSO_4$, or Pb_2OSO_4, and not with $Pb_2(SO_4)CO_3$. Analyses of the artificial product were made by D. Strömholm, A. de Schulten, C. T. Barfoed, and W. Reinders. The conditions of equilibrium, in its preparation by fusing mixtures of lead oxide and sulphate, worked out by R. Schenck and W. Rassbach, are indicated in Fig. 113. F. M. Jäger and H. C. Germs made it in a similar way. H. C. Jenkins and E. A. Smith made it by heating in a crucible at

a dull red heat, a mixture of equimolar parts of lead and lead sulphate. W. Reinders represented the reaction: $4Pb+5PbSO_4=4Pb_2OSO_4+PbS$. O. B. Kuhn, W. Reinders, and D. Strömholm obtained it by digesting lead sulphate with aq. ammonia; M. Pleissner, by shaking a mixture of a mol of lead sulphate and one-third of a mol of lead hydroxide, $PbO.\frac{1}{3}H_2O$, and water, or by shaking lead sulphate with freshly precipitated lead hydroxide and water; C. T. Barfoed, by treating basic lead formate with an excess of sodium sulphate soln.; and A. de Schulten, by the action of a soln. of sodium sulphate on basic lead acetate.

Lanarkite occurs in crystals, and also massive with a greenish-white, pale yellow, or grey colour. The artificial salt is white or colourless. The crystals are monoclinic prisms, with axial ratios $a:b:c=0.8681:1:1.3836$, and $\beta=91°\ 49'$. A. de Schulten's crystals were acicular with the same crystallographic constants as the natural crystals. The cleavage (001) is perfect; and the (100) and (103) cleavages in traces. The lustre of the cleavage faces is pearly; elsewhere, the lustre is adamantine or resinous. F. Pisani gave for the optic axial angles with red-light, $2H=65°\ 3'$; the optical character is negative. The birefringence is strong. The sp. gr. given by H. J. Brooke is 6·3–6·4; F. Pisani gave 6·8 for lanarkite; and for the artificial salt, A. de Schulten gave 6·923 at 15°. The hardness is 2–2½. R. Schenck and W. Rassbach gave 966° for the m.p., and F. M. Jäger and H. C. Germs, 977°. Hence, as C. T. Barfoed said, it melts more easily than lead sulphate. The molten liquid is yellow, but it becomes white on cooling; and, according to A. de Schulten, furnishes a felted mass of long prisms. C. T. Barfoed said the salt is very sparingly soluble in water, and, according to M. Pleissner, a litre of water at 18° dissolves 13·4 mgrms. of the salt, the sp. conductivity being 8.8×10^{-6} mho. According to W. Reinders, the oxysulphate reacts with lead sulphide: $2Pb_2OSO_4+3PbS\rightleftharpoons7Pb+5SO_2$, and the press. of the gas is 27·5 mm. at 712°; 78 mm. at 750°; and 233 mm. at 790°.

E. Toelle, and J. Kronen claimed to have made **hydrated lead oxysulphate**, $PbO.PbSO_4.$ H_2O, or *lead dihydroxysulphate*, $Pb(OH)_2SO_4$, by the gradual addition of sulphuric acid to lead oxide, or by grinding lead sulphate with water to a paste, and gradually adding lead oxide. Other oxysulphates have been reported, but the evidence is not sufficient to establish their individuality. Thus, D. A. MacInnes believed that *lead tetroxysulphate*, $4PbO.PbSO_4$, is formed during the discharge of a lead accumulator. E. Toelle, and J. Kronen reported *lead hexahydroxydisulphate*, $3Pb(OH)_2.2PbSO_4$, to be formed when sulphuric acid is gradually added to lead oxide; or lead oxide gradually added to a paste made of lead sulphate and water; *lead dihydroxydisulphate*, $Pb(OH)_2.2PbSO_4$, was also said to have been produced in the same way. According to L. F. Hughes, sublimed white-lead has nearly the composition of *lead oxydisulphate*, $PbO.2PbSO_4$. E. Frankland reported *lead dioxytrisulphate*, $2PbO.3PbSO_4$, to be produced in the discharge of lead accumulators. H. O. Hofman and W. Wanjukow supposed *lead pentoxysulphate*, $5PbO.PbSO_4$, to be formed when lead sulphate is roasted to 705°.

L. Brugnatelli [19] said that some basic lead copper sulphates are produced in nature by the weathering of cupriferous galena. The bluish-green, or sky-blue mineral from Leadhills, Lanarkshire, was regarded by H. J. Brooke as *cuprous lead sulphatocarbonate*, and called by F. S. Beudant, **caledonite**—W. Flight, and N. Collie showed that the carbonate was due to the presence of admixed cerussite; and that about 10 per cent. of cupric oxide was present. The results correspond with $2(Pb,Cu)O.SO_3.H_2O$, or $(Pb,Cu)(OH)_2.(Pb,Cu)SO_4$. Analyses of samples from Monte Challacollo, Atacama, by G. Berg correspond with *copper lead hexa-hydroxytetrasulphate*, $3Pb(OH)_2.4PbSO_4$, or $3PbO.4PbSO_4.3H_2O$. A. Pelloux examined samples from Sardinia. According to H. J. Brooke, the prismatic crystals are rhombic with the axial ratios $a:b:c=0.9163:1:1.4032$; but A. Schrauf, and P. von Jeremejeff regarded them as monoclinic twins with numerous twin lamellæ; the former gave for crystals from Rezbanya, Hungary, $a:b:c$ $=1.09134:1:1.57850$, and $\beta=89°\ 18'$, while the latter gave for the crystals from Berezoff, Urals, $a:b:c=1.08956:1:1.57725$, and $\beta=88°\ 22'$. Observations on the crystals were made by R. P. Greg and W. G. Lettsom, W. H. Miller, C. F. Peters,

F. Hessenberg, G. vom Rath, C. Busz, O. C. Farrington, A. F. Rogers, N. von Kokscharoff, H. L. Ungemach, F. N. Guild, etc. The optic axial angles given by A. des Cloizeaux are $2H_a=112°\ 27'$, $2H_0=142°\ 5.5'$, and $2V=82°\ 37'$ for the red-ray, and $2H_a=113°\ 27.5'$, $2H_0=141°\ 32'$, and $2V=83°\ 3'$ for the blue-ray. The index of refraction is $\beta=1.846$ for the red-ray, and 1.864 for the blue-ray. The (001)-cleavage is perfect, and the (100) less so. The sp. gr. is 6.4, and the hardness 2.5-3.0.

H. J. Brooke [20] reported a *cuprous sulphate of lead* found at Leadhills, Lanark-shire. W. Phillips named it *linarite*—after Linares, Spain, where it was formerly supposed to occur. F. Sandberger, T. Liweh, and others have reported samples occurring in Germany, Siberia, Urals, etc. Analyses were reported by H. J. Brooke, T. Thomson, F. von Kobell, F. Sandberger, A. Frenzel, and N. Collie from which the mineral appears to be a *lead copper hydroxysulphate*, $(Pb,Cu)SO_4.(Pb,Cu)(OH)_2$, or $PbO.CuO.SO_3.H_2O$. P. Dudgeon reported crystals from the slag of an old lead smelting hearth of Roman origin, in Troqueer, Scotland; and L. Michel also found linarite in the slag of a lead furnace. The colour of the mineral is deep azure-blue, and the prismatic or tabular crystals, according to N. von Kokscharoff, belong to the monoclinic system and have the axial ratios $a:b:c = 1.71613:1:0.82963$, and $\beta=77°\ 22'\ 40''$. Twinning is common. The (100)-cleavage is perfect, and the (001) less so. The crystals were discussed by P. von Jeremejeff, H. Höfer, W. H. Miller, R. P. Greg and W. G. Lettsom, A. Schrauf, G. vom Rath, V. von Zepharovich, A. Stelzner, and F. Hessenberg. The sp. gr. is 5.3-5.45; A. Frenzel gave 5.06 at 17°. The hardness is $2\frac{1}{2}$. The optical properties were examined by L. Brugnatelli.

Complex salts with lead sulphate.—W. Grahmann [21] examined the f.p. curves of mixtures of lead and potassium sulphates, and found the results summarized in Fig. 115. Solid soln. are formed with up to 27 molar per cent. of lead sulphate. Two compounds were prepared. One, **potassium disulphatodiplumbite,** $K_2SO_4.2PbSO_4$, shows as a maximum m.p. at 948°. It is dimorphous; the transition temp. is 544°; above that temp. what was called α-$K_2Pb_2(SO_4)_3$ is stable, and below that temp. β-$K_2Pb_2(SO_4)_3$ is stable. G. Calcagni and D. Marotta also examined the system and found the same complex salt. The other compound, **potassium disulphatoplumbite,** $K_2Pb(SO_4)_2$, is formed at 619° by a reaction in the solid state. The transition from α- to β-lead sulphate occurs at 852°. The transition from α- to β-potassium sulphate, at 588°, and the effect of lead sulphate on this transition is indicated in the diagram. This salt has also been obtained in the wet way. In 1825, J. B. Trommsdorff treated sugar of lead with a soln. of potassium sulphate and obtained a salt which "appeared to contain equimolar parts of lead and potassium sulphates." J. J. Fox obtained this salt by shaking an excess of a soln. of lead acetate with potassium sulphate, washing the solid phase with a soln. of potassium acetate, then with alcohol, and drying in air. F. G. Belton mixed slowly 20 c.c. of a sat. soln. of potassium sulphate at 75° with 10 c.c. of a 10 per cent. soln. of lead nitrate, washed the solid by suction with a soln. of potassium sulphate. A. Ditte, M. Barre, and J. N. Brönsted digested lead sulphate with a soln. of potassium sulphate, and dried the solid product by press. between bibulous paper. A. Ditte also used other potassium salts—e.g. the chloride, bromide, iodide, cyanide, chlorate, etc. Potassium disulphatoplumbite is a white amorphous solid, or a white mass of microscopic crystals, which, according to W. Grahmann, are optically uniaxial, and show a strong birefringence. F. G. Belton said that the salt is not

FIG. 115.—Freezing-point Curves of Lead and Potassium Sulphates.

attacked by a cold or hot sat. aq. soln. of potassium sulphate ; and, added J. N. Brönsted, at 22°, it is in equilibrium with $0.0227N$-K_2SO_4, and at 0°, with a $0.0112N$-soln. A. Ditte said that if the double salt is not to be decomposed, the conc. of the soln. should be at least 0.35 per cent. at 10° ; 0.49 per cent. at 15° ; and 1.45 per cent. at 100°. M. Barre said that for stability, the soln. should have the following proportion of potassium sulphate for 100 grms. of soln .:

		7°	17°	50°	75°	100°
K_2SO_4	. .	0.562	0.620	1.095	1.373	1.695

J. J. Fox found that the salt is almost insoluble in a soln. of potassium acetate at 25°, and sparingly soluble in a soln. of potassium acetoplumbite at 25°. G. Calcagni and D. Marotta examined the f.p. diagram of mixtures of lead and lithium sulphates, Fig. 116, but obtained no evidence of the formation of *lithium sulphatoplumbite*. Similar results were obtained with mixtures of lead and sodium sulphates, Fig. 117, no *sodium sulphatoplumbite* was formed, but solid soln. with up to 65 per cent. of sodium sulphate were obtained. The eutectic is at 735° with 35 per cent. of sodium sulphate. P. Berthier made some observations on fused mixtures of the two salts—*vide supra*—and H. le Chatelier said that the fusion curve corresponds with the formation of *sodium disulphatoplumbite*, $Na_2Pb(SO_4)_2$; but this lacks confirmation. A. Ditte said that lead sulphate is but very slightly soluble in a boiling
FIG. 116.—Freezing-point Curves of Mixtures of Lithium and Lead Sulphates.
FIG. 117.—Freezing-point Curves of Mixtures of Sodium and Lead Sulphates.

soln. of sodium sulphate ; and neither A. Ditte nor M. Barre could make the salt by the processes employed for the potassium salt ; and J. J. Fox was likewise unsuccessful. A. Lacroix discovered a mineral corresponding with $K_4Na_2Pb_4(SO_4)_7$, or $3(K,Na)_2SO_4.4PbSO_4$, *sodium potassium heptasulphatotetraplumbite*, which he called **palmierite**—after L. Palmieri. It was found in the fumerole deposits of Vesuvius in microscopic micaceous plates, often hexagonal in outline. The mineral is decomposed by water, and dissolved by nitric acid. The sp. gr. is near 3.33 ; F. Zambonini gave 4.5, and found the mineral to be uniaxial with $\omega=1.712$ for the D-line. He synthesized it by fusing at 1000° for an hour a mixture of potassium, sodium, and lead sulphates (5 : 9 : 7.5 parts by weight), and cooling the mass gradually. The tabular crystals were isolated by treating the fused mass with a 2 per cent. soln. of potassium sulphate.

The mineral *röblingite* is a complex of $(Ca,Pb)SO_4$ with CaH_2SiO_4—*vide* silicates. E. Mallard and E. Cumenge [22] observed a mineral from Boleo, Mexico, which they regarded as anglesite, but it was shown by F. A. Genth to be a *calcium sulphatoplumbite*. H. le Chatelier obtained crystals of **barium sulphatoplumbite** by fusing lead and barium sulphates in sodium sulphate, and extracting the excess of sodium sulphate with water. R. Ohashi reported a mineral deposited from a hot spring at Hokuto, Formosa, and hence named *hokutolite*. The composition and optical characters show that it is an isomorphous mixture of anglesite and barytes. The mineral is radioactive, and self-luminescent. G. H. Bailey reported that regular octahedral crystals of **aluminium pentasulphatodiplumbite**, $Al_2Pb_2(SO_4)_5.20H_2O$, were formed

by exposing a mixed soln. of alum and lead nitrate and acetate to a winter's cold. F. Zambonini observed no evidence of the formation of mixed crystals of *lead and didymium sulphates.* E. S. Larsen described a mineral from Beaver County, Utah, which he called *beaverite.* Its composition approximated that of a **copper lead aluminosulphate,** $CuSO_4.PbSO_4.(Fe,Al)_2O_3.4H_2O$. The optical character of the hexagonal plates was negative ; the index of refraction 1·83–1·87 ; and the birefringence was strong. According to R. F. Weinland and H. Kühl, **stannic sulphatoplumbite,** $SnPb(SO_4)_3.3H_2O$, is formed by mixing soln. of stannic acid in sulphuric acid with an equal proportion of a soln. of lead sulphate in hot conc. sulphuric acid. The cubic crystals are decomposed by water. They are insoluble in hydrochloric acid.

Sulphates with quadrivalent lead.—The formation of **lead disulphate,** or **plumbic sulphate,** $Pb(SO_4)_2$—lead quadrivalent—has been reported by a few investigators. B. Brauner [23] found that the yellow soln. of lead tetrafluoride in an excess of sulphuric acid is clear at ordinary temp., but, when warmed to 100° from time to time during a period of more than two months, it furnishes an orange-yellow crust. This product, said B. Brauner, *kann nur Bleidisulfat,* $Pb(SO_4)_2$, *sein.* K. Elbs and F. Fischer said that the result is not satisfactory, and that if red-lead or lead dioxide be treated with sulphuric acid, an impure lead disulphate is formed. A. Hutchinson and W. Pollard found that if lead disulphate is formed by the action of conc. sulphuric acid on lead tetracetate it is extremely unstable, and a satisfactory proof of its existence was not obtained. G. Panopolus said that unstable lead disulphate is present when a soln. of an alkali plumbite is treated with lead dioxide or potassium· persulphate.

K. Elbs and F. Fischer prepared lead disulphate by the electrolysis of sulphuric acid, sp. gr. 1·7–1·8, at temp. not exceeding 30°, using a current density of 0·02–0·06 ampère per sq. cm. The lead anode should be immersed in a considerable vol. of acid and separated from the cathode by a porous pot. The salt is partly deposited in the form of mud containing 60–85 per cent. of plumbic sulphate ; an 85 to 99 per cent. salt is afterwards deposited in indistinct crystals from the anode liquid. K. Elbs and F. W. Rixon found the salt in the mud, and in the sulphuric acid of a lead accumulator. F. Dolezalek and K. Finckh could not obtain the salt free from acid. K. Elbs and F. Fischer added that the rapid disintegration of the positive plates of an accumulator with too high currents is due to the formation of lead disulphate.

K. Elbs and F. Fischer found that lead disulphate has a faint greenish colour, and is stable under sulphuric acid, sp. gr. 1·7, in darkness at room temp. ; and F. Dolezalek and K. Finckh recommended keeping it under very conc. sulphuric acid. The compound is isomeric with lead persulphate—*vide* sulphuric acid. K. Elbs and F. Fischer said that the disulphate is sparingly soluble in sulphuric acid and pyrosulphuric acid, forming greenish-yellow soln.—100 c.c. of the conc. acid dissolves about 0·345 grm. of the salt at 30°. A. C. Cumming gave for the solubility in $7·45N-H_2SO_4$, 0·0003 mol per litre at 25° ; and F. Dolezalek and K. Finckh said that the solubility increases with increasing conc. of sulphuric acid ; thus, expressing conc. in grams per litre at 22°, they found :

H_2SO_4	948	1014	1130	1217	1352	1470	1532	1631	1703
$Pb(SO_4)_2$	0	1·719	2·115	9·303	16·17	9·30	9·46	19·80	35·22
Solid Phase		$PbOSO_4.H_2O$					$Pb(SO_4)_2$		

K. Elbs said that at 100°, the soln. is decomposed with the evolution of oxygen. Lead disulphate is decomposed by water into lead dioxide and sulphuric acid. According to F. Dolezalek and K. Finckh, it is hydrolyzed by dil. sulphuric acid. The hydrolysis takes place in two stages : $Pb(SO_4)_2+2H_2O \rightleftharpoons PbOSO_4.H_2O +H_2SO_4$; and $PbOSO_4.H_2O=PbO_2+H_2SO_4$, the oxysulphate and dioxide being in equilibrium with different conc. of acid as indicated by measurements of the e.m.f.

plotted in Fig. 119. The maximum work of hydrolysis is represented by 0·36 volt, and the calculated value 0·367 volt. The conditions of equilibrium solubility of the **plumbic monoxysulphate**, $PbOSO_4$, are indicated in Fig. 119. E. Frankland reported a *plumbic hexoxydisulphate*, $3PbO_2.2SO_3$, to be produced during the discharge of a lead accumulator; and H. O. Hofmann and W. Wanjukow, *plumbic tetroxysulphate*, $2PbO_2.SO_3$, to be formed by roasting lead hexoxypentasulphate, $6PbO.5SO_3$, at 952°–962°. There is no evidence establishing the chemical individuality of the two compounds last-named. K. Elbs and F. Fischer found that lead disulphate is soluble in an excess of a 20 per cent. soln. of sodium hydroxide, and it is doubtful whether $PbO(ONa)_2$ or $Pb(ONa)_4$ is formed. The disulphate is soluble in cold conc. hydrochloric acid, and the soln. has a yellow colour owing to the formation of lead tetrachloride, or hydrochloroplumbic acid. The salt also dissolves freely in glacial acetic acid, forming lead tetracetate. Like lead dioxide, lead disulphate is a strong oxidizing agent, but it acts rather more vigorously; thus, at room temp., ferrous salts are oxidized to the ferric state; alcohol forms aldehyde; oxalic acid gives carbon dioxide; the halide acids give the free halogen; and iodine forms iodic acid. R. Kempf studied the oxidation of some organic compounds through the agency of the disulphate. F. Dolezalek and K. Finckh found the oxidizing potential with different conc. of sulphuric acid against a
FIG. 118.—Solubility of Lead Disulphate in Sulphuric Acid at 22°.
FIG. 119.—Electromotive Force of Solutions of $Pb(SO_4)_2$ in Sulphuric Acid at 11°.

hydrogen electrode at 11·5° attains a maximum of 1·9 volts when the conc. of the acid is that required for the maximum solubility of the disulphate—*i.e.* nearly 0·57 mol H_2SO_4 per litre. The conc. of acid which gives the most powerful oxidizing effect, ν, at $\theta°$ is $\nu=0·55+0·0019\theta$ mol per litre.

F. Dolezalek and K. Finckh, and W. Esch suggested that the soln. of lead disulphate in conc. sulphuric acid, or the greenish-yellow soln. obtained by the electrolysis of sulphuric acid between lead electrodes, contains **hydrotrisulphatoplumbic acid**, *hydrosulphatoplumbic acid*, or *metasulphatoplumbic acid*, $H_2Pb(SO_4)_3$, because the soln. furnishes corresponding ammonium and potassium salts. The same acid is supposed to be produced by dissolving freshly precipitated lead dioxide in sulphuric acid. Water hydrolyzes the acid soln. by a reversible reaction as indicated above. K. Elbs and F. Fischer prepared **ammonium trisulphatoplumbate**, $(NH_4)_2Pb(SO_4)_3$, as a yellow crystalline powder, by treating the acid soln. of lead disulphate with ammonium sulphate or carbonate. It is more stable than lead disulphate; is almost insoluble in cold sulphuric acid, sp. gr. 1·7, and sparingly soluble in the warm acid; it is more soluble in the monohydrate, $H_2SO_4.H_2O$, and still more soluble in the fuming acid. The salt reacts with water, sodium hydroxide, hydrochloric acid, acetic acid, etc., very like lead diplumbate—but more slowly. They also prepared **potassium trisulphatoplumbate**, $K_2Pb(SO_4)_3$, as in the case of the ammonium salt. It is rather more stable, but behaves similarly towards various reagents. Working in the same manner, K. Elbs and F. Fischer

prepared the related salts **rubidium trisulphatoplumbate,** $Rb_2Pb(SO_4)_3$, and **cæsium trisulphatoplumbate,** $Cs_2Pb(SO_4)_3$. The lithium and sodium salts were not obtained.

§ 31. Lead Carbonates

Lead forms normal lead carbonate and a number of oxycarbonates. Acid carbonates have been reported. Over three hundred years before our era, the preparation of a basic carbonate, white-lead, was described by Theophrastus in his Περὶ Λίθων ; and there are frequent allusions to this substance in the ancient writings where it was named ψιμύθιον by the Greeks, and *cerussa* by the Romans. This preparation was used in making plasters, as an eye-salve, and as a hair-wash. It is doubtful if the Romans used white-lead for painting pictures because H. Davy [1] could detect no lead in his examination of the materials found in ancient baths, or in scrapings from pictures. Pliny, however, alluded to the painting of ships by means of white-lead, and he stated that they were previously painted with a native cerussa from Smyrna. Perhaps the earliest allusion to white-lead occurs in the Οἰκονομικός (**10**. 7) of Xenophon, probably written about 400 B.C., where Ischomachus said that he discouraged his wife using white-lead and other cosmetics because he did not like the practice, and because the artifice was so easily discovered among those who lived in intimacy. Plautus, in his *Mostellaria*

—c. 200 B.C.; Ovid, in his *Medicaminia faciei*—c. 10 B.C.; and Martial, in his *Epigrammata*—c. A.D. 100—made allusion to the whiteness of cerussa.

Theophrastus gave the following directions for preparing white-lead :

Lead is placed in earthen vessels over sharp vinegar, and after it has acquired some thickness by a kind of rust, which it commonly does in about ten days, the vessels are opened, as it were, in a kind of foulness, and the rust scraped off; the lead is then placed over vinegar again, repeating over and over the same method of scraping it until the lead is wholly dissolved. The scrapings are then beaten to powder, and boiled for a long time ; and what at last subsides to the bottom of the vessel is cerusse. Verdigris is made from copper in a somewhat similar way.

In the first century of our era, Pliny, in his *Historia naturalis* (**34**. 54), repeated the description by Theophrastus, and he added (**34**. 50) that white-lead is also made by grinding water in a lead mortar with a lead pestle ; or by grinding lead-filings with rain-water in a stone mortar—sometimes with the addition of vinegar, wine, fat, or rose-leaves. During the operation, the water darkens and becomes muddy, but, after a time, it whitens and resembles white-lead. The supernatant water is removed by straining through a linen-sieve, or by absorption with a sponge. The dried residue was made into pastilles. In both cases, the product must have been a basic carbonate. The white-lead made at Rhodes was considered to be the best, and that process of manufacture was described by Vitruvius in his *De architectura* (**7**. 12), written about the beginning of our era. He said :

The Rhodians placed a layer of vine-twigs at the bottom of a large jar. Vinegar was poured over the twigs, and in these were placed masses of lead. The vessels were covered to prevent evaporation ; and after a certain time they were opened when the lead was changed into *cerussa*.

Pliny said the thinnest lead shavings were employed ; and Dioscorides, in his *Περὶ Ὕλης Ἰατρικῆς* (**5**. 53), contemporaneous with Pliny, emphasized the importance of not allowing the lead to come in contact with the vinegar, and with this object placed the lead on a mat suspended by a stick in the middle of the jar. These writers did not recognize the part played by warmth and carbon dioxide in the process. The use of dung was mentioned about the second century by Galen, in his *De simplicium medicamentorum temperamentis ;* about the end of the eleventh century by Theophilus,[2] in his *De diversis artibus*, and by C. Eraclius. Theophilus described a method of preparation which resembles that employed to-day. In the twelfth-century Latinized *Summa perfectionis magisterii* of Geber, it is said that when lead is placed over acetous vapours, it becomes cerussa. The Venetian process was described by P. Vernatti in 1678 ; and the Dutch process, said to have been introduced in 1622, was described by G. Jars. In 1622, C. Eland obtained a patent for " makinge white and redd-leade, as is now made for painters," but this patent probably referred to a monopoly for the sale of these products, and not to a mode of manufactuing these products. A. Barba, in 1669, described the use of perforated lead plates. Observations on the history of white-lead were made by S. J. Cook, C. A. Klein, H. Faure, W. H. Pulsifer, R. Hitchcock, P. Beck, R. W. Atkinson, and W. H. Adolph. A list of patents from 1622 to 1890 has been compiled.

Normal lead carbonate, $PbCO_3$, occurs in nature. C. Gesner,[3] and A. Cronstedt spoke of *cerussa nativa ;* J. G. Wallerius of the *minera plumbi spathacea*, and A. Cronstedt, of *spatum plumbi* or *Blyspat*—hence the German *Bleispath*, the English *lead-spar*, and the French *plomb spathique*. The mineral has also been called white-lead ore. T. Bergman called it *plumbum acido aereo mineralisatum*, so that when his *aerial acid* came to be called *carbonic acid*, the lead salt was called *lead carbonate*. F. S. Beudant called the mineral *céruse*, and W. Haidinger, **cerussite**. A zinciferous variety analyzed by C. M. Kersten was called *iglésiasite* by J. J. N. Huot ; the same mineral was also analyzed by H. Traube.

Cerussite is a fairly common mineral, and it occurs in conjunction with other lead minerals, being formed by the action of carbonated waters on galena, or its oxidation products. Thus, R. B. Brinsmade [4] attributed the large deposit of

cerussite in the Terrible Mine, Ilse, Colorado, to the action of descending waters. Pseudomorphs after galena, anglesite, leadhillite, linarite, etc., have been noted. G. von Blöde found replacements in limestones and fossils which in some cases were transformed completely into cerussite. H. von Decken observed a thick coating of cerussite on the walls of an old mine; it seemed to have been deposited like sinter from soln. J. D. Whitney found some stalactites from Brighen's diggings, Wisconsin, to contain about 94 per cent. of lead carbonate. A. Lacroix found crystals of cerussite in the encrustation of Roman coins of the period A. Severus, 205–234 A.D.; F. Rathgen, on lead medals; W. G. Brown, on some old leaden bullets among the *débris* of a battle-field at Morris Island; A. de Schulten, on the old lead slags at Laurion, Greece; and L. Michel, in some old lead slags at Poullaouen, Finistère. A. F. Rogers found some cerussite on some Chinese coins dating from the seventh century—he added that the coins contained no lead, and that all the constituents have come from outside sources.

The preparation of lead carbonate.—A. C. Becquerel [5] claimed to have made crystals of cerussite by allowing a conc. soln. of sodium and calcium carbonates to act for seven years on a lead plate wrapped about with platinum wire. C. F. Carrier also said that the salt is formed when a soln. of sodium acetate and sulphite or sodium chlorate and carbonate is electrolyzed with lead electrodes —the acetate, in the former case, furnishes the required carbon dioxide. F. Auerbach and H. Pick obtained the normal carbonate by repeatedly digesting basic lead carbonate, the chromate or basic chromate, or the sulphate with a soln. of sodium carbonate; or lead sulphate with a soln. of sodium hydrocarbonate: $2NaHCO_3 + PbSO_4 \rightleftharpoons PbCO_3 + CO_2 + H_2O + Na_2SO_4$. W. Herz also made the carbonate by digesting lead bromide, chloride, or sulphate with an excess of a soln. of sodium carbonate. For equilibrium, he found the ratio of the conc.: $[Na_2CO_3]/[NaBr]^2 = 3 \cdot 1 \times 10^{-4}$; $[Na_2CO_3]/[NaCl]^2 = 1 \cdot 1 \times 10^{-4}$; and $[Na_2CO_3]/[Na_2SO_4] = 1 \cdot 1 \times 10^{-2}$, respectively. H. Becquerel also transformed lead sulphide into the carbonate by the action of a soln. of sodium hydrocarbonate; and E. Dittler, by the action of boiling water on galena in an extraction apparatus through which a current of carbon dioxide was passing. R. Böttger obtained lead carbonate by triturating lead dioxide with oxalic acid. C. R. A. Wright and A. P. Luff said that when red-lead, or lead monoxide, is heated to 200° in a current of carbon monoxide, part of the lead is reduced, forming carbon dioxide, which reacts with some of the unreduced oxide, forming lead carbonate; but neither carbon dioxide nor carbon monoxide has any action on lead dioxide at 100°. A. de Schulten passed a slow current of carbon dioxide over a soln. of 20 grms. of normal lead acetate and 2 grms. of sodium chloride in a litre of water. Bright crystals of laurionite first appear on the sides of the flask and at the surface of the liquid; then crystals of phosgenite appear; and finally cerussite is produced at the expense of the laurionite. When artificial laurionite or phosgenite is treated with carbon dioxide and water, the laurionite is converted into phosgenite; and the phosgenite, in turn, into cerussite.

J. J. Berzelius obtained lead carbonate by treating a soln. of lead nitrate with ammonium carbonate. O. Ruff and B. Hirsch studied the fractional precipitation of lead as carbonate in the presence of salts of manganese, zinc, cadmium, copper, silver, iron (ic and ous), chromium, and aluminium. J. A. Phillips added a boiling soln. of lead nitrate to an excess of a soln. of sodium carbonate. D. Strömholm mixed a cold soln. of lead nitrate with one of sodium carbonate containing 0·2 eq. of carbon dioxide per litre, and allowed the mixture to stand for some time. J. J. Berzelius said that if sodium carbonate be employed as precipitant, and the precipitate be boiled with the liquid, much sodium carbonate is adsorbed. G. J. Mulder used potassium carbonate as precipitant; J. Löwe, sodium hydrocarbonate; and A. Bette, and K. Feist added the ammonium carbonate to a soln. of lead acetate. M. Pleissner recommended mixing 100 c.c. of a 15 per cent. soln. of lead acetate, and 100 c.c. of a 5 per cent. soln. of ammonium carbonate, sat.

with carbon dioxide, washing the product with water sat. with carbon dioxide and free from ammonia, and drying in vacuo over sulphuric acid ; F. Auerbach and H. Pick used a similar process, drying the product at 100°—cf. Figs. 120 and 121. J. Lefort added that if the soln. of the lead salt be hot, the alkali carbonates precipitate basic lead carbonates ; normal lead carbonate is obtained only with cold soln. R. Salvadori made a similar observation with respect to the soln. of lead nitrate treated with ammonium carbonate. He also observed that if a mixed soln. of sodium sulphate and carbonate is added to a mixture of lead sulphate and carbonate, the whole of the sodium carbonate is converted into sulphate when the latter is present in large excess, and lead carbonate is formed. Similarly, if a lead nitrate soln. be added to a mixed soln. of sodium sulphate and carbonate, lead carbonate alone is precipitated. Unlike the cases of partition observed by A. Findlay, the whole of the sodium carbonate is utilized before any lead sulphate is formed. J. S. Stas recommended the following process for lead carbonate of a high degree of purity :

He digested a soln. of a commercial lead acetate at 40°–50° in a leaden vessel containing some strips of lead foil. This precipitated copper and silver. The filtered soln. was then poured into dil. sulphuric acid, and the washed precipitate digested with a mixture of ammonia and ammonium carbonate ; and the resulting lead carbonate washed with water. One part of the carbonate was heated in a platinum crucible to convert it into lead oxide, and the other part was dissolved in dil. nitric acid. The lead oxide was gradually added to the boiling soln. of nitrate so as to precipitate any iron present. The filtered soln. was poured into an excess of a sat. soln. of ammonium carbonate ; and the precipitate washed, and dried.

A. Drevermann, and E. Frémy obtained crystals of cerussite by the slow diffusion of very dil. soln. of potassium carbonate and lead nitrate separated by a porous membrane. H. Rose obtained lead carbonate by passing carbon dioxide into a soln. of lead acetate, and A. Altmann added that with soln. ranging from $0.02N$- to $2N$-lead acetate, and at temp. between 0° and 100°, the proportion of normal lead carbonate formed decreases with rise of temp. and increased conc. of acetate. With soln. heated for some time at 100° in a reflux apparatus, normal carbonate is precipitated, but if the acetic acid set free by hydrolysis can escape, the precipitate obtained with carbon dioxide and dil. soln. is a basic carbonate, $2PbCO_3.Pb(OH)_2$; but with conc. soln., a mixture of this basic salt and normal carbonate is precipitated. L. Falk passed carbon dioxide into a soln. of the basic acetate ; and A. Wultze, and L. Falk showed that the carbon dioxide is more effective if under an increased press. L. Bourgeois obtained a mixture of crystals of cerussite and hydrocerussite by heating a mixture of ammonium carbonate, water, and lead nitrate in a sealed tube at 140° ; urea can be substituted for the ammonium carbonate since it is converted into the carbonate during the operation. J. Riban obtained good crystals of cerussite by heating 10 c.c. of a 5 per cent. aq. soln. of lead formate in a sealed tube at 175° for 75 hrs. J. W. Morris and co-workers prepared lead carbonate by the action of ammonium carbonate on a soln. of lead formate ; and G. C. Smith, by treating the sulphate first with aq. ammonia and then with carbon dioxide.

W. Leuze [6] found that **colloidal lead carbonate** is produced by treating a 10 per cent. soln. of sodium protalbinate with a dil. soln. of lead acetate, dissolving the precipitate in a 10 per cent. soln. of sodium hydroxide assisted by warming on a water-bath, and passing carbon dioxide into the liquid for 15 minutes. No precipitation of lead carbonate occurs. The sol is stable only for a short time, for when allowed to stand, it becomes turbid.

Analyses of the normal salt were reported by M. E. Chevreul,[7] J. J. Berzelius, A. Bette, G. J. Mulder, D. Strömholm, J. Riban, J. A. Phillips, M. Pleissner, A. Altmann, K. Feist, J. F. Sacher, and analyses of the mineral cerussite by M. H. Klaproth, C. W. Bergmann, W. B. Hobbs, W. F. Petterd, F. Sandberger, P. von Jeremejeff, C. F. Rammelsberg, J. L. Smith, J. F. John, A. des Cloizeaux,

R. B. Green, C. H. Warren. The results agree with the empirical formula $PbCO_3$, and L. Falk regarded it as a derivative of metacarbonic acid; while the many basic salts were referred to orthocarbonic acid, $C(OH)_4$. He also suggested that the crystalline form is a ring compound $(PbCO_3)_2$, or

$$Pb{<}^{CO_3}_{CO_3}{>}Pb$$
The physical properties of lead carbonate.—Lead carbonate occurs in simple tabular, prismatic, or pyramidal rhombic or pseudohexagonal **crystals**; and in groups or aggregates of crystals; it rarely occurs fibrous, but is often granular, massive, or compact, and, maybe, earthy—*e.g. Bleierde*. The colour may be white, or the mineral may be more or less tinged grey so as to appear almost black. The so-called *Bleischwärze* is coloured black by carbonaceous matters. In some cases the crystals are tinted blue with copper. N. von Kokscharoff[8] gave for the axial ratios of the rhombic crystals $a : b : c = 0.609968 : 1 : 0.723002$; M. L. Huggins gave $0.6102 : 1 : 0.7232$. The crystals have been the subject of many observations. They are isomorphous with aragonite, witherite, strontianite, and potassium nitrate. F. Becke gave the following constants for the series:

	Mol. wt.	Sp. gr.	Eq. vol.	χ	ψ	ω
$CaCO_3$.	. 100·0	2·94	34·01	2·64	4·23	5·05
$SrCO_3$.	. 147·5	3·7	39·87	2·73	4·49	3·25
$BaCO_3$	. 197·0	4·3	45·82	2·84	4·70	3·44
$PbCO_3$	. 266·9	6·6	40·44	2·75	4·51	3·26

For mixed crystals with aragonite, *vide infra*, plumboaragonite. The **twinning** of the crystals is common. There may be contact and penetration twins often repeated, forming six-rayed, stellate groups. Some of the faces are often striated. The (110) and (021) cleavages are distinct; and the (010) and (012) **cleavages** are indistinct. The **optical character** is negative. The **optic axial angles** found by A. Schrauf are $2V = 8° 22'$ for the B-line, $8° 14'$ for the D-line, and $7° 35'$ for the E-line; while $2V = 17° 16\frac{1}{4}'$ for the B-line, $17° 8'$ for the D-line, and $15° 55'$ for the E-line. A. des Cloizeaux gave, with red-light, $2E = 18° 22'$ at $12°$; $20° 21'$ at $71.5°$; and $22° 2'$ at $95.5°$. C. Gaudefroy found the ratio of the birefringence to the wave-length is a maximum for $\lambda = 620\mu\mu$ for cerussite from Tsumeb, S.W. Africa. The crystals of Hungarian specimens of cerussite were studied by L. Tokody. F. M. Jäger and H. Haga examined the **X-radiogram**; and M. L. Huggins found that cerussite has the aragonite structure with unit cell of vol. 134·1 cubic Angström units. J. F. John[9] gave 6·5 for the **specific gravity** of cerussite; C. J. B. Karsten, for precipitated carbonate gave 6·4277; J. L. Smith gave for cerussite 6·60; M. L. Huggins, 6·574; and H. G. F. Schröder, 6·510–6·517. F. Becke, and P. Niggli gave 6·6 for the sp. gr., and 40·5 for the eq. vol. F. A. Henglein studied the mol. vol., and I. I. Saslawsky gave 0·76 for the ratio of the mol. vol. to the sum of the at. vols. of the constituent elements. The **hardness** of cerussite is 3–3½ on Mohs' scale; it is therefore harder than calcite; and F. Pfaff said that it is 8·4–8·6 times as hard as steatite. A. Reiss and L. Zimmermann studied the relation between the hardness and the mol. vol. E. Madelung and R. Fuchs gave 1.57×10^{-12} dynes per sq. cm. for the coeff. of **compressibility.**

F. E. Neumann[10] found the **specific heat** of cerussite to be 0·0814, and the **molecular heat,** 21·7; H. Kopp gave 0·0791 and 21·1 respectively, each taken between 16° and 47°. G. Linder found 0·08176 between 0° and 350°, and 0·06392 between 0° and 300°. The great difference is attributed by G. Linder to chemical change.

H. Debray[11] showed that, unlike the thermal dissociation of calcium carbonate, that of lead carbonate is not reversible; apparently a change which occurs in the lead oxide prevents it absorbing the gas reversibly. A. Colson said that the

action is reversible when the gas is moist. He also found that lead carbonate decomposes when heated in vacuo at 285°—silver carbonate breaks down at 220°. Traces of moisture accelerate the decomposition, thus, the **dissociation pressures,** p mm., when the system is undried, are :

	184°	210°	233°	280°
Dried	10	32·5	102	548 mm.
Moist	12	33	104	— ,,

The atm. press., by extrapolation, is attained at 302°; or, according to O. Brill, at 337°. O. Brill also represented the relation between the press. and temp. by the equation: $\log p = -22580/4 \cdot 571T + 1 \cdot 75 \log T + 3 \cdot 2$—*vide* basic lead carbonate. G. Mazzetti observed no sign of the formation of basic carbonate on the curve showing the loss of weight with temp., the temp. of decomposition was 346; W. Eitel, and L. Joulin made some observations on this subject. K. Friedrich said that the decomposition begins at 315° when in air, and the maximum thermal change occurs at 315°—the basic carbonate simultaneously formed requires a higher temp. for decomposition—the corresponding values being 430° and 460°. In air, L. Michel said that red-lead begins to appear at about 300°. The molar **heat of formation** of lead carbonate from its elements, given by J. Thomsen, is 169·8 Cals.; M. Berthelot gave 166·7 Cals.; P. Günther, 169·5 Cals.; and A. Colson, 166·6 Cals. J. Thomsen gave for the heat of the reaction a soln. of a mol of sodium carbonate in 400 mols of water: $Pb(NO_3)_2 + Na_2CO_3 = 2NaNO_3 + PbCO_3 + 6 \cdot 11$ Cals.; for (PbO,CO_2), 22·6 Cals.; and for (PbO,O_2,CO), 139·69 Cals. A. L. Marshall and B. Bruzs gave $(PbO,CO_2) = 21 \cdot 1$ Cals.; and $(PbO,PbCO_3) = 0 \cdot 34$ Cal.; and for the heat of soln. of $PbCO_3$ in nitric acid, and 50 per cent. by vol., 1·99 Cals., and for $PbO.PbCO_3$, 8·54 Cals.

H. C. Sorby [12] gave 1·977 for the mean **index of refraction** of cerussite, and 0·441 for the refractive power. A. Schrauf gave for the indices of refraction, $a = 1 \cdot 7915$, $\beta = 2 \cdot 0595$, and $\gamma = 2 \cdot 0613$ for the B-line; and 1·8037, 2·0763, and 2·0780 respectively for the D-line; and 1·8164, 2·0919, and 2·0934 respectively for the E-line. G. R. Negri gave for the D-line, $a = 1 \cdot 8036$, $\beta = 2 \cdot 0765$, and $\gamma = 2 \cdot 0786$. P. Sève made photograms of the interference figures, and found that the exterior angle varies with the wave-length of the monochromatic light until it becomes uniaxial in ultra-violet light at ordinary temp. C. Gaudefroy gave for the birefringence $\gamma - \beta = 0 \cdot 00205$ for rays of wave-length $\lambda = 700\mu\mu$ to 0·00073 for $450\mu\mu$. T. Liebisch and H. Rubens found the **reflecting power** for the ultra-red rays to be very high. C. Doelter found lead carbonate to be almost opaque to the **X-rays.** A. Pochettino found that the **luminescence** produced by the cathode rays is the same colour as the fluorescence and shows no signs of polarization. W. Heintze found the **photoelectric effect** for cerussite is a maximum for light of wave-length $\lambda = 280\mu\mu$.

The **dielectric constant** given by C. B. Thwing [13] is 18·58; and by W. Schmidt, $a = 25 \cdot 4$, $\beta = 23 \cdot 2$, $\gamma = 19 \cdot 2$. L. Ebert studied the dielectric polarization of lead salts. W. G. Hankel observed the **pyroelectrical properties** of the crystals. G. Cesaro said that the **electrical conductivity** of cerussite is very small. F. Kohlrausch, and W. Böttger measured the sp. electrical conductivity of aq. soln. of lead carbonate; and for sat. soln., the former gave $0 \cdot 0_5 2$ at 18° with soln. not quite free from carbon dioxide, the latter gave $0 \cdot 0_5 102$ to $0 \cdot 0_5 161$ at 19·96°; and M. Pleissner gave $0 \cdot 0_5 16$, and for the degree of **ionization** of a soln. of 0·0085 millimol $PbCO_3$ at 18°, but the true value is thought to be higher. M. Pleissner found the sp. conductivity of soln. containing, in milligrams per litre, at 18°, to be:

CO₂	0	2·8	5·4	14·4	26·0	43·5	105·5
Pb	1·7	4·8	5·8	8·1	9·8	11·8	15·7
Sp. cond.	$0 \cdot 0_5 27$	$0 \cdot 0_5 53$	$0 \cdot 0_5 68$	$0 \cdot 0_5 86$	$0 \cdot 0_5 99$	$0 \cdot 0_4 122$	$0 \cdot 0_4 160$

The chemical properties of lead carbonate.—H. Hélier [14] found that **hydrogen** reduces the salt completely at 325°, while the reduction of lead monoxide at 350°

is incomplete. H. Mennicke also found that nascent hydrogen—zinc and hydrochloric acid act more rapidly in the presence of platinum—reduces it rapidly and completely at ordinary temp. According to R. Fresenius, a litre of water dissolves 0·0198 grm. of lead carbonate at ordinary temp.; A. Drevermann gave 0·02 grm. F. Kohlrausch and F. Rose calculated values from the electrical conductivity of the aq. soln., and found 3 mgrms. of normal lead carbonate are dissolved per litre at 10°; W. Böttger gave 0·0015 grm. at 20°; and M. Pleissner, 0·05 mgrm. at 16°. The last-named showed that the values previously deduced from the electrical conductivity are too high. He gave for the solubility product, $0·33 \times 10^{-13}$, whilst F. Auerbach and H. Pick showed that the true value is nearer $1·0 \times 10^{-13}$ to $1·5 \times 10^{-13}$. M. Pleissner said that the **hydrolysis** at ordinary temp. is not perceptible; at 70°, the aq. soln. has an alkaline reaction which disappears on cooling. He said that if boiled in water, while a current of air is passing, a basic carbonate, $2PbCO_3.2Pb(OH)_2$, is formed. J. F. Sacher said that water at 18° slowly converts the normal salt into a basic carbonate, and that the change is rapid in hot water. R. Salvadori found that the basic carbonate is not formed at 30°, but is rapidly formed at 70°; and E. Dittler, that a 0·1N-soln. of **potassium hydroxide** dissolves cerussite with decomposition. H. Rose, and M. H. Klaproth noted the solubility of lead carbonate in soln. of potassium or **sodium hydroxide.** J. H. Walton and D. W. O. Jones found that **hydrogen dioxide,** in aq. amyl alcohol, amyl acetate, isobutyl alcohol, and quinoline soln., is catalytically decomposed by lead carbonate. V. Zotier studied the reaction.

H. Moissan found the salt becomes incandescent in **fluorine,** carbon dioxide is evolved, and lead fluoride is formed. Lead carbonate is readily soluble in **hydrochloric acid.** A. Voigt found it to be less soluble in a soln. of **magnesium chloride** than is lead oxide; and H. Hof observed that cold soln. of sp. gr. 1·3 dissolve it without decomposition, but near 80°, gas is evolved and a basic salt deposited. Unlike $2PbCO_3.Pb(OH)_2$, the soln. of normal lead carbonate in magnesium chloride of sp. gr. 1·16, when diluted with water, does not have an alkaline reaction. R. H. Brett, F. Weppen, and H. Rose said that lead carbonate is readily dissolved by a soln. of **ammonium chloride**; and P. L. Dulong, that it is partially decomposed by boiling with **sodium fluoride.** A. Ditte observed no reaction between freshly precipitated lead carbonate and a conc. soln. of **potassium iodide.**

According to J. B. Senderens, lead carbonate is decomposed more readily than the oxide when boiled with **sulphur** and water. L. Falk showed that when lead carbonate is suspended in water or alcohol, and treated with **hydrogen sulphide,** it is converted into lead sulphide. H. N. Stokes obtained crystalline lead sulphide by heating the carbonate under press. in hydrogen sulphide. L. Falk said that hydrogen sulphide reacts slowly with crystalline lead carbonate, and rapidly with the amorphous salt. J. F. Sacher showed that no carbon dioxide is evolved during the blackening of white-lead by hydrogen sulphide. P. L. Dulong said that a boiling soln. of **potassium or sodium sulphite** partially decomposes lead carbonate, while **ammonium sulphite** decomposes it completely. Lead carbonate is converted into sulphate by **sulphuric acid.** It is not dissolved by a mixture of one part sulphuric acid and six parts of absolute alcohol. P. L. Dulong found that a boiling soln. of **ammonium sulphate** decomposes lead carbonate completely. H. Rose, and F. J. Malaguti said that aq. soln. of **potassium sulphate** do not decompose lead carbonate; J. Persoz said that there is a slight decomposition. If lead carbonate be suspended in a soln. of **sodium sulphate,** F. Auerbach and H. Pick observed very little decomposition when carbon dioxide is passed at atm. press., but at higher press., more is decomposed; P. L. Dulong, that there is a partial decomposition by boiling soln. of potassium, sodium, **calcium, or magnesium sulphate.** According to C. A. Stetefeldt, lead carbonate is insoluble in an aq. soln. of **sodium thiosulphate,** but when the two salts are triturated together, P. Jochum observed a slight decomposition.

According to E. C. Franklin, lead carbonate is insoluble in liquid **ammonia.**

J. J. Berzelius said that the carbonate is insoluble in aq. ammonia. F. Rössler found that when heated in a stream of ammonia, lead cyanamide, $PbCN_2$, is formed, which furnishes cyanamide when treated with hydrogen sulphide. Lead carbonate is easily soluble in dil. **nitric acid,** but conc. nitric acid forms a protective, insoluble crust of lead nitrate. W. Spring said that the rate of dissolution of cerussite in 10 per cent. nitric acid is 0·757 times that of calcite. F. W. O. de Coninck said that aq. soln. of **sodium nitrate** decomposed lead carbonate perceptibly. J. J. Berzelius said that the carbonate is decomposed by a boiling soln. of **calcium nitrate.** P. L. Dulong said that a boiling soln. of **sodium hydrophosphite, sodium hydrophosphate, sodium ammonium hydrophosphate, or potassium or sodium arsenate** partially decomposes lead carbonate. Similar remarks apply to a soln. of **potassium chromate.** This reaction was also studied by H. Goldblum and G. Stoffella. According to E. Dittler, a soln. of **ammonium molybdate** at 150° converts precipitated lead carbonate partially into lead molybdate ; with cerussite at 100°, an olive-green mixture of molybdenum dioxide and trioxide is formed.

J. F. John was mistaken in saying that lead carbonate is insoluble in an aq. soln. of **carbon dioxide.** J. Tünnermann found the salt to be slightly soluble in carbonic acid, but added that the soln. is prevented by traces of various salts. G. Wetzlar said that an aq. soln. of lead oxide is rendered turbid by a small quantity of carbon dioxide, but regains its transparency on the addition of a larger quantity. The liquid reddens litmus, and becomes turbid when heated, or mixed with a soln. of sodium carbonate. Lead covered with an aq. soln. of carbon dioxide and exposed to air was found by J. Tünnermann to tarnish after the second day, and the clear soln. contains lead carbonate in soln., and gives a precipitate when boiled. The precipitated carbonate obtained by adding carbonic acid to lead acetate soln., was found by P. Yorke to contain between 0·167 and 0·200 grm. of lead oxide per litre. The soln. gives a precipitate with potassium carbonate or hydrocarbonate. J. L. Lassaigne found that 1000 grms. of a sat. aq. soln. of carbon dioxide dissolve 0·14 grm. of lead carbonate ; and R. Wagner added that if the carbon dioxide be under 4 to 6 atm. press., 0·5 grm. of the carbonate may be dissolved. O. Hähnel found that when the partial press. of the carbon dioxide is one atm., the solubility is 0·014 per cent. ; and when the partial press. is 50 atm., 0·015 per cent. C. A. Seyler, and T. Paul and co-workers showed that in a sat. soln. the conc. of the lead ions is directly proportional to the conc. of the free carbon dioxide, and inversely as the square of the conc. of the HCO'_3-ions. Expressing conc. in milligrams per litre, M. Pleissner found the solubility to be, at 18° :

CO_2	.	.	0	2·8	5·4	14·4	26	43·5	106
$PbCO_3$	.	.	1·75	6·0	7·0	8·2	9·9	10·9	15·4

It is assumed that in all these cases, the liquid contains unstable **lead hydrocarbonate,** $Pb(HCO_3)_2$. A. Ditte said that with potassium iodide, potassium tetraiodoplumbite is formed, but with an excess of lead hydrocarbonate, lead iodide is formed. F. Auerbach and H. Pick said that sodium chromate forms basic lead chromate by a reversible reaction, and E. Dittler, that calcium molybdate forms lead molybdate. J. B. J. D. Boussingault said that when a soln. of lead nitrate or acetate is mixed with sodium sesquicarbonate, a white precipitate is formed, which, when dried in air, has a composition corresponding with the formula $4PbO.5CO_2$, or $4PbCO_3.CO_2$. This statement wants reconsideration.

According to R. Fresenius, the solubility of lead carbonate in water is nearly doubled if a little ammonium carbonate and acetate, and free ammonia be present ; and is still further increased if some ammonium nitrate and carbonate, and free ammonia be present. A. Altmann made some observations on the solubility of lead carbonate in water containing carbonic and acetic acids. F. Auerbach and H. Pick showed that with **sodium carbonate** a complex salt is formed ($q.v.$). H. Rose said that the carbonate is not absolutely insoluble, at ordinary temp., in an excess of a soln. of sodium or **potassium carbonate,** but is insoluble in soln. of **ammonium**

carbonate, and in soln. of **potassium** or **sodium hydrocarbonate.** F. J. Malaguti showed that when a mol of lead carbonate is boiled with a soln. of a mol of potassium ·carbonate, 93·28 per cent. of the lead salt is decomposed. J. S. Stas showed that **potassium cyanide** reduces it to the metal. H. C. Bolton found that **formic acid** slowly dissolves cerussite; **acetic, oxalic, and tartaric acids** act similarly. J. Mercer showed that the carbonate is soluble in soln. of acetates; and F. Weppen, in soln. of **ammonium acetate.** A. Naumann said that lead carbonate is insoluble in **methyl acetate.** L. Falk, J. F. Sacher, and E. Euston studied the action of soln. of **lead acetate** or basic lead acetate on lead carbonate. According to L. Falk, when lead carbonate is shaken with a soln. of basic lead acetate, three parts of carbonate withdraw two parts of oxide from soln., as shown by titration, but the washed precipitate always contains too much carbonate for the formula. If boiled with the basic lead acetate soln., the ordinary basic carbonate, $2PbCO_3.Pb(OH)_2$, is obtained. Crystalline and amorphous lead carbonates differ in their chemical behaviour. Thus, whilst the amorphous compound reacts readily with lead oxide in presence of lead acetate, the crystalline modification only reacts very slowly. The formulæ

$$CO{<}^O_O{>}Pb \qquad\qquad Pb{<}^O_O{>}C{<}^O_O{>}C{<}^O_O{>}Pb$$
<div align="center">Amorphous lead carbonate.   Crystalline lead carbonate.</div>

are proposed for the two modifications, and a similar polymerization is assumed in the case of white-lead. Structural formulæ for the basic carbonates are proposed. P. L. Dulong said that the carbonate is partly decomposed by boiling with soln. of **potassium or sodium oxalate.** F. J. Malaguti added that when a mol of lead carbonate is boiled with a soln. of a mol of potassium oxalate, 15 per cent. of lead salt is decomposed. H. C. Bolton found that a cold conc. soln. of **citric acid** freely dissolves cerussite. J. Aub said that a litre of **serum** at 25° dissolves 0·0333 grm. of lead carbonate. R. Marc, and W. Suida noted the adsorption of **organic dyes** by lead carbonate. L. Kahlenberg and W. J. Trautmann studied the reduction of lead carbonate when heated with powdered **silicon.** R. Canaval found that **silicates** are broken down by heating to fusion with lead carbonate. P. L. Dulong noted that a boiling soln. of **sodium diborate** partially decomposes lead carbonate.

The basic lead carbonates.—Quite a large number of basic lead carbonates have been reported, and some occur as minerals in nature. M. Cszentnerszwer and co-workers [15] found that the partial press. of the carbon dioxide for lead carbonate is $\log p=-(19·816/4·571T)+1·75\log T+3·2$; and when lead carbonate is heated under 760 mm., the normal carbonate passes to **lead trioxypentacarbonate,** $3PbO.5PbCO_3$, at 274°; into **lead oxycarbonate,** $PbO.PbCO_3$, at 285°, for which the partial press. of the carbon dioxide is $\log p=-(23·047/4·571T)+1·75T+3·2$; into **lead dioxycarbonate,** $2PbO.PbCO_3$, at 360°, for which the partial press. of the carbon dioxide is $\log p=-(25·036/4·571T)+1·75\log T+3·2$; and into

lead monoxide at 4·2°. The composition-temperature diagram is shown in Fig. 120. R. Salvadori found that **lead dihydroxydicarbonate,** $2PbCO_3.Pb(OH)_2$, is formed when lead carbonate is boiled with water, or when lead sulphate or chloride is boiled with an aq. soln. of sodium carbonate. This agrees with the assumption that a chemical individual is formed; or else this substance is the end-term of a series of solid soln. On the other hand, A. Isenburg showed that when made electrolytically, the product

<div align="center">Fig. 120.—Composition-Temperature Diagram of the Basic Lead Carbonates.</div>

usually has a variable composition. L. F. Hawley found that the solubilities of lead carbonate and hydroxide in water are too small to permit of the application of water as solvent, but if a soln. of sodium acetate be employed as

solvent, and the conc. be kept constant, this soln. can be regarded as solvent, and the system treated as one with three components Pb(OH)$_2$-PbCO$_3$-solvent. Working at ordinary temp., and plotting the amounts of lead in the soln., expressed in milligrams per 100 c.c. of soln., as ordinates, and the molar proportions of lead hydroxide and lead carbonate in the solid phase or phases as abscissæ, the result shown in Fig. 121 was obtained. There are no solid soln., only one definite complex is formed, namely, 2PbCO$_3$.Pb(OH)$_2$. When mixtures of lead oxide and carbonate are employed, the amount of oxide changed to hydroxide is eq. to half the lead carbonate present. It is therefore inferred that only three solid phases are possible when mixtures of lead oxide and carbonate are treated with water, viz. PbO, Pb$_3$(OH)$_2$(CO$_3$), and PbCO$_3$.

Lead dihydroxydicarbonate is represented by the commercial product white-lead, which is probably a mixture of this compound with more or less lead hydroxide and carbonate. Indeed, E. Euston, for reasons stated below, regards this product as an adsorption compound of these two components, the basic lead carbonate occurring as a coating on native lead at Langban, Wermland,

FIG. 121.—Equilibrium in the System PbO–PbCO$_3$–H$_2$O at Ordinary Temperatures.

Sweden; and along with leadhillite and susannite at Leadhills, Scotland. P. P. Philipenko found it at Ridderovsky, Altai Mts., Siberia; and L. J. Spencer and E. D. Mountain, on the Mendip Hills, Somersetshire. Analyses reported by M. F. Heddle, P. P. Philipenko, L. Bourgeois, and L. J. Spencer and E. D. Mountain are in agreement with this formula, 2PbCO$_3$.Pb(OH)$_2$. The mineral was called **hydrocerussite** by A. E. Nordenskjöld, and *plumbonacrite*, by M. F. Heddle. A. Lacroix reported it in the lead slags at Laurion, Greece, and also in cavities in galena at Wanlockhead, Scotland. J. S. S. Brame, and F. Southerden found products of the same composition resulting from the corrosion of lead roofing.

C. Hochstetter said that this salt is obtained when carbon dioxide is passed into a soln. of basic lead acetate—*vide infra*, white-lead. L. Bourgeois employed a boiling soln. of the basic acetate and obtained crystals of hydrocerussite. A. Altmann boiled a soln. of 0·2N-lead acetate so as to evaporate the free acetic acid; dry carbon dioxide was passed through the soln., which was then filtered rapidly, washed, and dried at 100°. R. Salvadori, and M. Pleissner boiled normal lead carbonate with water for a long time and obtained this basic carbonate. The latter also obtained it by warming 4 grms. of the normal salt with 4 drops of a 30 per cent. soln., and the former, by boiling the normal carbonate with a soln. of sodium sulphate or chloride. M. Pleissner also obtained it by treating a soln. of lead hydroxide with carbon dioxide; by the action of oxygenated water on lead in the presence of air; and by shaking mixtures of freshly precipitated lead hydroxide and carbonate. L. Bourgeois obtained crystals of hydrocerussite by treating lead carbonate with a soln. of ammonium nitrate; and also by treating a boiling soln. of a mol of lead acetate with one and a half mols of litharge and, when cold, adding a mol of urea. The filtered liquid, when heated for some hours at 130°, furnishes nacreous spangles of hydrocerussite. C. Hochstetter, and H. Rose obtained this basic salt by adding sodium carbonate to a soln. of a lead salt; D. Strömholm recommended a soln. of sodium carbonate with 0·15 eq. CO$_2$ per litre. C. A. Stevens said that with strongly alkaline soln. no basic carbonate is precipitated by sodium carbonate. L. Bourgeois obtained crystals of hydrocerussite by the action of carbon dioxide on a dil. soln. of sodium plumbite. R. Salvadori obtained the basic salt by boiling lead sulphate or chloride with a 0·1N-soln. of sodium carbonate. F. Auerbach showed that the complex salt NaPb$_2$(OH)(CO$_3$)$_2$ may be formed, and finally normal lead carbonate. L. Falk, and J. F. Sacher employed variations of this process. E. Dittler said that this basic carbonate is formed by the weathering
of galena in air, and that the crystals are formed by boiling lead molybdate with soln. of sodium carbonate, and by allowing a soln. of lead molybdate, $2PbO.5MoO_3$, in one of sodium carbonate to stand in air.

A. E. Nordenskjöld, and H. Sjogren said that hydrocerussite furnishes white or colourless hexagonal plates, which, according to A. Lacroix, and E. Bertrand, are uniaxial. G. Flink said that the crystals belong to the hexagonal system, and have the axial ratios $a : c = 1 : 1.4187$. L. J. Spencer and E. D. Mountain gave $a : c = 1 : 0.61$, and showed that the symmetry is rather rhombohedral than hexagonal. The (0001)-cleavage is perfect, the birefringence is feeble and negative. L. J. Spencer and E. D. Mountain could not develop satisfactory corrosion-figures. E. S. Larsen gave for the refractive indices of the artificial crystals $\omega = 2.09$, and $\epsilon = 1.94$. In some cases the precipitated salt is an amorphous white powder. L. J. Spencer and E. D. Mountain gave for the sp. gr. 6.80 at $25°/4°$. L. Bourgeois gave 6.14 for the sp. gr. of the artificial crystals, and he showed that when heated to $400°$, these pass into lead monoxide tinted a rose colour, and preserve the crystalline form of hydrocerussite. L. J. Spencer and E. D. Mountain said that all the water is lost from the mineral at $250°$, and all the carbon dioxide on ignition. A. L. Marshall and B. Bruzs gave for the heat of formation $(PbO,PbCO_3) = 0.34$ Cals., and for the heat of soln. in nitric acid, 50 per cent. by vol., 8.54 Cals. According to M. Pleissner, the solubility at $18°$ is less than 0.05 mgrm. of the salt per litre ; and F. Auerbach and H. Pick gave for the solubility product at the same temp., $[OH']^2[CO_3'']^2[Pb^{..}]^3 = 3.5 \times 10^{-46}$. L. Falk found that hydrogen sulphide acts very little on the crystals suspended in water or in alcohol because they are protected by a thin superficial layer of lead sulphide ; the amorphous salt is decomposed in a short time. Hydrocerussite was found by L. J. Spencer and E. D. Mountain to change to cerussite, and pseudomorphs of cerussite after hydrocerussite were found. L. Bourgeois said that hydrocerussite is soluble in nitric and acetic acid. For F. Auerbach and H. Pick's observations on the behaviour of basic lead carbonate towards soln. of alkali carbonates and hydrocarbonates, *vide infra*, complex lead carbonates. T. Thunberg found that when basic lead carbonate is boiled with a soln. of hydrogen dioxide in the presence of boric acid, some formaldehyde is produced. The reaction was studied by F. Weigert.

M. F. Heddle's *plumbonacrite* was represented as having the composition $4PbO.CO_2.H_2O$, or $2PbO.Pb(OH)_2.PbCO_3$; but A. E. Nordenskjöld showed that it was probably hydrocerussite. According to M. Delaville, A. C. Becquerel, P. Yorke, and P. A. von Bonsdorff, hydrated *lead dihydroxycarbonate*, $Pb(OH)_2.PbCO_3$, or $2PbO.CO_2.H_2O$, is formed when lead immersed in water is exposed for a long time in open air. A. Vogel, J. N. Gannal, M. Versepuy, and C. Stalmann allowed lead to stand immersed in water made alkaline with potassium hydroxide or carbonate for a long time exposed to air, and obtained a basic carbonate. E. Euston believed this compound to be formed when carbon dioxide is allowed to act slowly on the basic acetate $2PbO.Pb(C_2H_3O_2)_2$. C. A. Klein said that this basic carbonate is probably the dihydroxydicarbonate. D. Strömholm obtained a white powder which he regarded as $7PbO.4CO_2.2H_2O$, or $PbO.2Pb(OH)_2.4PbCO_3$, by digesting freshly precipitated lead hydroxide with a 0.05N-soln. of sodium carbonate. L. Falk claimed to have made the basic carbonate $5PbO.3CO_2.H_2O$, by shaking normal lead carbonate with a soln. of the basic acetate $2PbO.Pb(C_2H_3O_2)_2$; and D. Strömholm, $5PbO.3CO_2.2H_2O$, or $2Pb(OH)_2.3PbCO_3$, by the action of sodium carbobate on a soln. of sodium carbonate. J. F. Sacher, L. Falk, M. Kerstmann, and H. Tomann claimed to have made the basic carbonate $8PbO.5CO_2.2H_2O$, or $PbO.2Pb(OH)_2.5PbCO_3$, by digesting a mixture of lead carbonate and oxide with a cold soln. of lead acetate ; etc. G. J. Mulder obtained a Dutch white-lead with the composition $7PbO.5CO_2.H_2O$; F. Clowes obtained a substance with the composition $4PbO.3CO_2.H_2O$ by the action of distilled water on lead ; H. Rose, from soln. of sodium carbonate and lead nitrate at $200°$. G. J. Mulder obtained a Dutch white-lead with the composition $5PbO.4CO_2.H_2O$, and H. Rose said that it is formed by the action of soln. of lead nitrate and sodium carbonate at $150°$. J. A. Phillips obtained white-lead of the composition $6PbO.5CO_2.H_2O$, and K. Feist prepared it by washing with water the product obtained by triturating a mixture of lead acetate and sodium carbonate. R. Krzizan reported the basic carbonate, $7PbO.6CO_2.2H_2O$, or $Pb(OH)_4.6PbCO_3.H_2O$, to occur in some limestones ; and H. Rose obtained it by the action of cold soln. of equimolar parts of lead nitrate and sodium carbonate. J. A. Phillips claimed to have made

$8PbO.7CO_2.nH_2O$ by the action of boiling soln. of sodium carbonate with a large excess of lead nitrate soln. There is nothing other than the analyses to justify the view that these products are chemical individuals.

§ 32. White-Lead

The manufacture of white-lead from metallic lead involves oxidation, hydration, and carbonation. In the most common method of manufacturing white-lead, the carbonation is made possible by the intermediate formation of an acetate or basic acetate. The Venetian process, clearly described by P. Vernatti [1] in 1678, is an elaboration of the methods practised about the beginning of the present era, and the process, as conducted in England, and in Holland, was described about a century

later by G. Jars, J. H. G. von Justi, J. A. C. de Chaptal, J. H. M. von Poppe, S. F. Hermbstät, K. P. Funke, and J. F. Demachy. This modification is commonly called the **Dutch process**, or the **stack process**. It is possible to obtain a product of a similar composition by other processes more economical in time and labour ; but the working properties of white-lead as a pigment depend on many factors other than composition—e.g. fineness and uniformity of grain, covering or hiding power, etc. The pigment made by the stack process is held in greater esteem than when made by other processes, although in some cases it is almost impossible to distinguish stack white-lead from, say, chamber white-lead.
Fig. 122.—Diagrammatic Arrangements in the Stack Process.

In some stack processes, corrugated straps of lead, Fig. 122, are laid over rows of pots, containing acetic acid and water and resting on spent oak-bark. The straps of lead are covered with boards resting on beams and wooden blocks. Another layer of spent oak-bark is laid on the boards, this is followed by layers of pots, straps of lead, and boards as before. This is repeated until the chamber is filled. The stack is left for about 3 months when it is taken down. The white, opaque, corroded lead preserves the form of the original straps, but is much more bulky. Fig. 123 gives the appearance of a stack partly taken down. Trays of corroded lead are immersed in a stream of water, and passed between corrugated rollers to separate most of the "blue-lead" which has escaped corrosion from the white-lead. The white-lead is then crushed between rollers ; and after churning in water containing a little sodium carbonate to pre-cipitate the lead present as soluble lead acetate, and levigation, a white slurry is obtained. The white-lead gradually settles, and much of the water is syphoned off. The remaining "pulp" is gradually dried in shallow dishes or in other ways. A chamber 12 ft. × 20 ft. in area holds, say, 12 sets—totalling about 12,000 parts, 36 tons of lead, and 2400 gallons of dil. acetic acid. From 40 to 80 per cent. of the lead is corroded. According to C. A. Klein, the world's output of white-lead is about 250,000 tons, and of this about 180,000 tons is made by the stack process ; 45,000 tons by the chamber process ; and 50,000 tons by other processes.

Fig. 123.—Photograph of Stack Chamber partly taken Down.

C. Hochstetter showed that if lead is exposed to the vap. of acetic acid in air free from carbon dioxide, lead acetate alone is formed ; this is taken to show that the carbon dioxide of white-lead is not derived from the decomposition of the acetic acid, and it must be obtained from some other source. If lead moistened with acetic acid be exposed for 24 hrs. to carbon dioxide free from air, between 30° and 40°, no change occurs, but if air be admitted, the metal becomes coated with white-lead in 6 hrs. This shows that the oxygen of the air is necessary for the oxidation of the lead. This conclusion was also made pre-viously by E. Reichardt. White-lead is formed when various basic salts of lead

are treated with carbon dioxide, and since the ratio $PbCO_3 : PbO$ or $Pb(OH)_2$ in white-lead varies with the mode and conditions under which it is produced, it follows that the composition of the white lead is independent of the degree of basicity of the salt employed. It is therefore inferred that during the formation of white-lead in the stack process (i) lead is oxidized by atm. oxygen in the presence of water, forming lead hydroxide ; (ii) this product is converted into normal lead acetate by the acetic acid, and the normal salt is converted into the basic acetate by the dissolution of more lead hydroxide ; and (iii) the basic acetate reacts with carbon dioxide, forming basic lead carbonate, and regenerates the normal lead acetate which acts as a solvent for more lead hydroxide. The acetic acid thus plays the part of a catalytic agent in a cycle of reactions involving the production of a soln. of lead hydroxide, the conversion of the hydroxide into basic acetate, and its precipitation as white-lead by carbon dioxide. The reaction can be symbolized in various ways dependent on what composition be postulated for the basic acetate. C. Hochstetter assumed

$$3\{Pb(C_2H_3O_2)_2.2Pb(OH)_2\} + 4CO_2 = 2\{2PbCO_3.Pb(OH)_2\} + 3Pb(C_2H_3O_2)_2 + 4H_2O.$$

Since the solvent action of a soln. of lead acetate on lead hydroxide increases to a maximum as the conc. of the soln. decreases, it is highly probable that many other basic acetates are concerned in the process, or else the function of the lead acetate is merely that of a solvent, so that the essential process is the direct conversion of lead hydroxide into the basic carbonate :

$$3Pb(OH)_2 + 2CO_2 = 2PbCO_3.Pb(OH)_2 + 2H_2O.$$

J. Pelouze showed that formic acid cannot be employed in place of acetic acid because it does not form a basic formate which can be decomposed by carbon dioxide. He also showed that when a lead plate is suspended within a vessel filled with oxygen and carbon dioxide, and having a layer of acetic acid at the bottom, the production of white-lead is accompanied by the disappearance of an equivalent quantity of carbon dioxide and oxygen, while the acetic acid " suffers scarcely any diminution." The unwashed white-lead contained some normal acetate—C. Hochstetter said 2–12 per cent. Of course there is a complicated by-play of reactions ; there is a steady flow of hydroxide into the reacting system ; the basic acetates and carbonates are open to attack by acetic acid ; there is a reaction between normal lead acetate and carbonate and carbon dioxide, forming in each case normal lead carbonate. If the oxidizing reactions predominate, then the carbon dioxide content of the product is low. As soon as the lead has been all converted into basic carbonate, the supply of lead hydroxide ceases, and normal lead carbonate begins to accumulate in the system. The corrosion product, as lifted from the stack, Fig. 124, is heterogeneous ; and in the grinding and washing, soluble lead acetate and free acetic acid are removed, along with adventitious impurities like tan-bark, etc. The soluble acetate is converted into carbonate by the addition of sodium carbonate, and, at the same time, any lead hydroxide also present is carbonated. Some blue-lead is oxidized and

FIG. 124.—Arrangement of Lead for corrosion in the Chamber Process.

carbonated. The process has been discussed by G. Lunge, J. G. Gentele, F. Bosshardt, J. A. Smythe, etc. ; and numerous modifications of the details of the process have been patented.

In the original Dutch process, and Venetian process, horse-dung was employed as the source of heat and carbon dioxide ; and wet hay has also been employed. R. Fishwick in 1781 proposed to employ " used tanner's bark," and T. Grace

" spent grapes," or " spent hops."   The use of tan-bark has been generally approved because there is less risk of decolorizing the white-lead by hydrogen sulphide, but the fermentation or the bacterial process of decay is slower, and the conversion of the blue-lead to white-lead is slower.   The temp. may rise as high as 80° during the fermentation, but 50°–60° is about the average.   Although the stack process is essentially the same as that which has been in operation for hundreds of years, the manufacturer has by numberless trials and failures found the conditions which enable him to ensure successful results—subject of course to the general perversity of inanimate objects.   In order to obtain more control of the operations—temperature, proportions of air, moisture, carbon dioxide, and acetic acid vapour—the so-called *chamber process* is employed.   Here the stable litter or tan-bark as a source of heat and carbon dioxide is eliminated.   The product, as a pigment, can be made to rival that obtained by the stack process.   This mode of manufacturing white-lead is sometimes called the *German process*, or the *Klangenfurth process*, having been extensively employed in Carinthia since the eighteenth century for the corrosion of the virgin lead of Bleiberg.   This process has been discussed by T. Richardson,[2] and many others.   These plates or straps of lead are suspended in brick chambers as illustrated in Fig. 124.   The mixture of gases—air, carbon dioxide, water vap., and acetic acid vap.—in the desired proportions is brought into the chambers through pipes in the floor.   Openings in the top and sides of the chamber enable the ventilation and the admission of air to be regulated.   A chamber temp. of 55°–70° is obtained by the hot gases supplemented by the heat of the chemical action.   The time occupied for the corrosion is from 42 to 60 days.   The appearance of a chamber ready for " stripping " is illustrated by Fig. 125.   The product is treated as indicated in connection with stack lead.   According to J. A. Smythe, normal stack white-lead is usually rather more carbonated than the chamber product since the ratio $PbCO_3 : Pb(OH)_2$ in the former case is from 2·22 to 2·72, and in the latter case from 1·88 to 2·56.

Numerous modifications have been described and patented.   The object is usually to increase the speed of the reactions by the comminution of the metal, as suggested by J. B. J. D. Boussingault.[3]   Thus, the Union Lead and Oil Co. proposed to use fibrous lead in place of the lead strips, but without success. In the so-called *L. Carter's process*, described by J. S. Staudt, and C. D. Holley, lead is sprayed by blowing a jet of steam against molten lead; and directed into revolving wooden drums.   A mixture of acetic acid and water is then sprayed into

Fig. 125.—Photograph showing the Corroded Lead in Chamber Process.

the drums, and the product carbonated.   The treatment is frequently repeated during 12 days.   The plant at Chicago, Ill., is said to have an annual capacity of 20,000 tons, and that at Omaha, Neb., 10,000 tons.   E. Bailey and co-workers volatilized the lead between carbon electrodes, and treated the vap. with the necessary gases.

In the stack and chamber processes, the basic acetates of lead are exposed to the action of carbon dioxide, the acetate or acetic acid serving as a catalytic agent. There is a series of patents in which it is proposed to make white-lead by the action of moist air and carbon dioxide or soln. of alkali carbonates on lead vapour, molten lead, spongy lead, etc.[4] Lead monoxide is not easily hydrated, and J. Pelouze [5] showed that the direct carbonization of lead monoxide is difficult, although in the presence of a soln. of lead acetate, it is readily hydrated and carbonated ; or, as R. W. E. MacIvor showed, in the presence of ammonium acetate. On the other hand, the so-called lead suboxide is readily oxidized, hydrated, or carbonated. In the so-called *mild process*, or the *W. H. Rowley's process* for making white-lead, metallic lead, air, water, and carbon dioxide are the only substances required. In the processes of J. Welch and J. Evans, of 1814, and of S. Gardner, of 1840, lead was oxidized in rotating barrels so arranged that the metal was subjected to continual attrition, and afterwards carbonated. W. H. Rowley extended the principle and atomized the lead with superheated steam so as to form oxides, suboxides, or basic hydroxides as a sludge. This is floated into wooden cylinders and carbonated. C. D. Holley said that the composition of the finished product approximates $3PbO.2CO_2.H_2O$, *i.e.* $Pb(OH)_2.2PbCO_3$. Only one-third of the total hydration, which the lead undergoes in its conversion to white-lead, is accomplished during the hydration stage ; the remainder occurs during carbonation when there is a considerable increase in the bulk of the material. In the so-called *G. Bischof's process*, carried on in a more or less modified form by the Brimsdown Lead Co., finely ground litharge is partly reduced by water-gas at 250°–300° so as to produce the so-called suboxide. The suboxide is agitated in water while exposed to air. This converts it into hydrated oxide which is then carbonated for about 24 hrs. so as to produce white-lead. The addition of a little lead acetate to the part of hydrated oxide is said to facilitate the carbonation.

P. Bronner [6] obtained a basic sulphate by the action of soda-lye on precipitated lead sulphate at 70°, and converted this into white-lead by digestion with a soln. of sodium carbonate. Several modifications have been patented. The Earl of Dundonald [7] exposed a moist mixture of lead oxide and alkali chloride to the air, and obtained basic lead carbonate. The original observation is due to C. W. Scheele. J. G. Dale and E. Milner passed carbon dioxide into the mixture until the mixture was neutral. The sodium carbonate which was formed reacted with the basic chloride to produce white-lead. H. Hof carbonated the mixture of basic chlorides of lead and magnesium obtained by dissolving lead oxide in an aq. soln. of magnesium chloride. Several variations of these processes have been proposed. In another series of processes,[8] mixtures of normal lead carbonate and lead hydroxide or oxide are treated with carbon dioxide, maybe with a little lead acetate as catalytic agent. R. Palmer, and I. Baggs treated basic lead acetate with sodium carbonate or hydro-carbonate, and dried the washed product.

Precipitation processes.—In another series of reactions, basic lead acetate—prepared from lead splashes or litharge—is treated with carbon dioxide. For instance, the process of L. J. Thénard,[9] designed in 1801, was employed in a works at Clichy, and hence is sometimes called the *French process*. A soln. of basic lead acetate was made by digesting a soln. of the normal acetate, or pyroligneous spirit with litharge ; the liquid was treated with carbon dioxide until it was neutral or only faintly acid ; the liquor now containing normal lead acetate was again treated with litharge, etc., and the precipitate was washed and dried. The process was patented in England by W. Gossage and E. W. Benson in 1836, but given up about 1880 owing to the difficulty of preventing the formation of an undue amount of normal lead carbonate. C. Hochstetter found that when carbon dioxide is passed through five separate portions of basic lead acetate soln. until the liquids are neutral, each of the five precipitates has the composition $2PbCO_3.Pb(OH)_2$.

A modification of the French process was suggested by F. H. Sharpe. The so-called *W. L. Matheson's process*, described by C. D. Holley, is a modification of that proposed by E. W. Dahl ; there, the lead is " feathered " by running the molten metal into water. The

spongy lead thus formed is put in tubs or tanks with dil. acetic acid, and converted into the basic acetate by a current of air and steam. The mixture is then treated with carbon dioxide, and the white-lead so produced is washed and dried. Some of these processes occupy only a few days, and the products are referred to as *quick process white-leads.* Instead of treating the soln. of basic acetate with carbon dioxide, H. J. B. Condy, R. Haack, J. H. Noad and Z. de Ferranti, Z. Peska, T. R. Sewell, E. Waller, and C. White and J. W. Patterson used ammonium or alkali carbonates as precipitating agents ; J. Löwe, lead carbonate. R. Matthews and co-workers, J. O. Handy, and J. Frölich recommended precipitating the basic lead carbonates in the presence of colloids—gelatin, gum, etc. In another set of processes, various soln. of lead salts are treated with carbon dioxide, alkali or ammonium carbonates, magnesia or magnesium carbonate, etc. O. Eyckens used soln. of lead nitrite ; P. Brown and B. Young, C. Button and H. G. Dyar, C. Delafield, J. Hemming, E. Lampe and L. Preuss, V. P. Lagrange, G. Lunge and C. H. M. Lyte, H. L. Pattinson, O. J. Steinhart and J. L. F. Vogel, and H. Wilcox, soln. of lead nitrate ; W. Gossage, H. L. Pattinson, and G. Robinson, soln. of lead chloride ; E. R. Blundstone, F. J. Corbett, H. Franzen, and J. S. MacArthur, soln. of lead tartrate ; and S. O. Cowper-Coles, and P. Spence, soln. of alkali plumbites.

Electrolytic processes.—Several proposals have been made to electrolyze acid soln., or salt soln. with anodes of lead or a lead compound ; and convert the soluble lead salt or lead hydroxide so produced into white-lead either in the cell itself, or outside. Electrolytic processes have been discussed by C. F. Carrier,[10] L. Falk, W. Hartmann, R. G. Bowman, P. Beck, D. M. Kyte, E. H. C. Monckton, T. Okuno, M. Nicolaieff ; as electrolyte, C. A. Stevens used dil. *nitric, hydrochloric, sulphuric, acetic, oxalic, tartaric, or citric acid ;* T. D. Bottome, A. B. Browne, E. D. Chaplin, S. O. Cowper-Coles, M. Manent, M. Nicolaieff, R. S. Owens, A. M. Söderlund, J. B. Tibbits, H. Weyer, R. P. Williams, and H. C. Woltereck, soln. of *ammonium or alkali nitrates ;* W. Borchers, C. F. Carrier, E. D. Chaplin, B. Huick, A. Isenburg, C. Luckow, J. Meyrueis, J. Oettli, R. S. Owens, A. J. Riban, E. Ronco, O. C. and H. H. Strecker, H. C. Woltereck, and A. Zucker, soln. of *sodium chloride ;* E. D. Chaplin, soln. of *sodium chlorate ;* J. W. Richards and C. W. Roepper, and C. F. Carrier, soln. of *sodium sulphite ;* T. D. Bottome, soln. of *sodium thiosulphate ;* F. W. Morris and co-workers, soln. of *alkali formates ;* and C. F. Carrier, Z. de Ferranti and J. H. Noad, E. A. Sperry, and C. P. Townsend, soln. of *sodium acetate.* W. G. France and D. McBurney studied the effect of gelatin on the electrodeposition of basic lead carbonate. G. Bredig and F. Haber suggested bubbling carbon dioxide and air through a soln. of sodium carbonate in which colloidal lead has been dispersed by an electrical discharge with platinum anode and lead cathode. They claimed that the product is good but the consumption of electrical energy is high.

The composition of white-lead.—In the twelfth-century Latin version of Geber's *De investigatione magisterii,* it is said that white-lead is not changed when dissolved in acetic acid and evaporated, but is purified only. This shows that Geber regarded white-lead as a compound of lead and acetic acid. A similar assumption was made in the seventeenth and eighteenth centuries by A. Libavius,[11] N. Lemery, and P. J. Macquer, but in 1774, T. Bergman showed that it contains a carbonate—*calx plumbi aerata*—because, when treated with an acid, it effervesces, giving off carbon dioxide. Analyses made between 1828 and 1874 by C. Hochstetter, C. Link, G. Bischof, A. Bette, G. J. Mulder, G. C. Wittstein, C. H. Pfaff, J. A. Phillips, F. Hofmann, etc., led to the view that white-lead is a basic carbonate, symbolized in the ideal case $Pb(OH)_2.2PbCO_3$, or $3PbO.2CO_2.H_2O$. This view is favoured by the known tendency of lead to form basic salts. If the action of the carbon dioxide in the precipitation of white-lead be long continued, the normal carbonate is formed, so that white-lead may be mixed with more or less normal carbonate. The composition of different varieties of white-lead on the market varies, and C. A. Klein said that the carbon dioxide then generally has between 11·8 and 12·5 per cent., but specimens are found with much lower and higher proportions of that gas. C. D. Holley quotes a specification in which the permissible variation in composition is $PbCO_3$, 67–80 per cent., and $Pb(OH)_2$, 20–32 per cent. G. W. Wigner and R. H. Harland regarded white-lead as a mixture

of lead hydroxide and lead carbonate in the molar proportion 1 : 3. Analyses have been reported by C. F. Carrier, P. Beck, E. Euston, J. F. Sacher, P. Hamberger, R. K. Meade, C. von Weise, W. A. Davis and C. A. Klein, etc. White-lead is therefore a mixture of one or more basic carbonates with lead carbonate, and more or less lead hydroxide or hydrated lead oxide and water ; and, as shown by E. Lenoble, and J. F. Sacher, in many cases, its composition approximates to $2PbCO_3.Pb(OH)_2$. Certain impurities may be present. Some may be deliberately added. Chalk, for instance, has been used for fraudulent adulteration. On this account, the anonymous Basil Valentine recommended chemists to make their own white-lead. E. Norgate also warned artists against adulterated white-lead ; and near the middle of the eighteenth century, G. Jars said that white-lead containing chalk was called ceruse, and that the pure white-lead was called *blanc de plomb*. P. Hamberger reported a sample of white-lead with 22·8 per cent. of chalk. G. J. Mulder found traces of lead sulphate and chloride ; C. Hochstetter, and E. Euston found a little lead acetate ; and G. C. Wittstein, silica, ferric oxide, and lead sulphate. F. Weil and F. Jean showed that if free lead oxide be present, the product mixed with oil of cloves becomes yellow in 24 hrs. Sometimes the cream-colour of white-lead is masked by the addition of a little blue pigment. Mixtures of white-lead with barium sulphate,[12] silica, zinc oxide, whiting, magnesia, soapstone, china clay, or gypsum, furnish the so-called *composite white-lead*.[13]

The properties of white-lead.—White-lead is normally considered to be a white, non-crystalline powder. According to C. Hochstetter,[14] white-lead is a dense, earthy mass which when diffused through water and examined under the microscope, consists of non-crystalline, transparent, round or oval globules having an average diameter of 0·000025 cm. and rarely attaining 0·00010 cm. The particles obtained with the quicker processes are usually larger and more transparent than those furnished by the stack process. W. Stein, R. S. Owens, and J. L. Breton made some observations on this subject. From data quoted by C. D. Holley, the extreme sizes of the particles of stack process white-lead are 0·00005 cm. and 0·00065 cm.—average, 0·000175 cm. ; and for quick process white-lead 0·00005 cm. and 0·00045 cm.—average, 0·0003 cm. According to W. G. France and D. McBurney, the average size of basic lead carbonate particles, electrolytically precipitated at 20° is reduced to approximately one-third by the presence of 0·013 per cent. of gelatin. The decrease after the first addition is not so large, being approximately proportional to the conc. of the gelatin added. The particles are of more uniform size when gelatin is present. The grain-size depends on the method of preparation and grinding. The granules of white-leads made by the quick processes are more uniform in size than those made by the stack process. This, according to G. W. Thompson, enables the particles of white-lead made by the stack process to be more closely packed, and to contain the smallest volume of voids. According to C. D. Holley, it is rare to find crystalline carbonate in white-lead which has less carbon dioxide than the theoretical amount required for $2PbCO_3.Pb(OH)_2$. According to L. Bourgeois, however, under high magnification, white-lead made by the stack process contains numerous crystals, too small to measure crystallographically ; but that precipitated by sodium carbonate from a soln. of lead acetate consists of small prisms or double pyramids ; and that obtained by the French process, consists for the most part of hexagonal plates of the basic carbonate, $3PbO.CO_2.H_2O$, and the remainder of strongly doubly refracting needles of normal carbonate. He said that white-lead consists of a mixture of cerussite and hydrocerussite. L. Falk said that the white-lead prepared by the hot chamber process is a mixture of crystalline and amorphous $3PbO.2CO_2.H_2O$; and that obtained by the cold chamber process is mostly amorphous ; J. F. Sacher said that both kinds are amorphous. According to E. Euston, the hardness of the "porcelain-like" crusts which form on the crusts of white-lead, as it comes from the corroding chamber, is due to the cementing effect of the colloidal basic acetate present during the formation of the crust.

According to C. D. Holley, an experienced painter can detect the difference between aged and unaged white-leads both in the dry state and in oil. The cause of the ageing is not known. G. Hauser found the sp. gr. of white-lead to vary with the mode of preparation from 6·4 to 6·5 ; H. A. Gardner gave 6·81.

L. Meister said that in darkness, white-lead may acquire a yellow tinge which disappears on exposure to light. J. A. Phillips found that white-lead made by the stack process is stable at 105°, all its water is expelled at 155°, and the carbon dioxide begins to come off at 183° ; W. A. Davis and C. A. Klein observed no effect at 110°, decomposition began at 120°, but it required a temp. of 212° to drive off the water. The carbon dioxide began to come off at 171°. K. Friedrich said that basic lead carbonate begins decomposing at 430° and that the maximum thermal effect is at 460°. At higher temp. red-lead is formed (q.v.). J. L. Breton said that white-lead paint is inferior to the zinc oxide paints in resisting heat, and sudden variations of temp. When used as a paint, in exposed places, white-lead has a tendency to become granular ; the disease is called chalking or flouring. The cause of the phenomenon has not been established. C. D. Holley said that it may be produced by the presence of fatty acids in the oils ; over-heating during the grinding of the white-lead ; and the presence of an abnormal quantity of lead acetate—in the white-lead. C. P. van Hoeck studied the hygroscopicity of white-lead. R. Salvadori said that ordinary basic lead carbonate is fully as stable as the normal carbonate, if not more so ; and that the latter is readily converted into the former by boiling with water, or by heating it under water for several hours.

J. L. Breton said that white-lead paint resists the action of certain acids better than zinc oxide paints, but this is not the case with hydrofluoric acid. According to W. Thomason, the solubility of white-lead in 0·15–0·25 per cent. hydrochloric acid is proportional to the conc., and in food-stuffs inversely proportional to the conc. of the proteins. E. Euston found that a soln. of ammonium chloride removes the lead hydroxide from white-lead. As indicated above, H. Hof reported that white-lead is completely dissolved in the cold without decomposition by a soln. of magnesium chloride of sp. gr. 1·16, forming $2PbCO_3.PbCl_2$; with a boiling soln., lead chloride is produced. J. L. Breton said that white-lead paints resist attack by strong oxidizing agents, like sodium hypochlorite, less readily than do the zinc oxide paints. White-lead is discoloured by hydrogen sulphide owing to the formation of dark brown lead sulphide. J. L. Breton said that white-lead paint resists attack by hydrogen sulphide less readily than zinc oxide paints. E. Täuber said that the darkening of the white-lead paint vanishes on exposure to light. When white-lead suspended in water is treated with hydrogen sulphide, J. F. Sacher said that only the lead hydroxide is attacked because no carbon dioxide is given off. At ordinary temp., the attack is incomplete, forming **lead hydroxysulpho-carbonate,** $Pb(OH)_2.PbS.4PbCO_3$, but at 90° the attack is complete. E. Beckmann and P. Waentig found that in liquid hydrogen sulphide, white-lead is immediately blackened. F. W. O. de Coninck said that five hours' boiling with a soln. of sodium or potassium nitrate does not decompose white-lead. J. L. Breton found that white-lead paint resists penetration by efflorescences of saltpetre better than does zinc oxide paint.

According to J. F. Sacher, carbon dioxide in the presence of water gradually transforms white-lead into the normal carbonate ; and, according to F. Auerbach and H. Pick, with alkali carbonate, there is a balanced reaction : $3PbCO_3 + K_2CO_3 + 2H_2O \rightleftharpoons Pb_3(OH)_2(CO_3)_2 + 2KHCO_3$. E. Euston found that when various samples of white-lead or lead carbonate are stirred or agitated with a soln. of basic lead acetate at room temp. lead hydroxide is invariably drawn from the soln., and there is a gain in weight ; at the same time, the carbon dioxide content was found to fall from 12·0 to 16·3 per cent. as low as 10·1 to 10·3 in extreme cases. The extent of the action depends on the basicity of the lead acetate soln., on the time, and on the relative proportion of the solid and soln. The reaction is completed only when

an excess of the basic acetate soln. is present. With a sample containing both normal and basic lead carbonate, the equilibrium can be disturbed in either direction by the addition of more basic lead acetate soln. or of normal lead acetate soln. According to J. L. Breton, alcohol, benzene, toluene, or carbon disulphide does not act on white-lead paint, but ether does react therewith. E. Euston found that the lead hydroxide is not dissolved from white-lead by a soln. of sugar. J. L. Breton stated that freshly applied white-lead paint gives an emanation containing lead which can be detected by the tetramethyl diaminodiphenyl-methane test; and, added M. Herman, the exhalation only occurs during the first two days. R. S. Owens showed that specimens of white-lead with small granules take up less oil than specimens with larger granules, and the colour is better. L. Meister said that linseed oil unites intimately with white-lead, and the lead hydroxide neutralizes the free fatty acids. There has been some discussion as to whether hydrolysis or saponification occurs with normal white-lead. If free lead hydroxide were present the saponification would occur. G. J. Mulder, and M. von Pettenkofer showed that no saponification occurs with dry white-lead, but slow oxidation of the oil occurs. J. B. Hannay and A. E. Leighton questioned if saponification occurs when white-lead is ground with linseed oil, giving rise to peculiar working properties which other pigments do not have. They showed that a very small trace of lead oleate in the oil will cause serious blackening under the influence of a small proportion of hydrogen sulphide in the air, and under conditions where good white-lead would hold its colour. Hence saponification would be deleterious. They concluded that no such reaction occurs between the lead and the oil, and that dry white-lead produces a slow oxidation of the oil. J. B. Hannay and A. E. Leighton's conclusion with lead oleate, however, does not necessarily apply to lead linoleate. W. A. Davis and C. A. Klein showed that lead soaps are really produced when white-lead is mixed with linseed oil, and that some of them are soluble, others insoluble, in ether. The reaction is ascribed to the free fatty acids present in the oil; if these were absent, the evidence is against saponification.

§ 33. Complex Salts of Lead Carbonates

D. L. G. Karsten [1] described a rare lead chlorocarbonate as *horn-lead—Horn-blei;* M. H. Klaproth, *salzsaures Bleierze;* R. Jameson, *corneous lead;* A. Breithaupt, *phosgene-spar*, and **phosgenite ;** F. S. Beudant, as *kerasine;* E. F. Glocker, as *galenoceratite;* and R. P. Greg and W. G. Lettsom, as *cromfordite*. Analyses, reported by M. H. Klaproth, C. F. Rammelsberg, K. von Nidda, J. Smith, and F. Philipenko, correspond with **lead chlorocarbonate,** $PbCl_2.PbCO_3$, or $(PbCl)_2CO_3$. It has been found at Cromford, Derbyshire; in Cornwall; near Elgin, Scotland; at Gibbas. Monte Poni, and Montevecchio, Sardinia; Bobrek, Silesia; and Syzjanoff, Altai. R. Köchlin, and A. Lacroix reported it together with laurionite, and cerussite, in cavities in the lead slags at Laurion, Greece, as a result of the action of sea-water to which the slags have been exposed for 2000 years. A. Daubrée found it to have been produced by the action of the thermal water of Bourbonne-aux-Bains on some lead tubes.

J. W. Döbereiner made this salt by boiling lead chloride, lead carbonate, and water; C. Friedel and E. Sarasin worked with the mixture in a sealed tube at 180°. A. de Schulten made it by the action of carbon dioxide on lead hydroxy-chloride, $Pb(OH)Cl$; and he also allowed a filtered soln. of lead chloride to stand in a large flask while a current of carbon dioxide was passed over the liquid. Crystals were formed in about 24 hrs. These were rapidly washed by water, alcohol, and ether. W. A. Hamor and H. E. Gill made the salt by heating a mixture of lead hydroxide and carbonyl chloride in a sealed tube at 175°. M. Amadori did not succeed in getting molten lead chloride to unite with lead carbonate.

The salt may be amorphous, or crystalline, and coloured white, grey, or yellow. The crystals are prismatic or tabular, and, according to N. von Kokscharoff, belong to the tetragonal system having the axial ratio $a : c = 1 : 1.0876$. The cleavages (100), (110), and (001) are distinct. G. vom Rath, A. Lacroix and A. de Schulten, W. H. Miller, and V. Hansel made observations on the crystals. F. Rinne and W. Anders studied the corrosion figures and the X-radiograms. The sp. gr. given by D. Lovisato is 6·0–6·9; C. F. Rammelsberg gave 6·305; W. A. Waldschmidt, 6·08; and A. de Schulten gave 6·134 for the artificial crystals at 15°; the hardness is 2·75–3·0. The natural and artificial crystals were found by A. de Schulten to melt very easily, and at a higher temp. the carbon dioxide is expelled, and the oxychloride, Pb_2OCl_2, remains. H. C. Sorby gave 2·120 for the mean refractive index, and 0·572 for the refractory power; N. von Kokscharoff reported for the refractive indices $\omega = 2.114$, and $\epsilon = 2.140$. H. Baumhauer made observations on this subject. The optical character is positive. L. Sohncke, J, Schincaglia, and

K. Keilhack made observations on the luminescence and fluorescence of this mineral; and A. Pochettino said that the luminescence produced by the cathode rays has the same colour as the fluorescence. A. de Schulten said that water soon makes the salt turbid, for, added C. F. Rammelsberg, cold water decomposes the mineral extracting the lead chloride. The salt is soluble in dil. nitric acid. A. de Schulten found that in the presence of moisture, carbon dioxide transforms the salt into the normal carbonate.

G. Lunge and C. H. M. Lyte reported a basic chlorocarbonate to be formed from a mixture of lead nitrate, and sodium chloride, carbonate, and hydroxide; and S. Ganelin, from a mixture of lead sulphate and sodium chloride, carbonate, and hydroxide; or from lead oxydichloride and alkali carbonate or hydrocarbonate. The composition is represented by the formula $Pb(OH)_2.PbCl_2.PbCO_3$, or $Pb(OH)_2PbCl_2.2PbCO_3$—*lead hydroxychlorocarbonate*—but there is no evidence of chemical individuality.

C. Löwig [2] reported **lead bromocarbonate,** $Pb_2Br_2CO_3$, to be formed by boiling a soln. of lead bromide with an equimolar part of lead carbonate. A. de Schulten prepared the salt by the action of carbon dioxide on a cold soln. of lead bromide as in the case of the corresponding chlorocarbonate. The colourless, transparent, tetragonal crystals are stated by A. de Schulten to resemble the chlorocarbonate, and to have a sp. gr. of 6·550 at 15°. The salt melts easily, giving off carbon dioxide. It is attacked by water more slowly than is the chlorocarbonate. A. B. Poggiale reported **lead iodocarbonate,** $Pb_2I_2CO_3$, to be formed by boiling lead carbonate with a soln. of lead iodide; and A. Ditte, by the action of a soln. of potassium iodide and hydrocarbonate on lead hydrocarbonate. The yellow product is said to be insoluble in water. A. de Schulten could not make it by the method analogous to that employed for the chlorocarbonate.

J. F. Sacher [3] reported *lead hydroxysulphocarbonate,* $Pb(OH)_2.PbS.4PbCO_3$, to be formed by the action of hydrogen sulphide on white-lead suspended in alcohol; if water is used in place of alcohol, the salt is hydrolyzed.

J. L. de Bournon [4] described a mineral which he called *plomb carbonaté rhomboidal* and which is considered to be the *lead sulphatotricarbonate* of H. J. Brooke; the *psimythite* of E. F. Glocker, and the **leadhillite** of F. S. Beudant. Analyses were made by N. Collie, F. Stromeyer, H. Laspeyres, C. Hintze, E. Bertrand, P. von Jeremejeff, L. V. Pirsson and H. L. Wells, etc. There is not a general agreement as to the best representative formula. H. Laspeyres regards it as a complex of equimolar proportions of hydrocerussite and anglesite, **lead dihydroxysulphatodicarbonate,** $PbSO_4.Pb(OH)_2.2PbCO_3$; and he applied the term *maxite*—after Max Braun—to a variety from the Mala-Culzetta mine, Iglesias, Sardinia, but E. Bertrand, and afterwards H. Laspeyres, concluded that maxite is really a more or less altered leadhillite. The mineral *susannite*, from the Susanna mine, Leadhills, was regarded as lead sulphatotricarbonate, and named by W. Haidinger. It was at first regarded as rhombohedral and dimorphous with leadhillite; but later observations have shown that it is only a modification of that mineral. L. J. Spencer found susannite to be optically uniaxial. Leadhillite occurs at Leadhills, Scotland; at Red Gill, Cumberland; Taunton, Somersetshire; Matlock, Derbyshire; Grenada, Central America; Seriphos, Grecian Archipelago; and Susannite, at Leadhills, Scotland; Moldawa, Hungary; Nerchinsk, Siberia; and W. Granby, Missouri. W. M. Foote found pseudomorph after calcite and galena. A. Russell found leadhillite crystals along with galena, anglesite, and cotunnite in cavernous masses of metallic lead mixed with charcoal taken up in 1846 from beneath the partly fused lead pump of a fire-ship wrecked in Falmouth Harbour in 1780. These minerals are supposed to have been formed by the action of seawater on lead. L. J. Spencer found leadhillite among the old lead slags from the Mendip Hills, Somersetshire. A. Ditte claimed to have obtained amorphous **lead sulphatotricarbonate,** $PbSO_4.3PbCO_3$, by the action of a soln. of potassium carbonate on lead sulphate. It is not altered by potassium sulphate soln. C. Friedel and

E. Sarasin also heated lead carbonate and sulphuric acid in a sealed tube at 200°–240°, and obtained crystals of this compound. The mineral *lanarkite* was formerly considered to be a sulphatocarbonate, but it was afterwards shown to be lead oxysulphate (*q.v.*). Leadhillite occurs in crystals which are commonly tabular, or in short prisms—R. Köchlin found crystals from Ljubija, Bosnia, almost octahedral. The crystals are transparent, white with a yellow, green, or grey tinge. The monoclinic crystals were found by H. Laspeyres to have the axial ratios $a : b : c = 1.74764 : 1 : 2.21545$, and $\beta = 89° \, 47' \, 38''$. The crystals are often twinned on the (110)-plane, like aragonite. A. des Cloizeaux found that the optic axial angle diminishes with rise of temp., and finally, a section becomes uniaxial and negative; thus, for red-light, $2E = 20° \, 32'$ at 15°; 20° 28' at 21·5°; 6° 46' at 47°; and zero at 121°. For blue-light, $2E = 22° \, 22'$ at 15°; in a second case, $2E = 20° \, 54'$ at 12°, and 0° at 146·5°; and in a third case, $2E = 23° \, 16'$ at 12°; 10° 22' at 47°; and 8° 26' at 175·8°. C. Hintze found the mineral to be uniaxial at 125°; and O. Mügge at 300° when the previous twin lamellæ had completely disappeared. E. Bertrand found for yellow-light, $2E = 72°$ at ordinary temp., and 66° at 250°; L. J. Spencer gave $2E = 72\frac{3}{4}°$ at ordinary temp., and $70\frac{1}{2}°$ at 97°. The cleavage (001) is perfect, and (100) in traces. The optical character is negative. The crystals were also examined by C. Palache and co-workers, A. F. Rogers, and W. M. Foote. The sp. gr. of maxite given by C. Hintze is 6·547 at 18·9°; and by H. Laspeyres, 6·874 at 19°. For leadhillite, H. Laspeyres gave 6·874 at 17°; E. Bertrand, 6·60; and L. V. Pirsson and H. L. Wells, 6·54. The hardness is $2\frac{1}{2}$. H. Steinmetz found that there is a transformation at 115°, when the monoclinic crystals become rhombic. The change is attended by a considerable expansion. C. Hintze found that there is no loss in weight at 100°, but about 0·1 per cent. is lost at 200°; and with 1–20 hrs.' heating, 0·45–1·74 per cent.

According to A. Ditte,[5] the salt **potassium tricarbonatodiplumbite**, $K_2Pb_2(CO_3)_3$, is formed when carbon dioxide is passed into a soln. containing potassium iodide, and an excess of potassium hydrocarbonate in contact with hydrated lead dioxide; it is also formed, as a yellowish-white powder, by the action of potassium hydrocarbonate on potassium iodocarbonatoplumbite. C. Immerwahr measured the electrical properties of the soln. A. Ditte obtained **potassium tetraiodocarbonatoplumbite**, $K_2CO_3.K_2PbI_4.3H_2O$, in white needles, by the action of carbon dioxide on hydrated lead dioxide suspended in a large excess of a soln. of potassium iodide; and by the action of a mixed soln. of potassium iodide and hydrocarbonate on hydrated lead dioxide. When the salt is heated, it loses its water and becomes yellow. When heated in its own mother-liquor, carbon dioxide is evolved; and potassium tricarbonatoplumbite is formed. It is decomposed by water; with dil. acids, carbon dioxide, lead iodide, etc., are formed. When the salt is fused and cooled, **potassium oxydiiodocarbonatoplumbite**, $K_2CO_3.Pb_2OI_2$, is formed. The *dihydrate* was produced by the action of a soln. of potassium iodide on hydrated lead dioxide and exposing the product to air for a few days, or treating it with a little carbon dioxide, or potassium carbonate or hydrocarbonate. The white or pale yellow needles give off water when heated; and carbon dioxide when treated with acids. A. Ditte also obtained **potassium dioxytetraiodotricarbonatotetraplumbite**, $3K_2CO_3.2Pb_2OI_2.2H_2O$, by using more carbon dioxide or potassium hydrocarbonate than is used for the preceding salt. The yellow crystals lose water when heated. A. Ditte also made **sodium tetraiodocarbonatoplumbite**, $Na_2CO_3.Na_2PbI_4.3H_2O$, in a manner analogous to that employed for the potassium salt. Likewise also for **sodium oxydiiodocarbonatoplumbite**, $Na_2CO_3.Pb_2OI_2.2H_2O$, and **sodium dioxytetraiodotricarbonatotetraplumbite**, $3Na_2CO_3.2Pb_2OI_2.2H_2O$.

E. Auerbach and H. Pick studied the conditions of stability of lead carbonate in the presence of soln. of potassium or sodium carbonate at 18° and 37°. The results with potassium carbonate show that the reaction is $3PbCO_3 + K_2CO_3 + 2H_2O \rightleftharpoons 2PbCO_3.Pb(OH)_2 + 2KHCO_3$, with soln. of all the conc. tried, Fig. 126. With sodium carbonate, however, when the conc. of the soln. exceeds one-tenth normal, a

complex salt, **sodium lead dihydroxytetracarbonate**, $3PbCO_3.Pb(OH)_2.NaCO_3$, or $NaPb_2(OH)(CO_3)_2$, is formed as a greenish-yellow powder—Fig. 127. Water decomposes it into basic carbonate and sodium carbonate.
FIG. 126.—Equilibrium between Solutions of. Potassium Carbonate and Lead Carbonate.
FIG. 127.—Equilibrium between Solutions of Sodium Carbonate and Lead Carbonate.

E. Euston obtained an adsorption product approximating $3BaCO_3.2Pb(OH)_2$. H. Vater prepared isomorphous mixtures of lead and barium carbonates. C. H. Warren obtained an isomorphous mixture of cerussite with 4·48 per cent. of strontium carbonate from the Terrible Mine, Colorado. E. Euston also obtained an adsorption product approximating $2CaCO_3.Pb(OH)_2$. The so-called *plumbocalcite* is an isomorphous mixture of lead and calcium carbonates, *i.e.* of cerussite and calcite. The mineral was mentioned by A. Breithaupt,[6] P. A. Dufrénoy, T. Böttger, A. des Cloizeaux, A. Lacroix, N. Collie, C. von Hauer, J. F. W. Johnston, C. F. Rammelsberg, J. S. Thomson, H. Hoefer, etc. N. Collie, and J. S. Thomson also described *plumboaragonite* from Leadhills, Scotland, containing 1·3 per cent. of lead carbonate ; and F. P. Dunnington, one from Wythe Co., Virginia, with 7·29 per cent. of lead carbonate. A. Breithaupt, W. Haidinger, M. Websky, and H. Traube called the combination *tarnowitzite* or *tarnovicite* from Tarnowitz, Silesia. E. Euston obtained an adsorption product with zinc carbonate approximating $Zn_2(OH)_2CO_3.3Pb(OH)_2$. C. M. Kersten reported a mineral from Iglesias, Sardinia, which he called *iglesiasite*, which, according to C. F. Rammelsberg, is an isomorphous mixture containing 7·02 per cent. of zinc carbonate, and the remainder cerussite. H. Traube, and F. von Kobell have also described specimens. W. F. Petterd [7] described a mineral from Dundas, Tasmania, which he called *dundasite*. He first assumed that it was a carbonatophosphate, but it was later shown to approximate $2Al(OH)_3.Pb(HCO_3)_2$. G. T. Prior found a sample near Trefriw, Wales. It forms white tufts or aggregates of radiating needles of sp. gr. 3·25, and hardness 3·25. The extinction is parallel and positive. G. T. Prior said that its physical properties resemble those of dawsonite, $Al(OH)_2(NaCO_3)$.

§ 34. Lead Nitrates

A. Libavius, in his *Alchemia* (Francofurti, 1595), described the preparation of crystals of **plumbous nitrate,** or **lead nitrate,** $Pb(NO_3)_2$, or, as he called it, *calx plumbi dulcis*, by cooling a soln. of comminuted lead in nitric acid. The action of nitric acid on lead has been previously discussed. The reaction is accompanied by the evolution of nitrous fumes which W. Shapleigh proposed to utilize by reconverting them into nitric acid by blowing air through the liquid while dissolving the lead. The crystallization of soln. of the oxide, hydroxide, or carbonate in dil. nitric acid, and of lead chloride in nitric acid or nitrates, furnishes the anhydrous

salt. The dissolution of red-lead is much facilitated by the addition of a small proportion of hydrogen dioxide. J. S. Stas [1] recommended the preparation of lead nitrate by the use of most conc. acid capable of dissolving the purified metal; the action is slow, but the acid dissolves only a trace of lead nitrate, so that the salt, as it is formed, is precipitated as a crystalline powder. The object is to get the salt in a state where desiccation is easy, owing to the ease with which lead nitrate is decomposed when heated. If the salt is deposited by the evaporation of a soln. of the nitrate, the desiccation is much more difficult than when prepared by the conc. acid as just described. The temp. should be kept below 155°. The salt is best dried in a current of air, at 140°–155°, until its weight is constant—this requires 8–12 hrs. There is even then " a legitimate doubt as to the possibility of absolutely drying large masses of salt when they cannot be raised to a high temp. without decomposition." A. Gutbier and J. Lohmann said that lead nitrate cannot be completely dried without decomposition. According to A. Knop, the slow evaporation of a cold soln. furnishes transparent crystals, but the crystals deposited by cooling hot soln., or by evaporating hot soln., are opaque; but C. von Hauer, and J. W. Retgers said that neutral aq. soln. always give opaque crystals, and the slow cooling of hot conc. soln., containing free nitric acid, yields large water-clear crystals. P. Gaubert added that small, transparent octohedra are precipitated when alcohol, or nitric acid is added to the aq. soln., while the slow evaporation of the soln. gives cubic crystals. Observations on this subject were also made by J. Morel. L. Wolff said that the clear crystals may include as much as 0·3 per cent. of water; the opaque crystals include a little less. The salt obtained from aq. soln. was found by W. K. Lewis to be slightly basic owing to the slight hydrolysis of the salt. The preparation of lead nitrate of a very high degree of purity was discussed by K. Fajans and co-workers, and by G. P. Baxter and F. L. Grover. W. Mills obtained lead nitrate by treating lead fluosilicate with a soln. of sodium nitrate, and filtering off the sodium fluosilicate. E. Bonjean observed the formation of lead nitrate in leaden tubes used for conveying ozonized air for sterilization purposes.

When lead dioxide is treated with nitric acid, A. Chwala and H. Colle believe that *plumbic nitrate*, $Pb(NO_3)_4$, or *lead tetranitrate*, is first formed, but is rapidly decomposed by water.

The physical properties of lead nitrate.—The **crystals** of lead nitrate are alleged to be dimorphous—since the salt crystallizes in the cubic and monoclinic systems. The latter statement is by no means well-founded. When prepared by rapid evaporation, or the cooling of hot soln., L. Wolff [2] found that the crystals belong to the cubic system; from dil. soln., the crystals are tetrahedra and pentagonal dodecahedra. A. Scacchi obtained the latter form by crystallization from soln. containing sodium nitrate; J. Morel, nitric acid; and L. Wolff, zinc nitrate. L. Wolff also obtained good crystals by the diffusion of aq. soln. of lead nitrate in alcohol, or nitric acid. P. Gaubert said that cubes are produced instead of octahedra by crystallization from a sat. soln. of methylene blue. The various habits of the crystals obtained with different soln. were also studied by W. G. Hankel, E. Giebe and A. Scheibe, P. Gaubert, J. Morel, W. Haidinger, and R. Wackernagel. The crystals are isomorphous with those of barium nitrate. Cubic crystals which act on polarized light were obtained by J. Morel by the slow evaporation at −4° to 18° of soln. containing free nitric acid, or feebly acid soln. containing about one per cent. of ammonium, potassium, or sodium nitrate, ferric, cupric, or lead sulphate, or the isomorphous barium or strontium nitrate. J. Morel found that the cooling of soln. containing fuming nitric acid, between 0° and 40° furnished monoclinic prisms with the axial ratios $a:b:c=0.7858:1:2.7185$, $\beta=70°\ 22'$; these crystals are geometrically isomorphous with those of potassium chlorate. The **corrosion figures** of the cubic crystals were studied by L. Wolff. P. Gaubert studied the adsorption of methylene blue by the growing crystals. T. V. Barker obtained no **overgrowths** of lead nitrate on the cubic crystals of zinc blende or fluorspar. According to

S. Nishikawa and K. Hudinuki, and L. Vegard, the **X-radiograms** of the nitrates of lead and the alkaline earth metals show that four chemical molecules are associated with each unit cube. The lead atoms form a face-centred lattice with eight cubes which have each three oxygen atoms and one nitrogen atom. The length of the sides of the unit cube for lead nitrate is 7.84×10^{-8} cm.

A. Breithaupt[3] gave 4·769 for the **specific gravity** of solid lead nitrate ; J. H. Hassenfratz, 4·068 ; C. J. B. Karsten, 4·3998 ; L. Playfair and J. P. Joule, 4·472 at 3·9° ; S. Holker, 4·41 at 15·5° ; H. J. Buignet, 4·235 ; H. G. F. Schröder, 4·423–4·509 ; E. Filhol, 4·581 ; J. Behr, 4·545 ; J. W. Retgers, 4·531 at 24° ; M. le Blanc and P. Rohland, 4·520 at 20°/20° ; H. Töpsöe and C. Christiansen, 4·521 ; and P. Niggli, 4·545 for the sp. gr., and 72·9 for the eq. vol. P. Gaubert gave 4·40 for sp. gr. of the opaque crystals, and 4·45 for that of the transparent crystals. L. Vegard calculated values for the mol. vol. from the radiographic data. F. A. Heglein studied this subject. G. T. Gerlach gave 4·40 for the sp. gr. of aq. soln. at 17·5° :

Pb(NO$_3$)$_2$.	5	10	15	20	25	30	35 per cent.
Sp. gr. .	1·044	1·092	1·144	1·200	1·263	1·333	1·409

H. Schiff, working at the same temp., gave for soln. containing 2, 4, and 6 per cent. of lead nitrate, the respective sp. gr. 1·016, 1·033, and 1·050. Observations were made by J. Wagner, J. H. Long, P. Kremers, K. Bindel, J. Thomsen, F. Kohlrausch, I. Traube, etc. H. Euler said that the sp. gr. of a soln. sat. at 17° is 1·405, and E. F. Anthon, 1·372 for a soln. sat. at 8°. K. Fajans and M. Lembert gave 1·444499 ± 0·000013 at 25·45°/4° for the sp. gr. of a soln. of ordinary lead nitrate sat. at 25·45° ; 1·443587 ± 0·000016 for the sp. gr. of a sat. soln. of nitrate made from carnotite-lead, and 1·443586 ± 0·000015 for that of a soln. of nitrate made from pitchblende-lead. K. Bindel obtained the following results :

Pb(NO$_3$)$_2$	8·4	37·9	42·3	47·8 per cent.
Sp. gr. (18°)	1·0771	1·4854	1·6045	1·6663
Contraction	1·0072	1·0498	1·0796	1·0501
Mol. vol.	3650	586	487	415

R. Broom found that when a soln. containing 48·3 parts of salt in 100 parts of water is mixed with an equal vol. of water, there is a 0·228 per cent. contraction. M. L. Jesersky said that the thermal change during the dissolution of the salt represents a rise of temp. smaller than corresponds with the coeff. of contraction. H. Gilbault gave 0·29 for the mol. contraction at 20° ; I. I. Saslawsky gave 0·70 for the ratio of the mol. vol. to the sum of the at. vols. of the constituent elements. J. N. Rakshit studied the contraction which occurs when lead nitrate is dissolved in water, and in alcohol. A. Heydweiller studied the changes in the sp. gr. and ionization with the dilution of the soln. J. A. Groshans compared the sp. gr. of soln. of lead nitrate with those of other salts. A. Taffel studied the effect of lead nitrate on the temp. of maximum density of water.

C. A. Valson[4] found the **capillary rise** in a tube of 0·5 mm. diameter to be 54·1 units for a soln. of sp. gr. 1·133 at 15°. H. Sentis gave 76·20 dynes per cm. for the **surface tension** of a 27·30 per cent. soln. of lead nitrate, at 12·8°, when that of water at $\theta°$ is $76.09 - 0.1540\theta$; the corresponding **cohesion constant**, a^2, is 11·98 per sq. mm. J. Wagner found the **viscosity** of a N-soln. to be 1·1010 (water unity) ; that of a 0·5N-soln., 1·0418 ; of a 0·25N-soln., 1·0174 ; and of a 0·125N-soln., 1·0066 at 25°. If x denotes the number of gram-eq. of salt per litre, the viscosity $= 1.0897x$. J. B. R. Scheffer found the **diffusion** coeff. in days for a soln. of a mol of lead nitrate in 136 mols of water to be 0·66 ; and in 514 mols of water, 0·71. J. C. G. de Marignac, and J. J. Coleman made some observations on this subject. The **compressibility** of the aq. soln. was measured by H. Gilbault, and P. W. Bridgman observed no evidence of a transition point when lead nitrate crystals are compressed from 1 to 12,000 krgms. per sq. cm., at 20° or 200°.

S. de Lannoy [5] represented the **thermal expansion** of soln. of lead nitrate by the expression $v=v_0(1+a\theta+b\theta^2)$, where the values of the constants a and b vary with the conc. and temp. of the soln.

Per cent.	40°–70°		0°–40°	
Pb(NO$_3$)$_2$	a	b	a	b
4	0·0$_4$963	0·0$_5$349	0·0$_4$200	0·0$_5$515
10	0·0$_3$141	0·0$_5$328	0·0$_3$103	0·0$_5$410
15	0·0$_3$175	0·0$_5$310	0·0$_3$127	0·0$_5$130
20	0·0$_3$2438	0·0$_5$267	0·0$_3$2438	0·0$_5$267

J. Morel said that when heated to 110°, the monoclinic form suffers no loss in weight, and, according to J. S. Stas, the ordinary salt does not decompose if dried in air at 200°, but acid vapours are given off at a higher temp. By extrapolation from the f.p. of ammonium trinitratoplumbite, B. Bogitsch estimated the **melting point** of lead nitrate to be 450°–470°; the decomposition of the salt prevents a comparison with fact. E. Maumené said that the salt can be melted without decomposition only under alkali nitrates; and O. Lehmann found that the m.p. is lowered when the salt is in contact with other nitrates. A. Colson found lead nitrate to be less stable than silver nitrate. H. Hess said that the salt decomposes in vacuo at 283°; and if heated in a silver crucible until a metallic film appears, and the cold mass boiled with water, the filtered liquid deposits the basic nitrate, $Pb(OH)_2.Pb(NO_3)_2$, while lead nitrate remains in soln. According to L. Baekeland, decomposition begins at 205°, it is very slow between 205° and 223°, and vigorous at 357°. In vacuo, between 205° and 223°, nitrous gases are given off copiously. The reaction $Pb(NO_3)_2 \rightleftharpoons PbO+2NO_2+O$ is reversible. The **dissociation pressure,** p mm., in vacuo, is as follows:

	223°	230°	250°	274°	297°	357°	448°
p	6·2	6·9	11·8	32·6	78·4	514·0	1180

An excess of oxygen or nitrogen peroxide lowers the dissociation press. Basic lead nitrate which has been heated in open vessels at 357° for 10 days shows the same dissociation press., so that it is probable that the first products of the dissociation are the basic nitrate, $PbO.2Pb(NO_3)_2$, together with oxygen, and nitrogen peroxide. If the products of the dissociation at 357° are removed from time to time, the dissociation press. falls from 514 to 260 mm., apparently owing to the decomposition of $PbO.2Pb(NO_3)_2$ to $2PbO.Pb(NO_3)_2$; and at a red-heat, this is converted into lead monoxide. L. R. Morgan showed that if p denotes the partial press. of the oxygen, p_2, that of nitrogen peroxide, the mass-action law $k=p_1^{\frac{1}{2}}p_2^2$ is valid; at 357°, the constant $k=0.062$.

The **freezing point** of aq. soln. was measured by L. C. de Coppet,[6] F. M. Raoult, M. le Blanc and A. A. Noyes, A. A. Noyes and K. G. Falk, M. Randall and A. P. Vanselow, F. Rüdorff, F. Guthrie, C. L. von Ende, A. Ponsot, K. Drucker, etc. According to H. Hausrath, if C denotes the number of grams of lead nitrate in 100 grms. of water; C', the number of millimols of the nitrate per litre; $\varDelta$, the lowering of the f.p. of water; and n, J. H. van't Hoff's constant (1. 15, 10):

C	0·01198	0·03985	0·09285	0·1844	0·5749
C'	0·362	1·204	2·805	5·570	17·37
$\varDelta$	0·00199	0·00638	0·01449	0·02770	0·815
n	2·98	2·87	2·79	2·68	2·54

M. Randall and A. P. Vanselow calculated the activity coeff. from the f.p. data. J. H. Walton and A. Brann attributed the lowering of the velocity of the crystallization of ice from under-cooled soln. to the formation of *hydrates of lead nitrate* in soln. P. Kremers [7] found that the **boiling point** of a sat. aq. soln. of lead nitrate is 103·5° in an enamelled-iron vessel, and 104·1° in a glass vessel. T. Griffiths said that a soln. containing 140 parts of the salt in 100

parts of water boils at 102·2°. G. T. Gerlach gave for soln. containing in 100 grms. of water :

$Pb(NO_3)_2$ . . .	11	26	44	65	87	111	137 grms.
Boiling point . .	100·5°	101·0°	101·5°	102·0°	102·5°	103·0°	103·5°

A. Smits measured the raising of the b.p., b ; and the mol. raising of the b.p., B, for sols. with w mol of the salt in 1000 grms. of water, and found for J. H. van't Hoff's constant n, 1. 15, 10 :

w . . .	0·0474	0·0869	0·4174	0·8793
b . . .	0·070°	0·0900°	0·418°	0·824°
B . . .	14·76	10·35	10·01	9·37
n . . .	2·84	1·99	1·93	1·80

F. M. Raoult, and G. Tammann measured the lowering of the **vapour pressure** of aq. soln. of lead nitrate, and the latter gave 12·3 mm. for the lowering of the vap. press., $\varDelta$, with soln. containing 0·5 grm. of salt in 100 grms. of water ; 23·5 mm. with 1 grm. ; 45·0 mm. with 2 grms. ; and 63·0 mm. with 3 grms.

H. Kopp [8] found the **specific heat** of the crystals dried at 100° to be 0·110 between 16° and 48° ; and the corresponding **molecular heat** is 36·4. J. Moser said that the aq. soln. of lead nitrate is cooled by dilution ; and J. H. Pollok said that when a soln., sat. at 9°, is diluted with an equal vol. of water, the temp. falls —0·35°. J. Thomsen said that the **heat of dilution** of a soln. of a mol of lead nitrate in 40 mols of water at 18°, by 60 mols of water, is —1·23 Cals. ; by 160 mols of water, —1·98 Cals. ; and by 360 mols of water, —2·50 Cals. He also gave —7·61 Cals. for the **heat of solution** of a mol of lead nitrate in 400 mols of water. M. Berthelot gave —8·22 Cals. with a mol of the salt dissolved in 930–1860 mols of water. K. Jauch gave 0·9621 for the sp. ht. at 18° of 0·5M-soln. ; 0·9179 for that of M-soln. ; 0·8559 for that of 2M-soln. ; 0·8045 for 3M-soln. ; and 0·7566 for 4M-soln. N. de Kolossowsky made some observations on this subject. K. Jauch also gave for the heats of dilution and soln., and for the sp. ht. and the mol. ht. of soln. of different conc. :

$Pb(NO_3)_2$ per cent. . .	8·4	37·9	42·3	47·8
Heat of solution . ·.	—7104	—4504	—4246	—4086 cals.
Heat of dilution . .	—7104	—2600	—2858	—3018 cals.
Specific heat . .	0·919	0·646	0·603	0·569
Molecular heat . .	3612	562	471	393

J. C. G. de Marignac gave for the sp. ht. of soln. with 50, 100, and 200 eq. of the salt respectively 0·7507, 0·8510, and 0·9162 between 21° and 26°, and 0·7500, 0·8507, and 0·9173 between 18° and 51° ; and —0·25 Cal. for the heat of dilution of an eq. of the salt in 2 litres of water, diluted with 2 litres of water at 16°. J. Thomsen gave for the **heat of formation** from its elements, 105·5 Cals. ; M. Berthelot, 105·6 Cals. ; P. Gunther, 108·1 Cals. ; and A. Colson, 105·4 Cals. J. Thomsen gave $(Pb,O_2,N_2O_4)=109\cdot51$ Cals. ; and M. Berthelot, $(PbO,N_2O_5)=40\cdot2$ Cals. The latter also gave $(PbO,2HNO_3,Aq.)=15\cdot4$ Cals. ; and J. Thomsen, 17·7 Cals. without and 25·38 Cals. with precipitation ; M. Berthelot gave 19·7 Cals. for the solid salt.

H. Töpsoe and C. Christiansen [9] measured the **index of refraction** and for C-light obtained 1·7730 ; for D-light, 1·7820 ; and for F-light, 1·8065 ; M. le Blanc and H. Rohland gave 1·7820 for Na-light at 20°, and the corresponding **equivalent refraction** in soln. 28·57—A. Heydweiller gave 15·72. F. Fouqué, and J. H. Gladstone and W. Hibbert made observations on this subject. T. W. Richards and W. C. Schumb gave 1·7815 for the index of refraction with Na-light ; and J. Behr, 1·7733 for Li-light, 1·7843 for Na-light, and 1·7933 for Ti-light. H. Marbach, G. Wulff, and F. Klocke studied the **optical anomaly,** or the abnormal **birefringence** of lead nitrate. P. Barbier and L. Roux found the **dispersion** of soln. increases with the conc. ; and the mean sp. dispersion, 0·351, is about the same as that of other salts. C. Schäfer and M. Schubert found the **reflecting power** shows maxima in the ultra-red at 7·5μ, 12·5μ, and 15μ ; and T. Liebisch and H. Rubens found a maximum at 79μ

in the **ultra-red reflection spectrum.** C. Schäfer, and W. N. Hartley made observations on the **ultra-violet absorption spectrum** of soln. of lead nitrate; and W. N. Hartley, on the **absorption spectrum** of soln. of different conc. T. E. Aurén measured the absorption coeff. of the salt for **X-rays.** H. Greinacher made the unexplained observation that its temp. in a Dewar's flask remains one or more hundredths of a degree below the temp. of its surroundings.

Numerous observations have been made on the **electrical conductivity** of aq. soln. of lead nitrate; for instance, by S. J. Bates,[10] E. Bouty, W. Conrad, J. H. Long, K. Jauch, G. Jäger, H. C. Jones and C. A. Jacobson, R. Salvadori, W. D. Harkins and F. L. Hunt, A. Heydweiller, F. Kohlrausch and E. Grüneisen, H. Fernau, E. Franke, A. Rosenheim and V. J. Meyer, A. A. Noyes and co-workers, and K. G. Falk. According to E..J. Shaeffer and H. C. Jones, the molecular electrical conductivity, μ, and the percentage **degree of ionization,** a, at 35° and 65° are :

		2	8	16	32	128	512	1024	2048
35°	v	2	8	16	32	128	512	1024	2048
	μ	111·5	170·2	196·6	220·4	261·0	291·0	300·0	309·6
	a	36·0	54·9	63·5	71·2	84·3	93·9	96·9	100·0
65°	μ	175·9	267·8	309·4	347·8	410·2	455·0	477·7	491·8
	a	35·8	54·5	62·9	70·7	83·4	92·5	97·2	100·0

K. Jauch found the eq. conductivity at infinite dilution to be 122·7. A. Thiel and L. Stoll questioned if a 0·5M-soln. is 80 per cent. ionized, as stated by R. Abegg. For conc. soln., A. Ferguson and I. Vogel gave for the eq. conductivity, $\lambda = 123\cdot44 - 164\cdot50C^{0\cdot452}$, where C denotes the concentration. The temp. coeff. has been measured by H. C. Jones and co-workers and by F. Kohlrausch. The **ionization constant** was found by C. Kullgren to be 40×10^{-8} at 100°. K. Beck and P. Stegmüller showed that the ionization occurs in two stages, $Pb(NO_3)_2 \rightleftharpoons PbNO_3{}' + NO_3{}' \rightleftharpoons Pb{}^{..} + 2NO_3{}'$. The ionization was investigated by C. L. von Ende, A. A. Noyes and K. G. Falk, W. D. Harkins and F. L. Hunt, W. K. Lewis, K. Fajans and M. Lembert, K. Drucker, H. C. Jones and C. A. Jacobson, W. Conrad, and H. Fernau. The tendency of the ions to form complexes is, according to S. Labendzinsky, and R. Abegg, very great. F. Kohlrausch and E. Grüneisen investigated the mobility of the ions. The **transport number** given by A. A. Noyes and K. G. Falk for Pb$^{..}$ at 25° is 0·487 in 0·1N-soln., and 0·03 in N-soln. M. Randall and A. P. Vanselow measured the activity coeff. of lead nitrate. J. Walker and E. Aston, and J. H. Long calculated the **hydrolysis** from the electrical conductivity; and C. Kullgren gave :

$Pb(NO_3)_2$		2	8	32	128 gram-eq. per litre		
Hydrolysis	85·5°	0·082	0·141	0·253	0·482	,,	,,
	100°	0·103	0·220	0·400	0·742	,,	,,

C. Immerwahr found that the **electrode potential** between lead and a N-soln. of the nitrate is 0·443 volt; and W. K. Lewis gave for 0·01N-soln., 0·469 volt; 0·05N-soln., 0·455 volt; 0·25N-soln., 0·445 volt; 0·4N-soln., 0·443 volt; and N-soln., 0·439 volt. H. Jahn, J. Moser, and J. Miesler studied this subject. A. C. Cumming measured the e.m.f. of cells: lead | lead nitrate soln. | soln. of the nitrate of ammonium, potassium, or sodium | and the calomel electrode. S. Lussana found that the current in a **concentration cell** goes from the more dil. to the more conc. soln.; and that the e.m.f. increases more rapidly than corresponds with proportionality. The polarization phenomena have been previously discussed. O. Lehmann studied the electrolysis of mixed soln. of lead and barium nitrates. A. Günther-Schulze studied the electrolysis of soln. of lead nitrate by using the vapour above the soln. as cathode, and as anode, a lead wire. W. G. Hankel [11] studied the **pyroelectricity** of the crystals; and M. von Laue, and E. Giebe and A. Schiebe, the **piezoelectricity.** W. Schmidt gave 16 for $\lambda = 75$ cms. for the **dielectric constant** of lead nitrate. A. Heydweiller calculated values for this constant. L. Ebert studied the dielectric polarization of lead salts.

The chemical properties of lead nitrate.—According to W. Ipatjeff and W. Werchowsky,[12] **hydrogen** under a press. of 150–219 atm. and at 209° during 48 hrs., precipitated a basic nitrate, but no metal, from aq. soln. of lead nitrate. H. Rose reported that the salt is stable in **air**, and dissolves in **water** with a marked cooling effect. J. Obermiller measured the hygroscopicity of lead nitrate. A. Mailfert found that lead nitrate is slowly converted by **ozone** into the dioxide. A number of isolated observations on the solubility of lead nitrate in water have been made by E. Mitscherlich, C. J. B. Karsten, H. Kopp, T. Griffiths, G. C. Wittstein, C. von Hauer, A. Michel and L. Krafft, W. K. Lewis, A. C. Cumming, W. D. Treadwell, C. Cheneveau, G. J. Mulder, H. Euler, T. W. Richards and W. C. Schumb, A. Ditte, M. le Blanc and A. A. Noyes, F. Mylius, and P. Kremers. The following results, expressed in S grms. of lead nitrate per 100 grms. of water, are averaged mainly from those of G. J. Mulder, and P. Kremers:

	0°	10°	20°	25°	30°	40°	50°	60°	80°	100°
S	37·6	46·3	54·4	58·5	63·6	72·2	81·8	92·5	111·3	132·9

According to K. Fajans and co-workers, the solubility of lead nitrate from carnotite-lead is the same as that from ordinary lead. J. Morel added that monoclinic lead nitrate is sparingly soluble in hot water, but more soluble in water acidified with nitric acid. According to W. D. Harkins, purified lead nitrate, recrystallized from water containing a slight amount of nitric acid, was heated to 100° for 6 hrs., and at 130° for 12 hrs. in a current of dry air. The soln. of the salt in water was acidic to rosolic acid, and alkaline to litmus. H. W. Fischer said that when heated in a sealed tube to 200°, aq. soln. of lead nitrate furnish crystals of basic nitrate; J. H. Weibel also examined the effect of temp. and press. on the hydrolysis of aq. soln. of lead nitrate. For the hydrolysis of lead nitrate, and also the basic nitrates, *vide supra*. A. Geuther found that **sodium hydroxide** furnishes a basic nitrate, lead hydroxide, or lead oxide, according to the conc. of the soln. V. Zotier studied the catalytic effect of the nitrate on **hydrogen dioxide**.

J. W. Thomas[13] said that solid lead nitrate takes up moist **hydrogen chloride** rapidly with the copious evolution of red fumes. J. J. Berzelius observed that when other salts of lead are precipitated from a soln. of an excess of lead nitrate, there is a tendency for the lead nitrate to be absorbed by the precipitate. H. Moissan found **fluorine** does not act on lead nitrate in the cold, but at a dull red heat, lead fluoride is slowly produced. F. Fischer and K. Thiele could not prepare a *lead fluonitrate*. There is a possibility that a *lead chloronitrate* is present in mixed soln. of lead chloride and nitrate—*vide* lead chloride. P. Fedoteéff studied the reversible reaction with **cuprous iodide and iodine**, $Pb(NO_3)_2+CuI +I\rightleftharpoons PbI_2+Cu(NO_3)_2$. Lead nitrate detonates slightly when triturated with **sulphur**. J. Thomsen gave 11·43 Cals. for the decomposition of a mol of lead nitrate in aq. soln. by **hydrogen sulphide**. According to E. Schürmann, **stannous and bismuth sulphides** are not attacked by soln. of lead nitrate; while **zinc, thallous, cobalt, and nickel sulphides** are transformed into nitrates and lead sulphide; **arsenic trisulphide** is transformed when heated with a soln. of lead nitrate under press. in a sealed tube. J. Lemberg found that **calcium sulphate**, $CaSO_4.2H_2O$, acquires a crust of lead sulphate when immersed in a cold conc. soln. of lead nitrate; and **copper hydroxysulphate**—brochantite—from lead sulphate when treated with a soln. of copper nitrate almost sat. with nitric acid. According to K. Elbs, **persulphuric acid** gives a white precipitate with neutral or almost neutral soln. of lead nitrate, which rapidly forms brown lead dioxide.

E. C. Franklin and C. A. Kraus found lead nitrate to be readily soluble in liquid **ammonia**, and F. M. G. Johnson and N. T. M. Wilsmore measured the electrode potential of lead against a soln. of lead nitrate in liquid ammonia, and R. Bossuet and L. Hackspill found that lead phosphide is precipitated from a soln. of lead nitrate in liquid ammonia by a soln. of rubidium phosphide in the same solvent. K. Friedrichs said lead nitrate is readily soluble in liquid ammonia,

and the soln. separates into two liquid phases at 45°. H. P. Cady studied the electrical conductivity, etc., of the soln. D. Strömholm, and N. Athanasescu studied the formation of basic nitrates by the action of aq. ammonia on soln. of lead nitrate. C. A. Lobry de Bruyn found lead nitrate is soluble in **hydrazine,** and sparingly soluble in **hydrazine hydrate.** T. W. B. Welsh and H. J. Broderson showed that anhydrous hydrazine dissolves 0·52 grm. of lead nitrate per c.c., but the soln. decomposes. The soln. is an electrical conductor. E. Divers said that **nitric oxide** has no action on lead nitrate. H. Braconnot found that **nitric acid** precipitates lead nitrate from a conc. aq. soln., and the crystallization of the salt from nitric acid soln. has been recommended by A. Ditte, and others for its purification. J. Morel found that soln. of the monoclinic variety in nitric acid furnishes octahedral crystals. A. Ditte said that the conc. acid dissolves only a trace of lead nitrate in the cold, while the boiling, conc. acid dissolves 0·7 grm. per litre. According to A. C. Cumming, the solubility of lead nitrate in nitric acid of different conc., at 25°, is :

HNO_3			2·02N-	4·64N-	8·77N-	14·35N-
$Pb(NO_3)_2$			178	61·0	13·9	0·536 grm. per litre

He added that it is very unlikely that a complex hydronitratoplumbous acid is formed. For the solubility of lead nitrate in soln. of ammonium, potassium, sodium, copper, silver, barium, and strontium nitrates ; or the mutual action of the fused salts, *vide infra*, the complex salts. F. Peters found that when treated with **potassium nitrite,** it forms a complex potassium lead nitritonitrate, and basic lead nitritonitrates. W. C. Williams found that **phosphoryl chloride** reacts with lead nitrate with the copious evolution of red fumes.

The older chemists knew that lead nitrate detonates with brilliant sparks when projected on red-hot **carbon ;** and that the inflammability of tinder, blotting-paper, etc., is greatly increased when they have been soaked in a soln. of this salt, and dried. W. D. Bancroft and H. B. Weiser [14] found that a flame fed with lead nitrate deposits a metallic mirror on a cold surface. According to H. Arctowsky, lead nitrate is insoluble in cold and very slightly soluble in hot **carbon disulphide.** C. A. Lobry de Bruyn found that 100 grms. of absolute **methyl alcohol** dissolve 1·37 grms. of lead nitrate at 20·5° ; and absolute **ethyl alcohol,** 0·04 grm. According to A. Gérardin, 100 grms. of ethyl alcohol of sp. gr. 0·9282, dissolve at 4°, 4·96 grms. of lead nitrate ; and 5·82 grms. at 8° ; 8·77 grms. at 22° ; 12·8 grms. at 40° ; and 14·9 grms. at 50°. W. H. Krug and K. P. McElroy, and A. Naumann said that lead nitrate is very sparingly soluble in dried **acetone.** A. Naumann found lead nitrate to be insoluble in **methyl acetate,** and in **ethyl acetate ;** H. Röhler said that **formamide** furnishes a complex precipitate with solid lead nitrate at ordinary temp., but at 200°, in vacuo, lead rapidly separates ; F. L. Shinn, insoluble in dried **ethylamine ;** H. Mandal, insoluble in **aniline ;** and A. Naumann, insoluble in **benzonitrile.** B. Lachowicz, said that compounds are probably formed with the **amines** of the fatty acids, aniline, **toluidine, pyridine, quinoline, piperidine, and mono- and diethylamine.** If an aq. soln. of lead nitrate be mixed with an equal vol. of alcohol, and then treated with aniline or *o*-toluidine, basic lead nitrate is deposited. The soln. of lead nitrate in pyridine was investigated by A. Werner, J. H. Walton and R. C. Judd, A. W. Speransky and E. G. Goldberg, A. T. Lincoln, and J. H. Mathews and A. J. Johnson. R. Müller found that 100 c.c. of pyridine dissolved 4·39 grms. of lead nitrate at 0°, and 5·46 grms. at 25°. B. Lachowicz said that with the **chlorides of the organic acids,** the anhydrides and lead chloride are produced. According to A. Smolka, a complex salt is formed when a mixed soln. of lead nitrate and **mannite** is boiled. J. H. Long studied the inversion of **cane-sugar** by a soln. of lead nitrate. M. Lilienfeld studied the action of lead nitrate on **plants ;** and H. Bechhold on **bacteria.** C. W. Correns studied the adsorption of lead from dil. soln. of the nitrate by **sand, china-clay,** and **chalk.**

L. Kahlenberg and W. J. Trautmann [15] studied the reduction of lead nitrate when heated with powdered **silicon.** J. L. Proust in 1802, and J. C. Bromeis in

1849 showed that the action of **lead** in soln. of lead nitrate is very complex. According to J. B. Senderens, a strip of lead, one side of which is polished and the other roughly crystalline, decomposes lead nitrate much more quickly than a strip polished entirely, the characteristic yellow colour of the nitrosonitrate appearing almost at once, whilst metallic lead and subsequently basic lead nitrate are precipitated. Since acetic acid is not capable of reduction under these conditions, the action does not take place in a soln. of lead acetate. K. Peters also observed that a complex series of basic nitrates and basic nitritonitrates are formed. J. B. Senderens found that **tin** has no action on a soln. of lead nitrate ; and likewise also with **antimony,** and **bismuth.** The precipitation by zinc was noted in the eighteenth century by T. Bergman, in his *De præcipitatis metallicis.* J. B. Senderens found that when a dil. or conc. soln. of lead nitrate is treated with **zinc,** lead is deposited, and zinc nitrate and hydroxide, and ammonia and ammonium nitrate are formed ; the lead reacts with the soln. as indicated above ; similar results were obtained with **cadmium.** Dil. soln. of lead nitrate, protected from air, do not act on **aluminium,** and conc. soln. only feebly, because a basic lead nitritonitrate is deposited as a protective film on the aluminium. N. W. Fisher said that **iron** has but a slight action on soln. of lead nitrate, but J. B. Senderens could find no evidence of the separation of lead from dil. or conc., cold or hot, acid or neutral soln. of lead nitrate. J. B. Senderens observed no action by **nickel** on neutral soln. protected from air at 10°–16° ; and with **cobalt** under similar conditions, the soln. becomes pink, and there is deposited a black film of lead which gradually forms a basic nitritonitrate. A. Ogata and T. Kai'un studied the action of **sodium hydroxide** soln. on lead nitrate and found that when the latter is in large excess, a dil. soln. of the alkali-lye gives a white precipitate : $Pb(NO_3)_2$ $+NaOH=Pb(OH)(NO_3)+NaNO_3$; if enough alkali be now added to make the filtrate alkaline, the reaction $3Pb(OH)NO_3+2NaOH=(PbO)_2Pb(OH)NO_3+2NaNO_3$ $+2H_2O$ takes place. A considerable time is required for the completion of the reaction. If a large proportion of alkali-lye is added to the lead nitrate soln., $Pb(NO_3)_2+4NaOH=Pb(ONa)_2+2NaNO_3+2H_2O$. W. Spring and M. Lucion found that when **barium dioxide** is triturated with lead nitrate, lead oxide, oxygen, and barium nitrate are produced. A. Mailhe obtained a basic lead nitrate by treating a soln. of lead nitrate with **copper hydroxide.**

Complex salts with lead nitrate.—According to B. Bogitch,[16] molten ammonium nitrate slowly dissolves lead nitrate. There is a eutectic with 33 per cent. lead nitrate, at about 131°, Fig. 128. There was no evidence of the formation of *ammonium nitratoplumbite* with mixtures containing up to 55 per cent. of lead nitrate. C. J. B. Karsten found that a sat. aq. soln. of one of the component salts dissolves some of the other ; and A. Kanitz, that the viscosity of mixed soln. of the component nitrates was greater than that deduced from the mixture rule. O. Pulvermacher discussed these experiments. A. C. Cumming measured the electrode potential of mixed soln. of the two nitrates. E. Maumené found a mixture of equal weights of sodium and lead nitrates fused at 282° when the calculated value is 374°, on the assumption that the m.p. of lead nitrate is 450°.
FIG. 128. — Freezing-point Curve of Lead and Ammonium Nitrates.

F. Guthrie gave 268° for the eutectic temp. obtained with mixtures containing 42·84 per cent. of lead nitrate. C. J. B. Karsten found that 100 parts of water at 18·75° dissolved 87·8 parts of lead nitrate and 34·1 parts of sodium nitrate. W. W. J. Nicol found that sodium nitrate lowers the solubility of lead nitrate in water ; and F. Isaac obtained the results indicated in Table XII, where the conc. are expressed in grams of salt per 100 grms. of sat. soln. He also studied the soln. in the metastable and labile states—1. 9, 6. M. le Blanc and A. A. Noyes found that the f.p. of the soln. agree with the assumption that a *sodium nitrato-*

plumbite is formed. The observations of S. Glasstone and H. N. Saunders on the lowering of the solubility; of A. C. Cumming, and W. K. Lewis on electrode potentials of lead in the mixed soln.; and of A. Kanitz on the viscosities of mixed soln., also agree with the assumption that a complex salt is formed. On the other hand, S. Glasstone and H. N. Saunders' study of the ternary system : $NaNO_3$–$Pb(NO_3)_2$–H_2O at 0°, 25°, 50°, and 100°, summarized in Fig. 129, shows
FIG. 129.—The Ternary System : $NaNO_3$–$Pb(NO_3)_2$–H_2O.
FIG. 130.—The Ternary System : KNO_3–$Pb(NO_3)_2$–H_2O.
FIG. 131.—The Ternary System : $Ba(NO_3)_2$–$Pb(NO_3)_2$–H_2O.

that no complex salt is formed under these conditions. F. Guthrie gave for the temp. of the beginning of the freezing of molten mixtures of lead and potassium nitrates :

$Pb(NO_3)_2$.	0	10	20	30	40	46·86	50	60	70 per cent.
F.p. . .	320°	300°	285°	268°	246°	207°	210°	238°	(335°)

Above 320° the decomposition interferes with the results. The eutectic temp. is therefore 207°. C. J. B. Karsten found that 100 parts of water at 18·75° dissolve 84·1 parts of lead nitrate and 29·9 parts of potassium nitrate ; F. Rüdorff, that 100 parts of water at 21·2° dissolve 119·6 parts of lead nitrate and 67·1 parts of potassium nitrate ; and M. le Blanc and A. A. Noyes, 100 parts of water at 20° dissolve 95·39 parts of lead nitrate and 61·05 parts of potassium nitrate. W. W. J. Nicol found that the solubility of lead nitrate is increased by the addition of potassium nitrate ; and the solubility results of A. Fock, and the above-mentioned observations, are considered to be in harmony with the assumption that a *potassium nitrato-plumbite* is formed. This conclusion is in agreement with the measurements of the electrode potentials by R. Abegg, S. Labendzinsky, W. K. Lewis, and A. C. Cumming working with the mixed soln. of the two salts ; of A. Kanitz on the viscosity of fused mixtures ; and of S. Glasstone and H. N. Saunders on the raising of the solubility of lead nitrate in water by potassium nitrate. On the other hand, S. Glasstone and H. N. Saunders' study of the ternary system : KNO_3–$Pb(NO_3)_2$–H_2O at 25°, 50°, and 100°, summarized in Fig. 130, shows that no complex salt is formed under these conditions. For complex potassium tetranitratoplumbite, $K_2Pb(NO_3)_4$, *vide infra*. E. Maumené found the fusibility of a mixture of equal

weights of lead, sodium, and potassium nitrates to be 259°, and he found that lead nitrate raised the transformation temp. of potassium nitrate. H. L. Wells and H. P. Beardsley inferred the existence of *caesium nitratoplumbite* in soln. because of the high mutual solubilities of the component salts. They were not able to obtain the salt in crystals owing to its high solubility.

P. Fedoteéff measured the solubility of aq. soln. of copper and lead nitrates at 20°, and, expressing conc. in grams of salt per 100 grms. of water, found :

| $Cu(NO_3)_2$ | . | . | 0 | 7·7 | 15·04 | 24·63 | 37·96 | 60·32 | 83·11 | 100·29 | 127·70 |
| $Pb(NO_3)_2$ | . | . | 55·11 | 39·34 | 27·80 | 19·05 | 13·08 | 8·19 | 5·37 | 3·53 | 2·33 |

when the solid phase in contact with the soln. was a mixture of $Pb(NO_3)_2$ and $Cu(NO_3)_2.6H_2O$. There is here, no evidence of a *copper nitratoplumbite*. A. Colson said that molten silver nitrate, at 250°, dissolves about 20 per cent. whereby heat is absorbed. The 25 per cent. soln. decomposes in vacuo at 350°, and under ordinary press. at 380°–385°. According to C. Stürenberg, if a boiling conc. soln. of lead and silver nitrates be cooled in vacuo, hexagonal crystals of **silver nitratoplumbite**, $Pb(NO_3)_2.2AgNO_3$, are formed. According to C. von Hauer, W. Herz, H. Ambronn and M. le Blanc, and A. Fock, strontium and lead nitrates furnish isomorphous mixed crystals ; but no *strontium nitratoplumbite* has been formed. A. Fock obtained the results indicated in Table XIII with soln. of

the mixed nitrates at 25°. G. Tammann found the salt decomposes too readily to form mixed crystals of the fused nitrates. According to E. Maumené, mixtures of lead and barium nitrates can be fused without decomposition if in the presence of fused sodium and potassium nitrates. The solubility of lead nitrate in water was found by F. W. Küster to be depressed by barium nitrate. H. Euler, W. Herz, G. Bödlander, and A. Fock have made observations on the mutual solubilities of the two salts. No *barium nitratoplumbite* has been isolated, but mixed crystals have been obtained and investigated by R. Brauns, C. von Hauer, P. Gaubert, J. W. Retgers, G. Tammann, H. Ambronn and M. le Blanc, and F. W. Küster. The velocity of cooling sat. soln. was found by D. Strömholm and T. Svedberg to influence the composition of the mixed crystals. S. Glasstone and E. J. Riggs studied the ternary system : $Ba(NO_3)_2$–$Pb(NO_3)_2$–H_2O at 25° and 100°, and the results are summarized in Fig. 131. The double salt could not be isolated, but in the quaternary system : KNO_3–$Ba(NO_3)_2$–$Pb(NO_3)_2$–K_2O, when the complex salt $2KNO_3.Ba(NO_3)_2$ is formed, there is also produced potassium tetranitratoplumbite, $2KNO_3.Pb(NO_3)_2$, which forms mixed crystals with the complex barium salt. G. Tammann and W. Krings said that the anomalous double refraction of mixed crystals of lead and barium nitrates is not connected with the heats of soln. because the latter are not altered at 340°, but the optical anomaly disappears at 340°, and does not reappear on cooling.

The basic lead nitrates.—The hydrolysis of lead nitrate in aq. soln. has been previously discussed. As is so often the case in reviewing the older reports on this and cognate subjects, a relatively large number of the alleged compounds are probably not chemical individuals but are mixtures whose chemical analyses have been represented by chemical formulæ. They are usually obtained by the action of alkali or ammonium or other hydroxides on a soln. of lead nitrate. For example, M. Pleissner [17] reported a white, caseous basic nitrate with 84·4 per cent. of lead to be precipitated from a cold soln. of lead nitrate; with a hot soln., the orange-red precipitate has 89·5 per cent. of lead. R. Weinland and F. Paul said that potassium ferricyanide gives a complex salt with different basic lead nitrates. F. Herles discussed the use of the basic lead nitrate for clarifying sugar-soln. in the refinery.

J. J. Berzelius treated a soln. of lead nitrate and ammonia, and digested the washed precipitate for 12 hrs. with the precipitant, while D. Strömholm left the precipitate to stand in contact with the mother-liquid. The analysis corresponded with **lead pentoxydinitrate,** $6PbO.N_2O_5.H_2O$, or $5PbO.Pb(NO_3)_2H_2O$, or $4PbO.Pb(OH)_2.Pb(NO_3)_2$. A. Ogata and T. Kai'un represented the constitution $NO_3.Pb.O.Pb.O.Pb.OH$; and F. Meissner regarded it as a salt of orthonitric acid, $N(OH)_5$, namely:

$$Pb<^O_O>N<^O_O>Pb$$
$$O.Pb.OH$$
D. Strömholm said that intermediate stages in the hydrolysis are represented by $2PbO.N_2O_5.H_2O$, and $10PbO.3N_2O_5.H_2O$. Modifications of the process were described by A. Geuther, J. Löwe, and N. Athanasescu. A. Ditte employed potassium hydroxide as precipitant; and M. Pleissner, barium hydroxide. D. Strömholm treated a soln. of lead acetate with sodium hydroxide free from carbon dioxide; and also excluded this gas from the water used for washing, and from the air in contact with the hydroxide. The product was shaken with 0·05N-ammonium nitrate, and washed as before. The washed precipitate was dried first on porous tiles, and then over sulphuric acid and soda-lime. A. Ogata and T. Kai'un recommended treating the lead nitrate soln. with just enough alkali hydroxide to make the filtrate alkaline towards phenolphthalein. The white powder has an astringent taste. According to N. Athanasescu, and D. Strömholm, the grains are micro-crystalline. J. J. Berzelius, and N. Athanasescu said that the salt is insoluble in and not decomposed by water; it is readily soluble in acids; and, according to A. Geuther, when shaken with a soln. of sodium hydroxide (1 : 10 or 1 : 20), it forms yellow lead oxide, whereas the dehydrated salt gives yellow lead oxide under similar conditions. J. J. Berzelius said that when moderately heated, it gives off water and assumes a yellow colour, but becomes white on cooling. A. Geuther said that it becomes anhydrous **lead pentoxydinitrate,** $5PbO.Pb(NO_3)_2$, at 170° (N. Athanasescu said 180°), and loses a little nitrogen oxide at 200°. When ignited, it furnishes lead oxide. F. C. Calvert reported *lead tetroxydinitrate,* $5PbO.N_2O_5$, or $4PbO.Pb(NO_3)_2$, to be formed by the action of aq. ammonia on a soln. of lead nitrate; but this has not been confirmed.

A. Smolka reported **lead oxyhexahydroxydinitrate,** $3Pb(OH)_2.Pb(NO_3)_2$, or $4PbO.N_2O_5.nH_2O$, to be formed when mannitol lead nitrate, $Pb(NO_3)_2.C_6H_8O_6$, is boiled with an excess of water for 4 days. N. Athanasescu made it as a white crystalline powder by digesting 50 grms. of powdered lead nitrate and 200 c.c. of aq. ammonia in a flask for 2 weeks, shaking daily. The solid product was washed with cold water and dried. It is insoluble in and not affected by water. It begins to give off water at 200°, and to give off nitrous fumes at about 300°. H. T. S. Britton found a critical point in the electrometric titration of lead nitrate soln. with sodium hydroxide, corresponding with $Pb(NO_3)_2.3Pb(OH)_2.nH_2O$. The

salt $10PbO.3N_2O_5.4$(or $5)H_2O$, or $3PbO.4Pb(OH)_2.3Pb(NO_3)_2$, **lead trioxyocto-hydroxyhexanitrate,** was prepared by T. Morawsky by adding ammonia eq. to two-thirds the N_2O_5 of a hot soln. of lead nitrate; the precipitate was washed, recrystallized three times, and dried at $100°$. He also made it by digesting lead glyceronitrate with much water. D. Strömholm obtained it by the action of much ammonia on a soln. of lead nitrate; and J. Löwe, by treating lead dioxydiacetate with a soln. of potassium nitrate, and recrystallizing the product from its aq. soln. A. J. Wakeman and H. L. Wells say that lead hydroxynitrate is formed under these conditions. Some other basic nitrates give this salt when recrystallized from water— e.g. $3PbO.N_2O_5.H_2O$. A. J. Wakeman and H. L. Wells said that the salt furnishes flat, tabular, triclinic crystals with an extinction angle of $35°$. It suffers no change when digested with boiling water or recrystallized from its aq. soln. T. Morawsky said that the salt is dehydrated at $170°$. J. H. Kastle suggested that the compound $10PbO.3N_2O_5.5H_2O$ can be regarded as an acid salt, $Pb_{10}H_{10}N_6O_{30}$, of the complex acid $(H_5NO_5)_6$. A. Vogel reported that when lead acetate is treated with potassium nitrate in dil. soln. a crystalline precipitate—**lead trioxydinitrate,** $PbO.Pb(OH)_2.Pb(NO_3)_2$, or $3PbO.N_2O_5.H_2O$—is formed; with conc. soln., the precipitate is glutinous. J. Löwe also obtained it by the action of potassium nitrate on lead dioxydiacetate. The salt was also prepared by A. Smolka. J. Löwe said that the white prismatic crystals are soluble in an excess of acetic acid, and that alcohol precipitates the crystals from the aq. soln. The soln. is rendered turbid by carbon dioxide. The crystals lose their water at $150°–160°$, or, according to A. Smolka, at $115°$, forming **lead dioxydinitrate,** $2PbO.Pb(NO_3)_2$. The anhydrous salt was obtained by L. Baekeland by heating lead nitrate to $357°$ under reduced press. for 10 days; at a red heat, it forms lead monoxide. J. J. Berzelius reported a higher hydrate, $3PbO.N_2O_5.3H_2O$, **lead oxyhexahydroxytetranitrate,** $PbO.3Pb(OH)_2.2Pb(NO_3)_2$, to be formed by precipitating a soln. of lead nitrate with a slight excess of ammonia, digesting the mixture in a closed vessel, dropping in a little more lead nitrate soln., again digesting, and repeating the treatment until too small an excess of ammonia is present to be detected by its odour, and only recognizable by the fumes it gives with hydrochloric acid. The washed precipitate is dried out of contact with air. When warmed it becomes yellow, but the white colour is restored on cooling; if heated to a higher temp., lemon-yellow lead oxide is formed. J. J. Berzelius said that the salt is slightly soluble in water, but not if various salts are present which do not decompose the basic nitrate.

Many observers have described the preparation of **lead hydroxynitrate,** $Pb(OH)NO_3$, or $2PbO.N_2O_5.H_2O$. J. J. Berzelius, and M. E. Chevreul supposed it to be free from water; but J. F. Persoz, J. Pelouze, and J. Löwe demonstrated that it is hydrated. N. von Lorenz, and F. Peters obtained this salt by the action of lead on warm water; and N. Athanasescu, by heating a conc. soln. of lead nitrate (1 : 1) in a sealed tube at $310°–320°$ for 4–5 hrs., washing the product with the smallest possible quantity of water, and drying. J. J. Berzelius obtained it by treating a hot soln. of lead nitrate with insufficient ammonia to precipitate the whole of the lead hydroxide and cooling the filtrate—D. Strömholm recommended half the theoretical proportion of ammonia; and A. Ogata and T. Kai'un recommended adding enough alkali hydroxide to furnish a filtrate which is just alkaline to phenolphthalein. Modifications of the process were used by T. Morawsky, N. Athanasescu, and A. Ditte. E. Borsbach, and B. Lachowicz used quinoline in place of ammonia; B. Lachowicz, aniline, toluidines, methylaniline, dimethylaniline, and xylidine. M. E. Chevreul boiled equimolar parts of lead oxide and nitrate with water, and allowed the hot filtered soln. to crystallize—N. Athanasescu said that half an hour's boiling is sufficient. T. Morawsky added 15 grms. of lead oxide to a boiling soln. of 20 grms. of lead nitrate, 20 grms. of glycerol, and 200 c.c. of water. The hot filtered soln. was cooled for crystallization. J. Pelouze used white-lead in place of lead oxide, and found that an excess is no disadvantage since the hydroxynitrate cannot decompose white-lead. J. F. Persoz boiled the

lead nitrate soln. with zinc oxide ; H. Klinger, cadmium oxide or hydroxide ; and A. Mailhe, copper hydroxide. J. Löwe treated a cold aq. soln. of lead nitrate with a slight excess of basic lead acetate ; and also digested a soln. of potassium nitrate with a slight excess of basic lead acetate—the slow cooling of the soln. gives prismatic crystals, and if lead nitrate is also present, tabular crystals. J. Ville obtained it by the action of ammonium nitrate on lead oxide. F. Peters treated a boiling soln. of 50 grms. of lead nitrate in 500 c.c. of water with 100 c.c. of a soln. of potassium nitrate (1 c.c.=0·0574 grm. N_2O_5) ; the white precipitate first formed disappears on boiling the mixture. On evaporating the soln. to about 100 c.c. and cooling, white crystals are formed. These are pressed between bibulous paper, and dried in air. E. Guignet made some observations on this subject ; so also have A. Ogata and T. Kai'un—*vide supra*, action of alkali-lye on lead nitrate.

J. J. Berzelius said that as the hot aq. soln. cools, the salt separates in white crystals which have different habits—needles, scales, prisms—dependent on the mode of preparation. N. von Lorenz said that they belong to the rhombic system. A. J. Wakeman and H. L. Wells said that the crystals are either monoclinic or triclinic with a strong double refraction. J. J. Berzelius said that the salt has a sweet, slightly astringent taste, and when ignited furnishes red-lead or lead monoxide acccording to the temp. employed. J. Pelouze said that when heated for a long time at 100°, the crystals lose a perceptible amount of water ; and they slowly become anhydrous at 160°–190° ; at 200°, the salt becomes coloured and gives off fumes. B. Lachowicz observed no loss of weight at 100° ; J. Löwe said that the crystals become anhydrous at 150°–155° in vacuo. N. Athanasescu said that the water is all given off at 250°, and decomposition occurs above 300°. T. Morawsky said that the salt fuses before decomposition is complete. J. Thomsen gave for the heat of formation (PbO,HNO_3)=24·25 Cals. ; (Pb,H,O_2,NO_2) =118·16 Cals. ; and $(PbO,HNO_3,Aq.)$=16·77 Cals. J. J. Berzelius, and J. Pelouze said that the salt is sparingly soluble in cold water, and much more soluble in boiling water. J. J. Pohl found that at 19·2°, 100 grms. of water dissolve 19·4 grms. of the salt. N. Athanasescu found that the powdered salt reacts distinctly alkaline towards litmus when moistened with water ; when allowed to stand in contact with water for a long time, lead hydroxide is formed. The salt is easily soluble in acids. A. Geuther said that when digested with a soln. of sodium hydroxide (1 : 10 or 1 : 20) in slight excess, yellow crystals of lead oxide are formed with intermediate formation of $6PbO.N_2O_5.H_2O$. M. E. Chevreul said that carbon dioxide reacts with half the contained lead.

According to J. B. Senderens, when a strip of lead is placed in a soln. of lead nitrate, **tetritahydrated lead hydroxynitrate,** $2PbO.N_2O_5.2\frac{1}{2}H_2O$, or $Pb(OH)NO_3.\frac{1}{4}H_2O$, is formed. It crystallizes from a soln. in hot water in monoclinic needles. It loses one-third its contained water at 100°, and the remainder at 190° ; decomposition begins at 200°. The salt is stable in air. 100 grms. of boiling water dissolve 6·7 grms. of salt most of which separates out on cooling.

L. Baekeland obtained **lead oxytetranitrate,** $3PbO.2N_2O_5$, or $Pb_3O(NO_3)_4$, or $PbO.2Pb(NO_3)_2$, by heating lead nitrate for 10 days in an open vessel at 397° ; and L. R. Morgan, by the dissociation of lead nitrate in the presence of much oxygen. It is more stable than lead nitrate ; its dissociation press. is 260 mm. when that of lead nitrate is 514 mm. G. Städeler [18] mixed conc. soln. of lead and mercurous nitrates and obtained white octahedral or cubic crystals of the basic salt, $2PbO.2Hg_2O.3N_2O_5$, **lead mercurous oxyhexanitrate,** $PbO.Pb(NO_3)_2.Hg4NO_3$.

Lead nitrosonitrates, or nitritonitrates.—As indicated above, when a soln. of lead nitrate is boiled with lead, a number of basic salts are formed ; and part of the lead nitrate is reduced to the nitrite. The salts are considered to be basic nitrosonitrates or nitritonitrates ; but the evidence as to their individuality is by no means satisfactory. According to J. J. Berzelius,[19] if a soln. of the basic

salt, $Pb_2(OH)_2(NO_2)(NO_3).nH_2O$, be treated with enough sulphuric acid to precipitate half the lead as sulphate; or, according to M. E. Chevreul, if carbon dioxide be passed through the soln. so long as lead carbonate is precipitated, the filtrate, on evaporation in vacuo, furnishes lemon-yellow octahedra which were regarded as **lead hexanitritodinitrate,** $3Pb(NO_2)_2.Pb(NO_3)_2.4H_2O$, or $Pb_2(NO_2)_3(NO_3).2H_2O$. C. F. Gerhardt, A. Gomès, and J. Nicklès regarded this product as the normal nitritonitrate; but E. M. Péligot and A. Chilesotti considered it to be a mixture of lead nitrite and nitrate.

The oldest of the basic nitritonitrates was obtained by J. L. Proust in 1812, who considered it to be lead subnitrate, whilst J. J. Berzelius called it lead subnitrite. The actual composition, according to the analyses of J. J. Berzelius, E. M. Péligot, and J. C. Bromeis corresponds with **lead tetrahydroxydinitritodinitrate,** $2Pb(OH)_2.Pb(NO_2)_2.Pb(NO_3)_2$, or $Pb_2(OH)_2(NO_2)(NO_3)$. A. Chilesotti regarded this as a chemical individual. J. J. Berzelius heated an aq. soln. of 100 grms. of lead nitrate and 78 grms. of lead-foil for some hours at 70°–75°. The liquid acquired a yellow colour, and, on cooling, deposited yellow scales of this salt. The action begins between 50°–55°, but is quicker between 70°–75°; J. C. Bromeis found that above 80°, a portion of the salt is decomposed, and nitric oxide is evolved. At the beginning of the reaction some basic lead nitrate is deposited. E. M. Péligot used a similar process, and added that if from the presence of too much lead, or boiling the liquid for too long a time, the crystals are contaminated with orange scales of $7PbO.N_2O_3.N_2O_5.3H_2O$, the required salt can be extracted with hot water and the soln. allowed to crystallize. According to J. J. Berzelius, the above mixture yields only the yellow salt when the lead is all dissolved, and no red or orange salt is formed. J. B. Senderens obtained a soln. of this salt by the action of lead on soln. of copper or silver nitrates.

N. von Lorenz reported the hydrate $2Pb(OH)_2.Pb(NO_2)_2.Pb(NO_3)_2.1\frac{1}{2}H_2O$ to be formed in lemon-yellow, six-sided plates by crystallization from water at 70°–80°—if a higher temp. is used, lead hydroxide may be formed; and F. Peters, the hydrate $2Pb(OH)_2.Pb(NO_2)_2.Pb(NO_3)_2.2H_2O$, in pale yellow rhombic plates, by the action of a soln. of 50 grms. of lead nitrate in $1\frac{1}{4}$ litres of water on 27·4–3·13 grms. of lead, and also by adding a boiling soln. of 150 c.c. of potassium nitrate (1 c.c. $=0·0574$ grm. N_2O_3) to a soln. of 37·5–56·26 grms. of lead nitrate in half a litre of water. J. Fritzsche found that if the vapours evolved from fuming nitric acid is heated are passed into water with finely divided lead oxide in suspension, the oxide becomes white, and then dissolves, forming a yellow liquid. The evaporation of the liquid furnishes silky scales of a lead nitrite or basic nitritonitrate, and some lead nitrate.

J. J. Berzelius described the crystals of lead tetrahydroxydinitritodinitrate as yellow shining laminæ, or long flat needles which, according to J. F. W. Herschel, exhibit two axes of double refraction. J. C. Bromeis described the crystals as rectangular prisms, with rhombic pyramids. J. J. Berzelius said that the moist salt reddens blue litmus. M. E. Chevreul found the taste to be slightly sweet and astringent. E. M. Péligot observed no evolution of water below 100°, but M. E. Chevreul reported that some acid is lost at 100°, and the salt at a higher temp. becomes pasty, and darker in colour. J. J. Berzelius added that at a still higher temp., before fusion occurs, water and acid vapours are evolved. M. E. Chevreul said that 100 parts of water dissolve 1·25 parts of salt at 25° (J. C. Bromeis said 1·18 parts at ordinary temp.), and 9·4 parts of salt at the boiling point. The yellow aq. soln. is rendered turbid by carbon dioxide. J. C. Bromeis found that the salt is not decomposed by long boiling with water, but it is decomposed if lead be present. J. J. Berzelius, and M. E. Chevreul noted that red fumes are evolved when the salt is treated with strong acids; and E. M. Péligot added that cold, conc. acetic acid furnishes a yellow soln. without decomposition provided the acid be added slowly to avoid a rise of temp. 100 parts of the salt in acetic acid soln. dissolve 44 parts of lead dioxide, forming lead nitrate and acetate. A. Chilesotti pointed out that the soln. in 4 mols of acetic acid contains 2 mols of

lead acetate, and a mol each of lead nitrite and nitrate. Baryta-water forms barium nitrite and nitrate ; and, according to C. F. Gerhardt, silver nitrate gives a precipitate of silver nitrite.

The following twenty-six basic nitritonitrates have been reported, but probably a large proportion are mixtures. Commencing with the most basic, J. C. Bromeis boiled a soln. of lead tetrahydroxydinitritodinitrate with lead, and E. M. Péligot, with lead oxide, and obtained yellow, rhombic prisms with the composition, $7PbO.N_2O_3.N_2O_5.3H_2O$: E. M. Péligot obtained the same salt by the action of a soln. of lead nitrate on lead. J. C. Bromeis reported $14PbO.3N_2O_3.N_2O_5.6H_2O$ to be formed in orange-red crystals in the same manner as the 7 : 1 : 1 : 3 salt. He also obtained rhombic prisms of $14PbO.N_2O_3.3N_2O_5.6H_2O$ by the action of a soln. of lead nitrate on an excess of lead. F. Peters obtained orange plates of $10PbO.2N_2O_3.N_2O_5.4H_2O$ by the action of a boiling soln. of 50 grms. of lead nitrate in $1\frac{1}{2}$ litres of water on 54·7 grms. of lead for $8\frac{1}{4}$ hrs.; and of a soln. of 25 grms. of lead nitrate in 500 c.c. of water on 23·4 grms. of lead for $7\frac{1}{4}$ hrs. He also obtained $16PbO.3N_2O_3.2N_2O_5.5H_2O$, in orange needles by boiling for $6\frac{1}{2}$ hrs., 50 grms. of lead nitrate, 2 litres of water, and 62·5 grms. of lead ; orange-coloured, rhombic scales of $6PbO.N_2O_3.N_2O_5.2H_2O$, by boiling for 4 hrs. a mixture of 50 grms. of lead nitrate, $1\frac{1}{2}$ litres of water, and 46·9 grms. of lead ; or 25 grms. of lead nitrate, 500 c.c. of water, and 19·5 grms. of lead ; dark yellow plates of $9PbO.N_2O_3.2N_2O_5.4H_2O$, by boiling for 7 hrs. a mixture of 25 grms. of lead nitrate, 15·3 grms. of potassium (or sodium) nitrate, $1\frac{1}{2}$ litres of water, and 31·3 grms. of lead ; yellow crystals of $23PbO.6N_2O_3.3N_2O_5.12H_2O$, by boiling for $7\frac{1}{2}$ hrs. a mixture of 25 grms. of lead nitrate, 500 c.c. of water, 50 c.c. of a soln. of potassium nitrite (1 c.c. $=0·0574$ grm. N_2O_3), and lead so that $Pb(NO_3)_2$: KNO_2 : Pb $=2 : 2 : 3$; orange-yellow crystals $10PbO.3N_2O_3.N_2O_5.16H_2O$; by boiling for $4\frac{1}{2}$ hrs. 50 grms. of lead nitrate, 2 litres of water, and 39·1 grms. of lead ; and yellow plates of $20PbO.6N_2O_3.3N_2O_5.17H_2O$, by boiling for 6 hrs. a soln. of 25 grms. of lead nitrate, 500 c.c. of water, 50 c.c. of a soln. of potassium nitrite (1 c.c. $=0·0574$ grm. N_2O_3), and 15·6 grms. of lead. H. von Lorenz reported $12PbO.5N_2O_3.N_2O_5.6H_2O$ to be formed by heating a soln. of 50 grms. of lead nitrate and 54·7 grms. of lead ; and F. Peters, yellow rhombic prisms of $12PbO.5N_2O_3.N_2O_5.10H_2O$, by boiling for 30 minutes a soln. of 25 grms. of lead nitrate, 500 c.c. of water, 15·6 grms. of lead with so much potassium nitrite to give the ratio $Pb(NO_3)_2$: KNO_2 : $Pb=1 : 3 : 1$. N. von Lorenz prepared yellow, rhombic plates of $10PbO.4N_2O_3.N_2O_5.5H_2O$, by boiling an aq. soln. of lead nitrate with an equal weight of lead ; and F. Peters, by crystallization from the mother-liquid from $10PbO.2N_2O_3.N_2O_5.4H_2O$. F. Peters reported citron-yellow prisms of $8PbO.3N_2O_3.N_2O_5.4H_2O$, by crystallization from the mother-liquid of $6PbO.N_2O_5.N_2O_3.2H_2O$; N. von Lorenz obtained $8PbO.3N_2O_3.N_2O_5.4\frac{2}{3}H_2O$, in yellow plates, from a soln. containing 50 grms. of lead nitrate and 46·9 grms. of lead ; and F. Peters, $8PbO.3N_2O_3.N_2O_5.6H_2O$ in yellow rhombic prisms, by boiling for 5 hrs. a soln. of 25 grms. lead nitrate, 500 c.c. water, with lead and potassium nitrite so that the ratio, $Pb(NO_3)_2$: KNO_2 : Pb is nearly 1 : 2 : 1. F. Peters obtained orange-yellow scales of $6PbO.2N_2O_5.N_2O_3.3H_2O$ from the mother-liquid of $10PbO.3N_2O_3.N_2O_5.16H_2O$; and N. von Lorenz, yellow six-sided plates of $6PbO.2N_2O_3.N_2O_5.5H_2O$, from a soln. of 50 grms. of lead nitrate and 42 grms. of lead ; and by using a mol of lead nitrate and $1\frac{1}{4}$ gram-atoms of lead he obtained $16PbO.3N_2O_3.5N_2O_5.10H_2O$. J. C. Bromeis so obtained $10PbO.3N_2O_3.2N_2O_5.7H_2O$ by the process employed for lead tetrahydroxydinitritodinitrate, but at a higher temp. F. Peters reported rhombic plates of $14PbO.4N_2O_3.3N_2O_5.12H_2O$ to be formed by boiling for 45 minutes a soln. of 25 grms. lead nitrate, 500 c.c. of water ; 150 c.c. of a soln. of potassium nitrite (1 c.c. $=0·0574$ grm. N_2O_3). N. von Lorenz obtained $26PbO.7N_2O_3.6N_2O_5.21H_2O$ by heating to 60°–100° for 7 hrs. a soln. of 50 grms. of lead nitrate and 31·27 grms. of lead. F. Peters obtained sulphur-yellow rhombic plates of $10PbO.2N_2O_3.3N_2O_5.9H_2O$ by heating for $2\frac{1}{2}$ hrs. a soln. of 50 grms. of lead nitrate in $1\frac{1}{2}$ litres of water and 23·5 grms. of lead ; and sulphur-yellow rhombic plates of $16PbO.3N_2O_3.5N_2O_5.14H_2O$, by boiling for $6\frac{1}{2}$ hrs. a soln. of 50 grms. of lead nitrate in $1\frac{1}{2}$ litres of water with 19·6 grms. of lead ; N. von Lorenz obtained sulphur-yellow rhombic plates of $6PbO.N_2O_3.2N_2O_5.3\frac{2}{3}H_2O$, by the action of a soln. of 50 grms. of lead nitrate and 31·27 grms. of lead at 60°–100° ; and F. Peters, $6PbO.N_2O_3.2N_2O_5.5H_2O$, in pale yellow plates by the action of 50 grms. of lead nitrate, $1\frac{1}{4}$ litres water, and 15·6 grms. of lead at 65°–70°, and cooling to 35°.

Metallic lead was found by A. N. Meldrum to be more readily attacked by a mixed soln. of lead and potassium nitrates than it is by a soln. of lead nitrate alone. The reaction between potassium nitrite and lead acetate, nitrate, chloride, bromide, or iodide results in the production of complex compounds which, in addition to potassium, lead, nitrosyl, and water, may contain one or more eq. of the negative ion originally associated with the lead. The products vary in colour

from yellow to orange, and as a rule contain potassium and lead in the at. ratio 3 : 2. S. D. Hayes passed nitric oxide and air into a soln. of lead nitrate containing an excess of potassium hydroxide, and obtained **potassium lead dinitritodinitrate,** $2KNO_3.Pb(NO_2)_2.H_2O$; in yellow prisms. A. N. Meldrum's analysis corresponds more nearly with $K_2Pb(NO_2)_3NO_3.H_2O$, *i.e.* $2KNO_2.Pb(NO_2)(NO_3).H_2O$. The salt becomes anhydrous at 100°. The salt is not changed by boiling water ; it gives red fumes with acids, and lead sulphate and potassium cobaltinitrite when treated with cobalt sulphate. J. Lang reported **potassium lead octonitritotetranitrate,** $K_6Pb_3(NO_2)_8(NO_3)_4.3H_2O$, from a soln. of lead nitrate and not too great an excess of potassium nitrite. The orange-yellow prisms are less soluble than potassium lead tetranitrite ; with an excess of potassium nitrite, potassium lead tetranitrite and potassium nitrate are formed, and with potassium carbonate, potassium nitrate is produced.

§ 35. Lead Phosphates

V. A. Kroll [1] determined the cooling curves of fused mixtures of lead and phosphoric oxides. The lag was found to be considerable, and the undercooling in the case of compounds and eutectics was very marked. The mixtures with a high proportion of phosphorus pentoxide are glassy, and freezing points could not be determined by thermal methods. Crystallization begins near the temp. at which the pyrophosphate first appears, and from this point onwards, the curve shows five distinct maxima corresponding respectively with the pyrophosphate, $2PbO.P_2O_5$; the anorthophosphate, or diphosphate, $5PbO.2P_2O_5$; the normal or orthophosphate, $3PbO.P_2O_5$; *lead oxyorthophosphate*, $4PbO.P_2O_5$; and the *lead pentoxyorthophosphate*, $8PbO.P_2O_5$. The temp. in Fig. 192 are expressed in terms of the pyrometer readings. To scale the diagram, the m.p. of lead monoxide can be taken as 877°, and that of the normal phosphate, $Pb_3(PO_4)_2$, as 1015°—*vide* Fig. 132. Many of the mixtures were found to expand after solidification, showing the other compounds are probably being formed at the lower temp. By measuring the temp. at which threads of the glasses are ruptured by a definite weight, A. V. Kroll found
FIG. 132.—Fusion Curves of Mixtures of Lead Oxide and Phosphorus Pentoxide.

evidence that the phosphates $PbO.3P_2O_5$ and $2PbO.3P_2O_5$ are capable of existence.

J. J. Berzelius, and H. Alders and A. Stähler obtained normal *plumbous orthophosphate*, or **lead orthophosphate**, $Pb_3(PO_4)_2$, by digesting lead hydrophosphate with aq. ammonia ; and by treating a soln. of lead acetate with sodium hydrophosphate ; W. Heintz used a similar process ; and E. Mitscherlich, and H. Alders and A. Stähler worked with boiling soln. C. F. Gerhardt used a soln. of lead nitrate. The precipitate is washed by hot water and suction, but dried over sulphuric acid in vacuo. W. Heintz, and C. F. Gerhardt showed that if a soln. of lead chloride be employed, the precipitate is always contaminated with chloride. D. Strömholm digested lead hydroxide with an excess of $0.05N$-Na_2HPO_4 and obtained the normal phosphate. K. Haushofer found that when kept in a molten state for a long time, pyromorphite breaks down into lead orthophosphate and chloride. A. Stähler and W. Scharfenberg discussed the precipitation of lead as orthophosphate as an analytical process. J. H. Fischer said that if an excess of lead acetate be added to an acetic acid soln. of sodium hydrophosphate, the air-dried product is *tri- or tetrahydrated lead orthophosphate*.

The white powder is amorphous. H. Alders and A. Stähler observed no signs of crystals under the microscope. If fused, and slowly cooled, F. Zambonini found the mass consisted of hexagonal prisms which were uniaxial without showing optical anomalies. The optical character is negative, the birefringence is strong ; the indices of refraction for the *B*-, *D*-, and *F*-rays are respectively $\omega=1.9549$, 1.9702, and 1.9994, and $\epsilon=1.9232$, 1.9364, and 1.9618. The dispersion for ω is stronger than for ϵ. H. V. Regnault gave 0.0798 for the sp. ht., and 64.7 for the mol. ht. F. Zambonini gave 1015° for the m.p., and 1014° for the f.p. ; M. Amadori found 1006° for the m.p. of a sample contaminated with a slight trace of lead oxide. F. Zambonini observed no transition point at 782°, although M. Amadori claimed that such a point does occur. S. Motylewsky said the drop-weight of molten lead orthophosphate at the m.p. is 275 units when that of water at 0° is 100 units. E. Bäcklin studied the *K*-series of the X-ray spectrum. According to W. Böttger, water at 19.95° dissolves 0.00135 grm. of lead orthophosphate per litre ; the soln. has the sp. conductivity 0.0_414, and about 98 per cent. is ionized. C. Immerwahr studied the potential of salts with a soln. of lead phosphate in alkali phosphate.

A. Mailfert found lead phosphate is slowly converted by ozone into the dioxide. R. M. Caven and A. Hill said that cold water does not hydrolyze the salt, but hot water attacks it very slowly. V. Zotier studied the catalytic action of the phosphate on hydrogen dioxide. G. Campani found that an excess of potassium iodide converts it into lead iodide or potassium lead tetraiodide. The lead orthophosphate is soluble in aq. ammonia, and more freely in potash-lye. The salt dissolves in nitric acid. H. Alders and A. Stähler said that it is precipitated therefrom by ammonia unchanged. E. Duvillier found that conc. nitric acid liberates orthophosphoric acid ; and dil. nitric acid converts it into the hydrophosphate. R. M. Caven and A. Hill found that lead phosphate is not soluble in a soln. of lead nitrate. A soln. of phosphoric acid—0.0469 per cent. H_3PO_4—begins to convert the orthophosphate into the hydrophosphate. A. Bertrand noted that 100 grms. of 38.94 per cent. acetic acid dissolve 0.128 grm. of lead orthophosphate. H. Mandal said that the salt is very sparingly soluble in aniline ; A. Naumann, insoluble in methyl and ethyl acetates.

L. Ouvrard obtained acicular crystals of **potassium lead orthophosphate**, $KPbPO_4$, from soln. of lead oxide in molten potassium hydrophosphate or pyrophosphate. He also prepared prismatic crystals of **sodium lead orthophosphate**, $NaPbPO_4$, in a similar manner. The crystals are readily soluble in dil. acids. J. A. Hedvall and co-workers found that lead orthophosphate begins to react with barium oxide at 335°, with strontium oxide at 453°, and with calcium oxide at 524°. T. H. Lee and L. F. de Moraes obtained an impure **barium lead ortho-**

phosphate, $(Pb,Ba)_3(PO_4)_2.8H_2O$, as a yellowish-white mineral of sp. gr. 3·0–3·3. It was called *ferrazite*—after J. B. de A. Ferraz. G. Saring obtained the complex $Ca_3(PO_4)_2(CaO)_2(K_2O)_2.PbO_2$. Mixed crystals of *lead and cerous orthophosphates* were discussed by F. Zambonini, and G. Carobbi.

F. M. Lyte and co-workers mentioned the formation of basic lead phosphate by the action of a soln. of a phosphate on basic lead sulphate, or basic lead chloride. A. V. Kroll obtained evidence of the formation of $8PbO.P_2O_5$, or $5PbO.Pb_3(PO_4)_2$, **lead pentoxyorthophosphate,** and of $4PbO.P_2O_5$, or $PbO.Pb_3(PO_4)_2$, **lead oxyortho-phosphate,** on the f.p. curve, Fig. 128. The last-named salt was obtained by C. F. Gerhardt, by calcining lead dinitratorthophosphate $Pb(NO_3)_2.Pb_3(PO_4)_2$. There was no sign of D. Strömholm's $3PbO.Pb_3(PO_4)_2$, or $6PbO.P_2O_5$, *lead trioxy-orthophosphate*, on the f.p. curve. D. Strömholm obtained this product by the action of $0·05N$-Na_2HPO_4 on freshly precipitated lead hydroxide. The oxy- and pentoxy-orthophosphates were also obtained by M. Amadori in his study of the f.p. curves of the system PbO–$Pb_3(PO_4)_2$, summarized in Fig. 132.

K. Busz found an emerald-green basic lead copper phosphate as a mineral occurring in tabular crystals in Tsumeb, Otavi, South Africa; and he called it **tsumebite;** immediately afterwards V. Rosicky described a similar mineral from Frejka, and called it *preslite*—after J. S. Presl. K. Busz described it as monoclinic, but V. Rosicky showed that it is rhombic with the axial ratios $a : b : c$ $=0·977 : 1 : 0·879$. Twinning is common. The sp. gr. is 6·09–6·13, and the hardness, 3·5. It is readily soluble in hydrochloric acid. K. Busz represented the composi-tion as a **copper lead oxyphosphate,** $5(Pb,Cu)O.P_2O_5.8H_2O$, with $Pb : Cu=2 : 1$; it may be $Pb_3\{(Cu,Pb)(OH)_2\}_2PO_4.6H_2O$, or an isomorphous mixture of $Pb_3\{Pb(OH)_2\}_2(PO_4)_2.6H_2O$ and $Cu_3\{Cu(OH)_2\}_2(PO_4)_2.6H_2O$.

J. Démeste, and J. B. L. Romé de l'Isle referred to a *plomb rouge en stalactites ou en globules;* G. de Laumont, to *sel acide phosphorique martial* and to *plombegomme.* A similar term was used by F. S. Beudant, and J. J. Berzelius. C. U. Shepard called it **plumbogummite;** A. Breithaupt, *Gummispath;* J. D. Dana, *plumbo-resinate;* and R. J. Häuy, *plomb hydroalumineux.* The mineral occurs at Huelgoet, Brittany; Nussière, Dept. Rhône; Roughten Gill, Cumberland; Mine la Motte, Missouri; and Canton Mine, Georgia. The mineral usually looks like drops of gum, or coatings of gum, and at times like chalcedony or allophane. Unlike pyromorphite or sphalerite the globules are not fibrous. The **hitchcockite** of C. U. Shepard is a related mineral occurring in botryoidal crusts, and thin coatings, sometimes concentric in structure. Analyses of plumbogummite by J. J. Berzelius made it a hydrated lead aluminate, but A. Damour showed that the phosphoric acid was probably precipitated with and reported with the alumina. J. Smithson also regarded it as a native lead aluminate. Analyses by A. Damour, and E. G. J. Hartley showed that it is probably a hydrated **lead aluminophosphate,** $2PbO.3Al_2O_3.2P_2O_5.7H_2O$; and, according to G. T. Prior, it is one member of the trigonal family of minerals:

						$a : c$
Hamlinite	.	.	$2SrO.3Al_2O_3.2P_2O_5.7H_2O$	.	.	.	1 : 1·1353
Svanbergite	.	.	$2SrO.3Al_2O_3.P_2O_5.2SO_3.6H_2O$	.	.	.	1 : 1·2063
Hinsdalite	.	.	$2PbO.3Al_2O_3.P_2O_5.2SO_3.6H_2O$	.	.	.	1 : 1·2667
Corkite	.	.	$2PbO.3Fe_2O_3.P_2O_5.2SO_3.6H_2O$	.	.	.	1 : 1·1842
Beudantite	.	.	$2PbO.3Fe_2O_3.As_2O_5.2SO_3.6H_2O$	.	.	.	1 : 1·1842
Florencite	.	.	$Ce_2O_3.3Al_2O_3.2P_2O_5.6H_2O$	.	.	.	1 : 1·1588

studied by G. Wyrouboff, A. Cossa, etc. Hitchcockite was analyzed by F. A. Genth, and E. G. J. Hartley. The latter represented it by $5PbO.9Al_2O_3.4P_2O_5.2CO_2.24H_2O$, or $2PbCO_3.Pb_3(PO_4)_2.6\{AlPO_4.2Al(OH)_3.H_2O\}$. According to E. Bertrand, the mineral is uniaxial, and belongs to the hexagonal system. The sp. gr. is 4·014–4·88. A. Breithaupt probably erred in giving 6·42. E. Hussak's *lead phosphate-fava*, from Diamantina, is a kind of plumbogummite with the composition $2(Pb,Ca)O. 2P_2O_5.3Al_2O_3.10H_2O$. The hardness is between 4 and 5. The mineral is soluble in

nitric acid. E. S. Larsen and W. T. Schaller described a mineral from Hinsdale Co., Colorado, which he called **hinsdalite**. Its idealized composition corresponds with $2PbO.3Al_2O_3.P_2O_5.2SO_3.6H_2O$. The crystals are colourless but for a greenish tinge. The cube-like rhombohedra or six-sided plates are trigonal with the axial ratio $a : c = 1 : 1\cdot12677$. The optical character is negative. The indices of refraction are $\alpha = 1\cdot670$, $\beta = 1\cdot671$, and $\gamma = 1\cdot689$. The crystals are zoned and exhibit optical anomalies, for a uniaxial centre may be surrounded by sectors with the optic axial angle $2E = 32°$. The hardness is 4·5, the sp. gr. 3·65. The **rosierésite** of A. Lacroix was found in greenish-yellow, yellow, or light brown stalactites, in an abandoned copper mine at Rosières, Tarn. An analysis by P. Berthier corresponds with that of a hydrated **lead copper aluminophosphate**. Its sp. gr. is 2·2 ; the refractive index about 1·5 ; and it is inactive to polarized light. It is soluble in nitric and hydrochloric acids.

L. T. Fairhall studied the ternary system, $PbO-P_2O_5-H_2O$, at 25°, and his results are summarized in Fig. 133. The area ACE represents a region where no solid phase is present. B represents lead hydrophosphate. The area ABC represents a solid phase in contact with various soln. The amount of lead oxide in soln. is a maximum at C, and this represents a univariant system where two solid phases are present : AC, lead hydrophosphate ; CE, lead dihydrophosphate.
FIG. 133.—Equilibrium Conditions in the Ternary System : $PbO-P_2O_5-H_2O$, at 25°.
FIG. 134.—Fusion Curves of Mixtures of Lead Oxide and Orthophosphate.

These two curves therefore represent the solubilities of the respective phosphates in soln. of phosphoric acid. For equilibrium, normal lead phosphate cannot exist in the presence of even a small amount of phosphoric acid. The product of the reaction between sodium hydrophosphate and a lead salt at room temp. is normal lead phosphate. This slowly forms lead hydrophosphate which is the equilibrium product. W. Heintz reported **lead hydrophosphate**, $PbHPO_4$, to be formed by adding an aq. soln. of phosphoric acid to a boiling soln. of lead nitrate. A modification of the process was used by H. Alders and A. Stähler. J. J. Berzelius mixed sodium hydrophosphate with a hot aq. soln. of lead chloride ; and E. Mitscherlich said that the former should be added drop by drop to the lead salt so that the latter may always be in excess, or else the normal orthophosphate will also be precipitated. W. Heintz, and C. F. Gerhardt said that the precipitate obtained when the lead chloride is used is always contaminated with chloride. A. de Schulten recommended warming on a water-bath, for 7 days, a soln. of 15 grms. of lead nitrate and 10 c.c. of nitric acid of sp. gr. 1·2 in 1¼ litres of water, mixed with a soln. of 16 grms. of sodium hydrophosphate in 2 litres of water. H. Alders and A. Stähler treated at room temp. sodium hydrophosphate with an excess of a feebly acid soln. of lead acetate. H. Debray obtained needle-like crystals of the salt by the action of water on lead pyrophosphate in a sealed tube at 250°. According to H. Alders and A. Stähler, the salt forms rhombic plates and prisms ; A. de Schulten said that the crystals belong to the monoclinic system, and have the axial ratios $a : b : c = 0\cdot7096 : 1 : 0\cdot8715$, and $\beta = 97°\ 40'$. The sp. gr. is 5·661 at 15°. When the salt is heated, it loses water, forming the pyrophosphate.

.W. Heintz said that the salt can be melted before the blow-pipe, and when fused on charcoal, H. Rose said that it is not reduced to the metal. J. N. von Fuchs said that the solidification of the fused salt is attended by vivid incandescence. V. Ipatieff found that hydrogen reduces it to phosphite, phosphorus and lead oxide. When mixed with carbon and heated to a high temp., lead is formed and phosphorus volatilized. P. H. Bayrac found it to be insoluble in water and in acetic acid. F. Weppen said that it is more soluble in a soln. of ammonium acetate at 18·8°-25° than it is in water. The salt is soluble in nitric acid, and in a soln. of potassium or sodium hydroxide. E. Becquerel said that it is less soluble in a sat. soln. of sodium chloride than lead sulphate; and R. H. Brett found that it is soluble in a cold soln. of ammonium chloride and is completely precipitated therefrom by an excess of ammonia. H. Alders and A. Stähler found that ammonia precipitates the normal phosphate from the nitric acid soln. of the hydrophosphate. J. Spiller found that the salt is soluble in a soln. of sodium citrate. H. Alders and A. Stähler said that lead hydrophosphate can be recrystallized from dil. phosphoric acid—below 15 per cent. soln. If the conc. of the phosphoric acid is over 70 per cent., the dihydrophosphate is formed. The solubility in phosphoric acid is:

H_3PO_4	1	5	10	20	50	65	70	75	85	90 per cent.
PbO .	73·19	73·49	73·14	73·23	72·18	72·16	58·51	55·71	55·87	55·97 ,,

The compound can be regarded as **lead deuterotetraphosphate,** being derived from orthotetraphosphoric acid, $H_{14}P_4O_{17}$, or $(HO)_4P.O.P(OH)_3.O.P(OH)_3O.P(OH)_4$, by the loss of two mols of water so as to furnish deuterotetraphosphoric acid, $H_{10}P_4O_{15}$, or

$$(HO)_3 \equiv P <^O_O> P(OH)_2.O.P(OH)_2 <^O_O> P \equiv (OH)_3$$
—*vide* the polyphosphoric acids. L. T. Fairhall and C. P. Shaw found that lead hydrophosphate is soluble in water to the extent of 0·0129 grm. per litre, at 25°; its solubility in lactic acid soln. is always less than that of the lead phosphate. The amount of lead adsorbed from lead chloride soln. by bony material increases with the time of contact and with the p_H value of the soln.; with decalcified bone and kelp-charcoal true adsorption takes place, but with crushed and with ignited bone, there is a displacement of calcium which is not eq. to the amount of lead adsorbed. The chloride ion is unaffected.

J. J. Berzelius prepared impure **lead dihydrophosphate,** $Pb(H_2PO_4)_2$, by dissolving lead orthophosphate or hydrophosphate in phosphoric acid, and evaporating for crystallization. Lead dissolves slowly in aq. phosphoric acid when exposed to air and the soln. furnishes this salt on crystallization. H. Alders and A. Stähler said that this salt is best obtained by heating either of the other phosphates with 90 per cent. phosphoric acid. The salt crystallizes from conc. phosphoric acid in slender needles which, after washing with ether, are stable in air. When heated to dull redness, water is given off and lead metaphosphate is formed. The salt is decomposed by water. It also passes into one of the other salts if in contact with dil. phosphoric acid, say, below 70 per cent. conc. The salt is soluble in soln. of potassium or sodium hydroxide; when digested with aq. ammonia, the normal salt is formed. It is readily soluble in dil. nitric acid, and it is decomposed by conc. nitric acid with the separation, according to E. Duvillier, of lead nitrate. H. Alders and A. Stähler said that ammonia precipitates the normal salt from a nitric acid soln. of the dihydrophosphate. The salt is converted into lead sulphide by hydrogen sulphide and alkali sulphides. Hot conc. hydrochloric acid dissolves it completely, and lead chlorophosphate is precipitated as the soln. cools. The salt is insoluble in 50 per cent. acetic acid.

· A. V. Kroll[2] reported what he called *lead anorthophosphate,* $5PbO.2P_2O_5$, intermediate between lead orthophosphate and pyrophosphate, $Pb_2P_2O_7.Pb_3(PO_4)_2$,

to be formed when lead oxide and phosphoric oxide are fused together. The region of stability is indicated in Fig. 132. J. J. Berzelius, and P. Berthier found that if lead hydrophosphate be calcined, **lead pyrophosphate**, $Pb_2P_2O_7$, is formed; and, according to F. Stromeyer, A. Schwarzenberg, F. W. Winckler, and C. N. Pahl, if a soln. of a lead salt be treated with normal sodium pyrophosphate, a precipitate is formed when lead dissolves in an excess of the reagent. The washed precipitate is dried by press., etc. C. F. Gerhardt added that the precipitate which is formed by mixing an alkali pyrophosphate with an excess of lead nitrate is lead pyrophosphate, but if the alkali pyrophosphate be in excess, the precipitate is redissolved on the application of heat, and it contains a variable proportion of alkali. J. Müller obtained the pyrophosphate by stirring insoluble sodium or potassium metaphosphate with a conc. soln. of lead nitrate for 5 days at 50°–60°. L. Ouvrard dissolved lead oxide in molten potassium or sodium metaphosphate at a bright red heat, and extracted the cold mass with boiling water. If the temp. of fusion is not high enough, a complex sodium phosphate is produced; alkali pyrophosphate under similar conditions gives an alkali lead phosphate. The rhombic prisms of this salt are isomorphous with the barium and strontium salts. The sp. gr. is 5·8 at 20°. H. V. Regnault found the sp. ht. to be 0·0821, and the mol. ht. 48·3. T. Carnelley gave 799°–815° for the m.p., but remarked that there is a change to the metaphosphate on heating. L. Ouvrard said that lead pyrophosphate is easily soluble in dil. acids; A. Schwarzenberg, soluble in nitric acid and potash-lye, insoluble in aq. ammonia, acetic acid, and sulphurous acid; F. Stromeyer, soluble in a soln. of sodium pyrophosphate, and a boiling soln. of sodium hydrophosphate decomposes it into lead phosphate and sodium pyrophosphate. When heated with water in a sealed tube at 280°–300°, A. Reynoso found that it decomposes into normal lead orthophosphate, and an acid salt which in turn decomposes into the normal phosphate and phosphoric acid. A. Naumann found lead pyrophosphate to be insoluble in acetone. J. A. Hedvall and J. Heuberger observed that lead pyrophosphate begins to react with barium oxide at 364°, with strontium oxide at 461°, and with calcium oxide at about 528°.

C. N. Pahl prepared **lead dihydroxytripyrophosphate**, $Pb(OH)_2.3Pb_2P_2O_7.H_2O$, by the addition of sodium pyrophosphate to a soln. of lead acetate, and drying at 100°. The salt is easily fused, and the cold mass is crystalline. N. Menschutkin prepared *lead acetylpyrophosphate*, $Pb_3\{(C_2H_3O)P_2O_7\}_2$. C. N. Pahl mixed soln. of sodium pyrophosphate with a mixed soln. of lead and ammonium nitrates, but did not obtain a definite *ammonium lead pyrophosphate*. He added lead nitrate to a soln. of sodium pyrophosphate and a potassium salt, and found microscopic needles of a complex **potassium lead heptapyrophosphate**, $K_6Pb_{11}(P_2O_7)_7.8H_2O$, were precipitated. The crystals were washed, pressed, and dried at 100°. The salt becomes anhydrous when ignited. When the salt is boiled with water, another salt is formed, namely, $K_2Pb_{13}(P_2O_7)_7.3H_2O$. This, when calcined, is dehydrated. A. Rosenheim obtained **potassium lead pyrophosphate**, $K_2[PbP_2O_7].5H_2O$. C. F. Gerhardt reported that if lead pyrophosphate be boiled with an excess of sodium pyrophosphate in aq. soln., the resulting **sodium lead pyrophosphate** has the composition $Na_2PbP_2O_7$. A. Rosenheim also obtained this salt. G. Tammann also obtained it in columnar crystals by melting an equimolar part of lead nitrate and ammonium sodium hydrophosphate. The salt is readily dissolved by hot hydrochloric and nitric acids. C. N. Pahl mixed soln. of sodium pyrophosphate and lead nitrate or acetate and allowed the mixture to stand for some hours. The washed precipitate, consisting of microscopic needles, was dried at 100°. Its composition corresponded with **sodium lead pentapyrophosphate**, $Na_6Pb_7(P_2O_7)_6.5H_2O$. When calcined, the salt becomes anhydrous. If boiled for some time with a soln. of ammonium nitrate, four-sided plates of the composition $Na_2Pb_{13}(P_2O_7)_7.2H_2O$, are formed, and this salt becomes anhydrous when calcined.

J. Persoz [3] said that when a soln. of lead nitrate is mixed with metaphosphoric acid, and then with ammonia, a precipitate is produced which is insoluble in an

excess of ammonia. A. Michaelis said that a **lead metaphosphate** is formed by the action of phosphorous chloride on lead oxide. F. Warschauer added that when lead oxide is dissolved in fused orthophosphoric acid below 400°, the tetrametaphosphate is formed, and above that temp., the hexametaphosphate. A. Glatzel said that **lead dimetaphosphate,** $Pb(PO_3)_2$, is not formed by strongly heating lead acetate and phosphoric acid, but T. Fleitmann prepared it by mixing a very dil. soln. of sodium dimetaphosphate with an excess of lead nitrate. The crystals are contaminated with a little lead nitrate. If ammonium dimetaphosphate is employed as precipitant, the precipitate is amorphous. The salt readily fuses without bubbling, and congeals to a transparent glass. T. Carnelley gave 800° for the m.p. of lead dimetaphosphate—a result which seems much too high. S. Motylewsky said that the drop-weight, at the m.p., is 256 units when that of water at 0° is 100. A. Glatzel found that dil. soln. of sodium dimetaphosphate gives a crystalline precipitate with lead acetate. The composition corresponds with the *hemitrihydrate*, $Pb(PO_3)_2.1\frac{1}{2}H_2O$. The salt is dehydrated at 150°, and melts at 350°, furnishing, when cooled slowly, the tetrametaphosphate. The salt is almost insoluble in water, and is readily decomposed by boiling sulphuric acid. A. Glatzel obtained only lead dimetaphosphate from a mixture of equimolar parts of lead dimetaphosphate and ammonium chloride ; but T. Fleitmann obtained crystals of **ammonium lead dimetaphosphate,** $(NH_4)_2Pb(PO_3)_4$, from a mixed soln. of lead and ammonium dimetaphosphates. There was no loss in weight at 150°, but at a higher temp., ammonia was given off. The salt is sparingly soluble in water ; and acids attack it with difficulty. A. Glatzel could not prepare *potassium lead dimetaphosphate* from mixed soln. of lead dimetaphosphate and potassium chloride.

T. Fleitmann and W. Henneberg made a conc. soln. of sodium trimetaphosphate with an eq. quantity of lead nitrate ; the filtered liquid, on standing, furnishes oblique prismatic crystals of **lead trimetaphosphate,** $Pb_3\{(PO_3)_3\}_2.3H_2O$. G. von Knorre, and C. G. Lindbom employed modifications of this process. T. Fleitmann and W. Henneberg found that the water is expelled with intumescence when the salt is heated ; and C. G. Lindbom added that at a higher temp. the salt fuses to a colourless glass which is insoluble in water, and freely soluble in nitric acid. Lead trimetaphosphate is the least soluble of all the trimetaphosphates. M. Stange reported a basic salt, **lead dioxytrimetaphosphate,** $2PbO.Pb_3\{(PO_3)_3\}_2$, obtained as a caseous precipitate when sodium triphosphate, $Na_5P_3O_{10}$, is added to an excess of lead nitrate or acetate. The precipitate is contaminated with soda, and rapidly changes into lead pyrophosphate.

T. Fleitmann prepared **lead tetrametaphosphate,** $Pb_2(PO_3)_4$, by fusing a mixture of lead oxide and orthophosphoric acid—according to F. Warschauer, the temp. should not exceed 400°. A. Glatzel, and F. Warschauer employed modifications of this process. The product consists of columnar or acicular crystals, which melt when heated and, on cooling, yield a glassy mass. The precipitate was stated by T. Fleitmann, and A. Glatzel to be insoluble in water, and by F. Warschauer to be *nachweisbar löslich*. When boiled with acids it decomposes more easily than the other tetrametaphosphates—*e.g.* those of barium, aluminium, and copper. Alkali hydrosulphides decompose it in the cold. The salt is decomposed by molten sodium chromate. A. Glatzel reported an *octohydrate* to be formed when a soln. of sodium tetrametaphosphate is treated with an excess of lead acetate. The white crystals become anhydrous when heated, and melt at a red heat. The cold mass is partly crystalline. The octohydrate is soluble in dil. acids, and is easily decomposed by hot, conc. sulphuric acid. A. V. Kroll prepared a basic salt, **lead oxytetrametaphosphate,** $PbO.Pb_2(PO_3)_4$, by passing the strongly heated vapour of phosphorus pentoxide mixed with a little oxygen, over lead contained in a combustion tube. The molten mass solidified to a mass partly crystals, partly glass. F. Schwarz added sodium triphosphate in slight excess to a soln. of lead nitrate, and heated the hydrated product in a platinum crucible. M. Stange could not prepare it by

this process.   H. Lüdert said that boiling water converts the crystalline salt into lead pyrophosphate.

F. Warschauer found that **lead hexametaphosphate,** $Pb_3(PO_3)_6$, is formed when a mixture of lead oxide and phosphoric acid is heated above 400° to a clear liquid, and gradually cooled.   The mass of radiating crystals so obtained is decomposed by a soln. of sodium sulphide.   H. Lüdert obtained a *hydrate* by mixing slowly, with constant stirring, a soln. of lead nitrate and sodium hexametaphosphate.   The flocculent mass was washed with cold water, and dried at 60°.   The white amorphous powder melts, forming a colourless glass.   It is almost insoluble in water ; soluble in acids ; and when treated with hydrogen sulphide, liberates metaphosphoric acid.

A. V. Kroll called the lead phosphates containing higher proportions of phosphoric oxide, **lead ultraphosphates**—*vide* polyphosphoric acids.   They can also be called *lead phosphatophosphates.* .When heated, they form glasses, whose f.p. cannot be investigated in the usual manner.   He therefore prepared threads of the glassy phosphate by dipping a platinum needle into the molten mixture and drawing it into threads.   Threads of constant sectional diameter were selected by drawing them through dies.   The threads were loaded with a definite weight, and heated until rupture occurred.   The curve showing the composition and temp. of rupture has distinct breaks corresponding with the two ultraphosphates—**lead hexaphosphate,** $PbO.3P_2O_5$, and **lead hemihexaphosphate,** $2PbO.3P_2O_5$.   The metaphosphate caused no discontinuity, while the phosphate $5PbO.3P_2O_5$ gave a distinct break ; and there is also a discontinuity on the curve corresponding with lead hexaphospate, $4PbO.3P_2O_5$.   The tendency to devitrify corresponded with the mechanical properties.   Devitrification occurred with these glasses at a temp. much below the m.p. A. V. Kroll therefore suggested that glasses are not undercooled liquids, but colloidal solids, *i.e.* a soln. of one amorphous solid in another, for which he proposed the term *cryosol.*

M. Stange[4] reported what is possibly *sodium lead triphosphate,* $Na_4Pb_5P_3O_{27}.10H_2O$, to be formed when a soln. of sodium triphosphate is poured into one of acid-free lead nitrate.

Mixed salts.—M. Amadori[5] examined the f.p. curves of mixtures of lead ortho-phosphate and fluoride, and the results are summarized in Fig. 135.   There is a

eutectic at 698° and 5 molar per cent. of phosphate ; and a maximum at 1098° and 75 molar per cent. of phosphate corresponding with **lead fluotriorthophosphate,** or *fluopyromorphite,* PbF_2. $3Pb_3(PO_4)_2$, a compound analogous with apatite. There is a eutectic at 1004° with 95 molar per cent. of lead phosphate.   There is a transformation point at 782° in lead orthophosphate, and one with fluotriorthophosphate at 696°, and probably also a third transition.   The α-forms of the ortho-phosphate and the fluophosphate are completely miscible ; and an extensive solubility in the solid state between the fluoride and the α-fluotri-orthophosphate.   There is probably also complete miscibility between β-orthophosphate and β-fluotri-orthophosphate, and the latter compound and the fluoride probably also form a series of mixed

FIG. 135.—Freezing-point Curve of Mixtures of Lead Ortho-phosphate and Fluoride.

crystals.   The γ-fluotriorthophosphate is probably not miscible, or miscible only to a very limited extent with β-orthophosphate, and is not miscible with the fluoride. F. Fischer and K. Thiele were unable to prepare either the fluophosphate, or the hydrofluophosphoric acid in the wet way.   J. G. Wallerius[6] described a *grön blyspat,* or *minera plumbi viridis,* and C. F. Schulze, a *Grünbleierz* which was shown by
M. H. Klaproth to contain phosphoric acid. J. F. L. Hausmann called it *polychrom*, and also **pyromorphite**—from πῦρ, fire; and μορφή, form—in allusion to the crystalline form a mòlten globule assumes on cooling. A. Breithaupt alluded to a calcareous form as *polysphærite*, and to a brown variety from Mies, Bohemia, as *miesite*. G. Barruel called an impure variety from Nussière, Beaujeu, *nussierite*; and C. U. Shepard, a milk-white or pink variety from Cherokee Co., Georgia, *cherokine*. Analyses by P. Berthier,[7] C. M. Kersten, G. Barruel, F. Sandberger, L. E. Rivot, E. Jannettaz and L. Michel, M. Amadori, A. Hilger, C. Hidegh, M. F. Heddle, N. Collie, J. Eyermann, T. Haege, F. Wöhler, C. F. Rammelsberg, C. Baerwald, etc., show that the composition of the idealized mineral is $PbCl_2.3Pb_3(PO_4)_2$. A. Werner represented it by the formula $[Pb\{(PbPO_3.O)_2Pb\}_3]Cl_2$. Many pyromorphites contain much lime, and it is thought that part of the lead chloride is replaceable by calcium chloride, or lead phosphate by calcium phosphate. C. W. C. Fuchs, A. F. Rogers, F. Sandberger, E. Jannettaz and L. Michel, H. Ungemach, G. Barruel, T. Petersen, O. Bowles, and F. Gonnard also showed that some calcareous pyromorphites can be regarded as mixtures of apatite and pyromorphite. The replacement of lead phosphate by lead arsenate or mimetite in arsenious pyromorphites has been considered by E. Bertrand, H. Struve, C. F. Rammelsberg, F. Wöhler, E. Jannettaz and L. Michel, F. Sandberger, T. Petersen, O. Bowles, G. Barruel, and H. Ungemach. The analyses by C. Baerwald were taken to represent mixtures of $(Pb,Ca)_3Al_2O_6$, $Pb_3(PO_4)_2$, and $(Pb,Zn)_3(VO_4)_2$ in the proportion $1:2:4\cdot2$. A. F. Rogers regarded a sample of pyromorphite as having the chlorine partly replaced by the carbonate radicle. According to J. Danne, the pyromorphite of Issy-l'Éveque contains radium in variable quantity; B. B. Boltwood found no uranium in pyromorphite. M. Bamberger and C. Weissenberger found $9\cdot66\times10^{-2}$ to $1\cdot30\times10^{-9}$ grm. of radium per gram of pyromorphite from Johanngeorgenstadt, and $8\cdot20\times10^{-5}$ to $9\cdot88\times10^{-5}$ grm. of thorium; they also found $3\cdot04\times10^{-13}$ to $8\cdot44\times10^{-13}$ grm. of radium and $1\cdot32\times10^{-5}$ to $4\cdot78\times10^{-5}$ grm. of thorium per gram of pyromorphite from Ems.

W. Heintz [8] obtained anhydrous lead chlorotriorthophosphate by heating **hydrated lead chlorotriorthophosphate,** $PbCl_2.3Pb_3(PO_4)_2.H_2O$, which he obtained by pouring an excess of sodium hydrophosphate soln. into a boiling soln. of lead chloride, boiling the mixture for some time, and washing with boiling water. When this compound is ignited, lead chloride and water are volatilized. The hydrate was said to be insoluble in water; and easily soluble in dil. nitric acid. Conc. pitric acid transforms it into sparingly soluble lead nitratophosphate. M. Amadori's observations on the f.p. of mixtures of lead chloride and lead orthophosphate are summarized in Fig. 136. Only one compound is formed, namely, lead chlorotriorthophosphate. The two eutectics are at 480° with 4·44 molar per cent. of phosphate, and 996° with 95·75 molar per cent. of phosphate. The anhydrous salt was prepared by N. S. Manross by fusing lead chloride and normal sodium phosphate; H. St. C. Deville and H. Caron fused a mixture of lead phosphate, lead chloride, and sodium chloride. L. Michel omitted the sodium chloride. E. Weinschenk heated a mixture of lead chloride,

FIG. 136.—Fusion Curves of Mixtures of Lead Chloride and Orthophosphate.

ammonium hydrophosphate, and an excess of ammonium chloride for several hours in a sealed tube at 150°–180°. L. Ouvrard melted a mixture of lead oxide, sodium pyrophosphate, and an excess of sodium chloride. J. H. Debray heated a mixture of lead chloride, lead pyrophosphate, and water in a sealed tube at 250°. A mixture of lead chloride soln. and calcium hydrophosphate furnished

a mixture of pyromorphite and apatite. The synthesis of pyromorphite was also discussed by G. Lechartier, A. Ditte, A. Daubrée, A. de Schulten, G. Forchhammer, F. Briegleb, F. K. Cameron and W. J. McCaughey, F. Zambonini, C. C. McDonnell and C. M. Smith, W. Eissner, and M. Amadori. F. Gonnard referred to the formation of pyromorphite in Pontgibaud by the action of a soln. of apatite in carbonetted water upon galena. G. Bischof, and E. Dittler pointed out the derivation of pyromorphite from galena with the intermediate formation of cerussite. J. J. Nöggerath found crystals of pyromorphite in furnace slags.

Pyromorphite occurs in prismatic crystals with the (10$\bar{1}$0)-face striated vertically ; in branching groups of acicular crystals, and in moss-like forms ; in barrel-shaped crystals ; in globular, reniform, botryoidal, or verruciform groups or masses of crystals with an angular surface ; in fibrous or granular masses ; and in earthy incrustations. The colour may be green, yellow, various shades of brown, greyish-white, and cream colour. O. Clerc[9] has reported blue and black pyromorphites. When pure, the salt is colourless. M. Bamberger and R. Grengg found a green pyromorphite was colourless at $-190°$. P. Groth showed that many green and yellow pyromorphites contain chromium either mechanically mixed, or in solid soln. N. Collie found no chromium in an orange-coloured sample he analyzed, and no ferrous iron in a green sample. According to R. Brauns, the crystals are hexagonal bipyramids with the axial ratio between $a : c = 1 : 0.72926$ and $1 : 0.73544$; W. Haidinger gave $1 : 0.7362$. R. Brauns emphasized the close analogy between the crystals of pyromorphite and those of apatite and mimetesite. Thus, the axial ratio $a : c$ are $1 : 0.7330$ for apatite, $1 : 0.72926$ for pyromorphite, 1.73544 for a calcareous pyromorphite, and $1 : 0.7282$ for mimetesite. M. Amadori and E. Viterbi obtained mixed crystals of pyromorphite with mimetesite, and vanadinite. G. Carobbi and S. Restaino found that cerium, lanthanum, didymium, and samarium can replace the lead isomorphously in pyromorphite. The crystals of pyromorphite were also studied by E. Tacconi, E. V. Shannon, R. J. Haüy A. Lévy, C. F. Naumann, W. H. Miller, G. Seligmann, V. Goldschmidt, J. D. Dana, G. Cesaro, V. Dürrfeld, A. Breithaupt, O. Bowles, A. Lacroix, J. Gerstendörfer. K. Zimanyi, G. Rose, J. Schabus, G. A. Kenngott, A. Karpinsky, G. R. Traverso, E. Weinschenck, L. Michel, J. H. Debray, N. S. Manross, H. Rose, J. Schabus, P. von Jeremejeff, and L. J. Spencer. The corrosion figures were found by H. Baumhauer to be conformable with the pyramidal hemihedrism of the crystals. The (10$\bar{1}$1) and (10$\bar{1}$0) cleavages are imperfect. The optical character is negative. The twinning was described by C. Klein, and V. Goldschmidt. W. Eissner found the change of the crystal angles with temp. between $-160°$ and $650°$ exhibits certain abrupt changes ; an example with the angle (1121) : ($\bar{1}2\bar{1}1$) is illustrated by Fig. 137.

This is taken to mean that pyromorphite is dimorphous, so that β-pyromorphite begins to change into α-pyromorphite as the temp. rises from $-160°$ to about $-140°$.

N. S. Manross[10] gave 7.008 for the specific gravity of artificial pyromorphite ; G. Rose, 7.054–7.208 for that of the mineral ; C. W. C. Fuchs, 7.36 ; H. Struve, 6.715, and for a sample mixed with mimetesite, 5.537 ; O. Bowles, 7.013 for a yellow sample with apatite, and 7.051 for a green one with apatite and mimetesite ; and T. Petersen, 6.461 also for a sample with both impurities. The hardness is 3.5–4. W. Eissner

FIG. 137.—The Effect of Temperature on the Crystal Angle of Pyromorphite.

found no transition point on the heating curve of natural or artificial pyromorphite. M. Amadori gave 1156° for the melting point of pyromorphite free from lead oxide ; and for the m.p. of mixtures of fluomorphite with 20 per cent. of chloropyromorphite, 1108° ; with 50 per cent., 1126° ; and with 80 per cent., 1144°. E. Jannettaz found for the ratio of the thermal conductivity in the direction of the base to that in the direction of the chief axis. H. L. Bowman gave for the

indices of refraction respectively for red-, yellow-, and blue-light, $\epsilon = 2\cdot042$, $2\cdot0494$, and $2\cdot0832$; and $\omega = 2\cdot0504$, $2\cdot0614$, and $2\cdot0964$. Hence the **birefringence** for yellow-light, $\omega - \epsilon = 0\cdot0120$. E. Jannettaz and L. Michel said that the crystals are uniaxial unless they consist of groups of small prisms. Observations were also made by M. Kirpatic. Samples from various localities were reported by J. Danne, P. Gaubert, E. Jannettaz, L. Francesconi and co-workers, M. Bamberger and G. Weissenberger, and E. Puxeddu and A. Marini to be **radioactive**. The luminescence of pyromorphite when exposed to the **X-rays**, or to the **cathode rays** has been studied by K. Keilhack, and C. Doelter. The latter also investigated the action of **radium rays**, and W. G. Hankel, the pyroelectricity of the crystals. W. Schmidt gave $26\cdot0$ for the **dielectric constant** perpendicular to the extraordinary ray, and 150, parallel thereto; and $47\cdot5$ for $\lambda = 75$ cms. A. Coehn and A. Lotz studied this subject.

G. Bischof [11] found that 1000 grms. of water sat. with carbon dioxide dissolve $0\cdot047$ grm. of pyromorphite; the mineral also freely dissolves in nitric acid, and the non-calcareous varieties also dissolve in alkali-lye. H. C. Bolton found citric acid feebly attacks pyromorphite when cold. J. Barlot and E. Chauvenet showed that pyromorphite is attacked by carbonyl chloride at $350°$; and at $500°$, the lead is all transformed into chloride. The mineral occurs in nature altered to galena, cerussite, calamine, calcite, and limonite. This subject was investigated by G. Bischof, J. R. Blum, and G. Sillem.

W. Heintz [12] reported **lead chlorodiorthophosphate**, $PbCl_2.2Pb_3(PO_4)_2$, to be formed by pouring into a soln. of lead chloride insufficient sodium hydrophosphate soln. for complete precipitation. The product was boiled with water. C. F. Gerhardt obtained crystals of **lead chlorobishydrophosphate**, $PbCl_2.2PbHPO_4$, by the process employed by W. Heintz. The crystals are slowly dehydrated at $100°$. L. Ouvrard mentioned the formation of a *sodium lead chlorophosphate* by melting a mixture of lead oxide and sodium pyrophosphate with an excess of sodium chloride. A. Ditte reported **lead bromotriorthophosphate**, $PbBr_2.3Pb_3(PO_4)_2$, or *bromopyromorphite*, by fusing a mixture of 12 parts of lead orthophosphate and 5 parts of lead bromide together with a great excess of sodium bromide. The yellowish-white crystalline powder consists of hexagonal prisms or plates, soluble in dil. nitric acid. A. Werner regarded it as being constituted like pyromorphite. A. Ditte also made small golden yellow prisms of **lead iodotriorthophosphate**, $PbI_2.3Pb_3(PO_4)_2$, by fusing a mixture of two parts of lead orthophosphate and one of lead iodide, together with a great excess of sodium iodide.

According to J. J. Berzelius,[13] when phosphoric acid is poured into an aq. soln. of lead nitrate, or a soln. of lead phosphate in nitric acid is evaporated, crystalline grains of **lead nitratobisdihydrophosphate**, $Pb(NO_3)_2.2Pb(H_2PO_4)_2$, are formed. F. Dujardin said that a soln. of lead phosphate in warm nitric acid deposits crystals of lead nitrate on cooling. The octahedral crystals are elongated into four-sided prisms. When the salt is heated, lead orthophosphate is formed. C. F. Gerhardt poured a soln. of sodium hydrophosphate into excess of a soln. of lead nitrate and obtained **lead nitratorthophosphate**, $Pb(NO_3)_2.Pb_3(PO_4)_2.2H_2O$, as a crystalline precipitate. The soln. in hot conc. nitric acid deposits monoclinic crystals on cooling. When calcined, a white basic phosphate remains. The salt is soluble in cold water, and is decomposed by boiling water into lead nitrate and orthophosphate.

The plumbic phosphates.—C. F. Schönbein [14] noted that when red-lead is shaken with conc. phosphoric acid, a strongly oxidizing liquid is obtained which in the cold loses oxygen slowly and rapidly if heated. B. Brauner said that when lead tetracetate is treated with a phosphate an unstable plumbic phosphate is precipitated. F. Fischer electrolyzed dil. phosphoric acid, sp. gr. $1\cdot02$, using a lead anode and a current density of $0\cdot05$ ampère per sq. dm. for 24 hrs., and obtained a golden-yellow or wine-red soln. from which acids or salt soln. precipitate a lemon-yellow or orange-yellow voluminous compound. The precipitate dissolves in

phosphoric acid; it is hydrolyzed by water, forming hydrated lead dioxide; with hydrogen dioxide, oxygen is evolved, and lead phosphate is formed. Aq. ammonia and alkali hydroxides when added to the phosphoric acid soln. give a precipitate which readily decomposes. With hydrochloric acid, chlorine is liberated; with potassium iodide, iodine is liberated and lead iodide is formed; and ferrous sulphate is converted into ferric sulphate with the precipitation of a plumbous salt. All this agrees with the assumption that a plumbic phosphate has been formed. K. Elbs and R. Nübling electrolyzed orthophosphoric acid of sp. gr. 1·75 at 10° with an anode compounded of two lead plates and a carbon plate, and a lead cathode surrounded by a porous pot. Half the current is arranged to pass through the lead part of the anode, and the other half through the carbon plate where the current densities are respectively 0·007 and 0·04 ampère per sq. cm. In the anode compartment a brown liquid is formed which deposits most of the lead as a mud. When the mud is drained on a porous plate and dried at 70°, its composition corresponds closely with **plumbic dihydrophosphate**, $Pb(H_2PO_4)_4$. This salt is fairly stable, and its properties agree with F. Fischer's preparation just indicated. It is suggested that the brown anode liquid contains *hydrophosphatoplumbic acid*. According to A. Hutchinson and W. Pollard, when a 50 per cent. aq. soln. of orthophosphoric acid is allowed to act on lead tetracetate, a pale yellow gelatinous mass is formed, which readily turns brown when treated with an excess of water, and evolves chlorine in contact with hydrochloric acid. Analyses show that an impure **plumbic bishydrophosphate**, $Pb(HPO_4)_2$, is formed. G. Saring reported **potassium calcium phosphatoplumbate**, $Ca_3(PO_4)_2(CaO)_2(K_2O)_2PbO_2$, analogous with the corresponding phosphatosilicate.

CHAPTER XLVIII

INERT GASES

§ 1. The History of the Inert Gases

THE **inert gases** represent a family of elements including (1) *helium*, (2) *neon*, (3) *argon*, (4) *krypton*, (5) *xenon*, (6) *thoron* or *thorium emanation*, (7) *niton* or *radon* or *radium emanation*, and (8) *actinon* or *actinium emanation*. The three last-named are not well known, and they are considered in connection with thorium, radium, and actinium respectively. The nomenclature has been discussed by W. Ramsay and J. N. Collie,[1] J. Perrin, C. Schmidt, N. R. Campbell, E. Q. Adams, J. A. Gray and W. Ramsay, S. Meyer, etc. F. O. Giesel obtained indications of yet another inert gas as an emanation from actinium.

While investigating the density of nitrogen, Lord Rayleigh [2] compared the values obtained with atm. nitrogen, and nitrogen derived from ammonia. The former weighed about one-thousandth part more than the gas of chemical origin. Actually, the mean value for the relative density of chemical nitrogen was found to be 2·2990 and that of atm. nitrogen, 2·3102.

It was shown that chemical nitrogen does not contain a gas specifically lighter than nitrogen; that chemical nitrogen is not partly dissociated into atomic nitrogen; and that atm. nitrogen does not contain mols. consisting of more than two atoms. There remained the possibility that atm. nitrogen contains an unknown gas specifically heavier than nitrogen. Lord Rayleigh and W. Ramsay tested this hypothesis, and found that when the nitrogen was removed by heating it in contact with magnesium, the one per cent. residuum contained a new gas which was named **argon**—from the Greek privative and ἔργον, work, in allusion to the chemical inertness of the gas. The first announcement of this discovery was made August 13, 1894.

Over a century previously, H. Cavendish seems to have obscurely anticipated this discovery, for he laboriously eliminated all the known constituents of atm. air, and obtained a remnant which could not be removed. This must have been impure argon. H. Cavendish asked if there are not many different substances in atm. air confounded together under the name phlogisticated air (nitrogen). He therefore passed electric sparks through a mixture of air and oxygen (dephlogisticated air) and absorbed the resulting nitrous acid with soap-lees. The illustration, Fig. 1, gives an idea of the apparatus employed. The experiment was continued until the addition of more oxygen and sparking gave no more products soluble in the soap-lees. H. Cavendish said:
FIG. 1.—H. Cavendish's Experiment.

> Having by these means condensed as much as I could of the phlogisticated air, I let up some soln. of liver of sulphur to absorb the dephlogisticated air; after which, only a small bubble of air remained unabsorbed, which certainly was not more than $\frac{1}{120}$th of the

889

bulk of the phlogisticated air let up into the tube ; so that if there is any part of the phlogisticated air of our atm. which differs from the rest, and cannot be reduced to nitrous acid, we may safely conclude that it is not more than $\frac{1}{110}$th part of the whole.

The spectrum of argon was first seen by H. F. Newall, for he observed seventeen unfamiliar bright lines which frequently flashed out when an electric discharge was passed through tubes containing highly rarefied air. W. Crookes showed that these lines had a place amongst the 200 lines which he mapped in the spectrum of argon.

W. Ramsay and M. W. Travers liquefied argon, and obtained a solid, whose spectrum, when gasified, was different from that of argon. They named this substance *metargon.* J. Dewar questioned the validity of this discovery ; and A. Schuster, and later W. Ramsay and M. W. Travers, showed that the spectrum was that of a mixture of argon with a hydrocarbon derived from the phosphorus used in the absorption of the oxygen from the air. Soon after the discovery of argon, J. Dewar,[3] and others discussed the possibility that argon is not a new element, but rather an allotropic modification of nitrogen—possibly N_3. This hypothesis, however, was soon definitely disproved.

On August 18, 1868, J. N. Lockyer [4] observed a bright orange-yellow ray in the spectrum of the sun's photosphere taken during an eclipse of the sun. At first, the yellow ray was confounded with the D-line of sodium. P. J. C. Janssen, and E. Frankland and J. N. Lockyer established the separate identity of this line, which, forming a trio with the two D-lines of sodium, came to be known as the D_3-line. At first, J. N. Lockyer regarded the substance emitting the D_3-line as a form of hydrogen, or as a product of the dissociation of hydrogen ; but A. Secchi, and later J. N. Lockyer, showed that the D_3-line is not produced by hydrogen, and the existence of a new element was postulated to which the name **helium** was applied —from $\eta\lambda\iota os$, the sun. In 1881, L. Palmieri recognized the D_3-line in the spectra of the gaseous ejecta of Vesuvius. After the discovery of argon, W. Ramsay and co-workers recalled an observation of W. F. Hillebrand that uraninite and cleveite evolved nitrogen when treated with sulphuric acid, or fused with alkali carbonate. In 1895, W. Ramsay extracted some of the supposed nitrogen, and W. Crookes found that the spectrum gave the vivid-yellow D_3-line as its distinctive feature ; A. Bélopolsky showed that the D_3-line is double ; and the observations of C. Runge and F. Paschen, W. Huggins, G. E. Hale, and H. Deslandres showed that the spectrum of terrestrial helium is the same as that furnished by the helium in the solar chromosphere. At first, C. Runge and F. Paschen found that the spectrum extending from the ultra-red to the ultra-violet furnished three rhythmically arranged series of doublets, and many more solitary lines ; true helium was supposed to give rise to the first doublet ; the second was attributed to an admixed gas which was provisionally called co-helium. J. N. Lockyer named the components helium and *asterium.* E. A. Hill believed that the spectrum of helium by W. Crookes indicated the existence of 15 new elements ! The divided ownership of the spectrum has not been confirmed. W. Ramsay and J. N. Collie, however, by atmolysis, were able to separate helium into two portions with the relative densities 1·874 and 2·133, and refractive index 0·1350 (air unity) and 0·1524 respectively. Both fractions gave identical spectra. It was therefore assumed that atmolysis had separated helium into light and heavy mols. of one elemental form of matter. W. Ramsay, and M. W. Travers obtained no evidence of the separation of helium into two different elements by atmolysis. The later experiments of C. Runge and F. Paschen, and of M. W. Travers, showed that the complexity of the spectrum is no proof that the element is heterogeneous, for oxygen can be made to give similar evidence of complexity. J. S. Ames and W. H. Humphrey also showed that the so-called light and heavy constituents of helium give the same spectra. Hence, helium is an elemental gas.

W. Ramsay and J. N. Collie tested the homogeneity of argon by atmolysis, and obtained fractions of sp. gr. 19·93 and 20·01 respectively. This difference was considered to be within the limits of experimental error. W. Ramsay and

M. W. Travers [5] fractionally distilled liquid argon, and obtained a first fraction consisting of a gas which they called **neon**—from νέος, new. It had a characteristic spectrum and a relative density 14·67 (O=16). They also obtained a gas with a characteristic spectrum, and relative density 22·51 (oxygen 16), which they called **krypton**—from κρυπτός, hidden; and yet another gas, **xenon**—from ξένος, the stranger—with a characteristic spectrum, and relative density 65 (oxygen 16).

J. J. Thomson, and R. B. Moore, could find no evidence of a gas *heavier than xenon* in atm. air; while W. Ramsay said that if such a gas be present, air must contain less than one vol. in 2,560,000,000 vols. of air. Later, J. J. Thomson reported constituents with mol. wts. 163 and 260, but F. W. Aston could not verify the existence of new elements to the extent of more than one vol. in 10^{15} or 2×10^{16} vols. of air. G. D. Liveing and J. Dewar, E. C. C. Baly, and R. Schmidt discussed the spectroscopic properties of the higher boiling constituents of air from this point of view; and F. W. Aston likewise examined these constituents by positive ray analysis. R. Nasini and co-workers, G. D. Liveing and J. Dewar, and J. E. Coates, reported unknown spectral lines in the lighter constituents of the atm., but H. E. Watson, and F. Bordas and F. Touplain found no spectroscopic or other evidence of the existence of a constituent *lighter than helium*. C. Borel and A. Jaquerod sought for any hitherto unrecognized gas in atm. air, by diffusion through quartz, but with negative results.

W. Ramsay found helium in liquid argon. Hence, crude argon obtained by removing the oxygen and nitrogen from atm. air contains five elements— helium, neon, argon, krypton, and xenon. There is approximately one vol. of helium in 1800 vols. of crude argon. Otherwise expressed, the crude argon has the percentage composition :

Helium.	Neon.	Argon.	Krypton.	Xenon.
0·055	0·16	99·785	0·0005	0·00006 per cent.

The following memoirs, etc., treat the subject in a general manner : Lord Rayleigh, *Proc. Roy. Inst.*, **14**. 524, 1895 ; *Collected Scientific Papers*, Cambridge, **4**. 188, 1903 ; J. N. Lockyer, *Nature*, **51**. 386, 1895 ; **52**. 8, 55, 214, 327, 1895 ; **53**. 319, 342, 1896 ; W. Ramsay, *The Gases of the Atmosphere*, London, 1905 ; *Ann. Chim. Phys.*, (7), **13**. 433, 1898 ; *Arch. Sciences Genève*, (4), **25**. 329, 1908 ; (4), **26**. 237, 1909 ; *Zeit. angew. § 2. The Occurrence of the Inert Gases

Air contains about one per cent. of **argon**. This small proportion, however, represents an enormous total. It follows, therefore, that about 800,000,000 lbs. of argon must be supported by each square mile of the surface of the globe. The total argon content of the earth's atm. is prodigious. The seas and oceans must also contain a proportionate share, since this gas is appreciably soluble in water. T. Schlösing[1] showed that atm. nitrogen contains an average of 1·182 per cent. of argon, and A. Kellas, 1·186 per cent. With the former value, it follows that air contains 0·934 per cent. of argon ; and taking a litre of nitrogen to weigh 1·2511 grms., and a litre of argon, 1·7809 grms., a litre of atm. nitrogen should weigh 1·2573 grms.—Lord Rayleigh found 1·2572 grms. H. Cavendish's estimate would agree with the presence of about 0·83 per cent. of argon in air ; Lord Rayleigh and W. Ramsay estimated between 0·986 and 1·11 per cent. C. Moureu estimated 1·29 by weight and 0·9323 by vol. in 100 parts of air. H. Moissan obtained 0·9492 per cent. of argon in air over the Atlantic Ocean, and for air of

Mer de Glace	0·9335 per cent.	London	0·9325 per cent.
Mt. Blanc	0·9339 ,,	Berlin	0·9323 ,,
Mt. Pelée	0·9366 ,,	St. Petersburg	0·9329 ,,
Paris	0·9337 ,,	Moscow	0·9323 ,,

T. Schlösing gave for air from the ground in a pine forest at a depth of 0·20 metre, 1·170 per cent. of argon; for air from the soil, 0·40 metre deep, 1·155–1·169 per cent.; and for air from the soil of a garden, 0·40 metre deep, 1·118 per cent. G. W. Morey found 2·8 per cent. of argon in commercial liquid air. Estimates of the composition of air in the higher regions of the atm. have been made by J. Hahn, G. D. Hinrichs, W. J. Humphreys, J. H. Jeans, and A. Wegener—*vide* air. Results by A. Wegener are given in Table I—*vide* atmospheric air.

A. Voller and B. Walter found the natural gas of Neuengamme contained 0·05 per cent. of argon. T. Schlösing, and C. Moureu and A. Lepape found 1–3 per cent. of argon in some mine gases in Alsace-Lorraine. R. Nasini and co-workers found argon in the gases and vapours from the boric acid soffioni, as well as in volcanic gases. R. J. Strutt, and H. Grossman proved the presence of argon in lavas and pumice-stone. H. Moissan detected 0·68–0·71 per cent. of argon in the gases from the fumaroles of Mt. Pelée, Guadeloupe, etc.

TABLE I.—ESTIMATED PERCENTAGE COMPOSITION OF THE ATMOSPHERE AT DIFFERENT ELEVATIONS.

Height (km.)	Pressure (mm. Hg)	H_2	He	N_2	O_2	A
0	760	0·0033	0·0005	78·1	20·9	0·937
20	41·7	0	0	85	15	0
40	1·92	1	0	88	10	—
60	0·106	12	1	77	6	—
80	0·0192	55	4	21	1	—
100	0·0128	67	4	1	0•	—
120	0·0106	65	3	0	—	—
140	0·0090	62	2	—	—	—
200	0·00581	50	1	—	—	—
300	0·00329	29	—	—	—	—
400	0·00220	15	—	—	—	—
500	0·00162	7	—	—	—	—

Lord Rayleigh and W. Ramsay found the ratio of argon to nitrogen in rainwater to be greater than it is in air. This is due to the greater solubility of the argon. L. Troost and L. Ouvrard, and J. Dewar found argon in river-water and sea-water. Lord Rayleigh and W. Ramsay found 1·36 per cent. of argon in the gases from the spring-water of Bath; and W. Ramsay obtained 0·964 per cent. of inert gases of which 0·7363 per cent. was argon. Numerous other observations on the occurrence of argon in the gases from various springs have been made by Lord Rayleigh, E. Czako and co-workers, A. Kellas and W. Ramsay, F. Heinrich and co-workers, F. Prytz and T. Thorkelsson, W. Ramsay and M. W. Travers, R. Nasini and co-workers, M. Bamberger and A. Landsiedl, C. Bouchard, H. Moissan, G. Massol, F. Pesendorfer, P. Ewers, F. Heinrich and G. Prell, C. Moureu and co-workers, B. Walter, F. Diaz de Rada, etc. (*vide* Table 1). C. Moureu found argon in the gases of 49 thermal springs—Alsace-Lorraine, Madagascar, Réunion, etc.—and in 39 cases the argon was accompanied by helium. P. P. Bedson and S. Shaw found it mixed with nitrogen effervescing from rock-salt springs near Middlesbrough, where it must have been immured for ages. This evidence shows that argon formed part of what has been called the " geological " atmosphere of antediluvian periods.

H. F. Newall, W. N. Hartley, and O. Neovius found argon lines in the spectrum of air; but not in the spectrum of the sun and stars; nor did W. Ramsay and M. W. Travers observe any signs of argon in the spectra of light from extraterrestrial sources. This does not necessarily mean that argon is absent from those regions. A mixture of argon with 3–4 per cent. of nitrogen gives only the nitrogen spectrum; the main bulk of gas in the tube is not revealed because the electric discharge

preferentially selects as its vehicle the insignificant quantity of nitrogen, and passes by the argon. W. Ramsay found argon in extraterrestrial minerals, in the meteoric iron which fell in Augusta County, Virginia ; but R. J. Strutt considers this statement doubtful.

W. Ramsay and M. W. Travers, R. Thomas, A. Eggert, and C. Runge and F. Paschen found small quantities of argon occluded with helium in some minerals— e.g. cleveite, malacone, etc. P. T. Cleve found no argon in cleveite ; R. J. Strutt found only helium in Norwegian malacone; while E. S. Kitchen and W. G. Winterson found that the gas from 100 grms. of malacone contained

	Carbon dioxide.	Hydrogen.	Nitrogen.	Argon.	Helium.
C.c. . .	33·24	0·57	0·34	2·82	0·94
Grm. . .	0·06530	0·00005	0·00042	0·00504	0·00017

C. F. Hogley found that the helium from malacone contained one per cent. argon. A. von Antropoff found argon in a Brazilian zirconiferous mineral ; R. E. Hodgkinson, in minerals of the euxenite and samarskite family; H. Moissan and H. Deslandres, and G. Tschernik, in some cerium minerals ; A. Gautier, in garnet ; R. J. Strutt, in quartz, basalt, phonolite, diorite, granite, and garnierite ; E. Hochheim, in bröggerite ; and J. Schniederjost, in monazite. In the opinion of R. J. Strutt, the argon associated with the helium occluded in these different minerals is not produced by an internal change, as suggested by B. B. Boltwood, but was extracted from the atm. by the mineral at the time of its formation.

A. Kellas and G. W. Macdonald could detect no trace of argon in the nitrogen obtained from peas, or from mice ; J. Zalesky, none in the colouring matter of blood ; but C. Regnard and T. Schlösing found 0·419 c.c. of argon per litre in the blood of a horse ; and T. Schlösing and J. Richard, 1·18 per cent. of the gas in the air-bladder of the whale (physalia) ; 1·85 per cent., in the air-bladder of the murœna helena ; and 1·94 per cent., in the air-bladder of the synapobranchus pinnatus. The argon in these cases is doubtless derived from the air. A. Kellas showed that the proportion of argon to nitrogen in atmospheric air is not altered by the respiration of animals even when the composition has been greatly altered. Argon, like free nitrogen, plays no important part in the animal economy, save as a diluent. G. Tolomei showed that the argon in the roots of legumes is only mechanically absorbed, and not chemically combined.

H. Kayser [2] first demonstrated the presence of helium in atmospheric air. He showed that the spectrum of crude argon contained some helium lines ; and S. Friedlander demonstrated that some of the lines at first attributed to argon were really due to helium. G. J. Stoney explained the air-less condition of the moon's atm. by assuming that solid globes possess an atm. in virtue of their gravity ; and the strength of the gravity determines the composition of the atm. Unless the velocity of the particles of a gaseous atm. be checked by gravitation, they would fly off into space to return no more. Neglecting the impeding effect of air, a particle shot from the surface of the earth at the rate of seven miles a second, would finally escape. The average velocity of a hydrogen mol. is about 70 miles a minute ; but the range of deviation on either side of this average is very wide. Hence, the critical rate seven miles a second would from time to time be attained by individual mols., which would then pass away from the earth into outer space. Similar remarks apply to helium mols. which have a velocity related to that of hydrogen as about seven to ten. The problem has been further discussed by E. Rogowsky, J. E. Jones, S. R. Cook, E. A. Milne, G. H. Bryan, and J. W. Evans. According to F. W. Aston, the rarity of the inert gases in the earth's atm., etc., is not solely due to the tendency of a gravitating planet to collect heavier molecules in certain circumstances and to lose lighter ones ; but it is also an effect of their chemical inertness. In the collisions of bodies resulting in the formation of a solar system, the atoms unconstrained by chemical combination would collide and rebound indefinitely, gravitating towards the larger masses—e.g. the sun. As pointed out by H. Jeffreys,

if the light elements can form stable compounds with other heavier elements, they will not so readily escape.

Lord Rayleigh found argon to be more soluble in water than helium, and therefore the dissolved gas has a higher ratio—argon : helium, than the original gas. W. Ramsay and co-workers, and E. C. C. Baly showed that the spectral lines obtained by H. Kayser, and S. Friedlander were probably due to krypton, not helium. Argon must have 25 per cent. of helium before the latter can be so detected by spectral analysis ; and, according to O. W. Richardson and R. C. Ditto, the green not the yellow line appears first. The presence of helium in atm. air was proved by E. C. C. Baly, F. Bordas and F. Touplain, J. N. Coates, W. Crookes, W. Ramsay and M. W. Travers, G. D. Liveing and J. Dewar, J. Dewar, S. Valentiner and R. Schmidt, L. T. de Bort, A. Piutti, H. and E. Erdmann, and H. E. Watson. W. Ramsay found one part of helium in 245,300 vols. of air, or 0·0004 per cent. by vol. ; and one part of helium in 1,800,000 parts of air, or 0·000056 per cent. by weight. C. Moureu estimated 0·00007 per cent. by wt., and 0·0005 per cent. by vol. G. Claude, and H. E. Watson also estimated that there is one vol. of helium per 185,000 vols. of air—vide Table I.

A. Voller and B. Walter[3] found about 0·01 to 0·02 per cent. of helium in the natural gas at Neuengamme ; and H. Sieveking and L. Lautenschläger, 0·025 per cent. The latter also reported 0·007 per cent. of helium in the natural gas at Siebenbürgen. C. Moureu and A. Lepape found less than 0·05 per cent. of helium in the gas at Liévin, Anzin, Lens, Mons, and Frankenholz ; and 0·0006 to 1·68 per cent. in mines, borings, and mineral springs in Alsace-Lorraine. H. P. Cady and D. F. McFarland found that the natural-gas bore at Dexter, Kansas, contained a trace up to 1·84 per cent. of helium. G. S. Rogers also found an average of 0·5 per cent. of helium in the natural gas in the zone extending from Texas through Oklahoma, South-East Kansas, South Illinois, up through Ohio into Pennsylvania and New York. The heliferous gas is also found in Indiana, Kentucky, and West Virginia, but the richest gas is found in Texas, Oklahoma, and Kansas. J. C. McLennan and co-workers reported on the helium content of the natural gas of Canada and New Zealand. The percentage of helium in the former case ranges from 0·017 to 0·052 ; and the latter case from 0·001 to 0·077. It is estimated that the natural gas at Calgary, Canada, with about 0·3 vol. per cent. of helium could furnish 10^6 c. ft. of that gas per annum. A. G. G. Leonard and A. M. Richardson found 0·074 per cent. in the gas from St. Edmundsbury's well in Lucan. Y. Kano and B. Yamaguti found helium in many natural gases of Japan; and J. E. G. Harris in natural gas from Hurghoda, Egypt. E. Erdmann found helium in the gas from the carnallite deposits of Leopoldshall ; E. Czako, in the gases from Kissarmas, Pechelbronn, Zeche Gneisenau, Wels, Neuengamme, and Elsass ; L. Palmieri, R. Nasini and co-workers, and R. J. Strutt detected helium occluded in the lava of Vesuvius ; and C. Porlezza and G. Norzi, and R. Nasini and co-workers in the boric acid soffioni of Larderello. W. Ramsay and M. W. Travers found no helium in the lava of Iceland. H. Grossmann detected helium in the pumice-stone of Mt. Pelée, while R. J. Strutt found pumice-stone free from helium.

Helium is present in air, and is soluble in water, hence, as might have been anticipated, J. Dewar[4] proved that helium is present in rain-, river-, and sea-water. Argon and helium occur together in the gases dissolved in many spring-waters. For example, H. Kayser, and E. Czako and co-workers, found helium in the waters of Wildbad, Schwarzwald ; and H. Sieveking and L. Lautenschläger found 0·71 per cent. of helium in the gases from the Wildbad spring ; 0·85 per cent. in the gas from Baden-Baden ; 0·38 per cent. in the gas from Elsass spring ; 0·009 per cent. in the spring-water of Baden-Baden. C. Bouchard, W. Ramsay, and] M. W. Travers found helium in the spring-water at Cauterets, Pyrenees ; Lord Rayleigh, and W. Ramsay, in the spring-water at Bath—0·0297 to 0·12 per cent. ; Lord Rayleigh, at Buxton ; F. Pesendorfer and A. Herrmann, Carlsbad ; P. Ewers, Gasteiner

Thermen; F. Henrich and G. Bugge, Wiesbaden; F. Prytz and T. Thorkelsson, Iceland; G. Massol, Uriage, Isère; C. Moureu, and C. Moureu and R. Biquerd, in the gases from the waters at Plombieres, Bains-les-Bains, Luxeuil, Maizières, Bourbon-Lancy, Aix, and Eaux-Bonnes, in amounts ranging from 0·097 to 5·34 per cent.; A. Gautier and C. Moureu, 1·6 per cent. in the waters at Lanternier, Nancy, and 0·0194 c.c. of helium per litre of the artesian water at Ostend; R. Nasini and co-workers, Uliveto; and C. Moureu and co-workers, in the springs at Santenay, Alsace-Lorraine, Madagascar, and Réunion. No relationship has been observed between the helium content and the radioactivity of spring-water.

Helium has been detected in a large number of minerals. The occluded gas can be obtained by heating the powdered mineral in a hard glass tube, A, Fig. 2, with or without conc. sulphuric acid, or sodium pyrosulphate. The tube is fitted as shown in the diagram, and exhausted by means of an air pump—say Toepler's mercury pump. The mineral is heated under reduced press., and the gases are collected in D, the receiver of the pump —vide infra. The gases on their way to the pump travel through a flask, B, containing sticks of solid potassium hydroxide to absorb water and sulphur compounds. The gas collected in the gas-holder D can then be analyzed, or freed from hydrogen and hydrocarbons by passage over hot copper oxide (or molten phosphorus); from oxygen by passage over hot copper; from carbon dioxide by soda-lime, or potassium hydroxide; from nitrogen by hot magnesium; and from moisture by phosphorus pentoxide. The residue can be

FIG. 2.—Removal of Occluded Gases from Minerals.

examined by the spectroscope for helium, etc. The helium occluded in monazite sand can be readily obtained by this process. The following minerals have been examined:

Æschynite, 0·0043–0·17 per cent.—W. Ramsay and M. W. Travers,[5] and R. J. Strutt; bröggerite, 0·18 per cent.—W. Ramsay and E. Gleditsch; carnotite, 0·0002 per cent.— R. J. Strutt, and E. Gleditsch (E. P. Adams found only argon); cerite, 0·0₅18–0·0₄23 per cent.—W. Ramsay and co-workers, and R. J. Strutt; cleveite, 0·014–0·146 per cent.— W. Ramsay, M. W. Travers, R. Thomas, P. Ewers, E. Gleditsch, A. Sieverts and E. Bergner; columbite, 0·023 per cent.—W. Ramsay; cuprouranite, 0·0018 per cent.—R. J. Strutt; cyrtolite, 0·02 per cent.—R. J. Strutt; euxenite, 0·013 per cent.—R. J. Strutt; fergusonite, 0·19–0·32 per cent.—W. Ramsay and M. W. Travers, and M. W. Travers; fluorspar, 0·00048 per cent.—J. Thomsen; gadolinite, 0·043 per cent.—R. J. Strutt; malacone—W. Ramsay and M. W. Travers, and E. S. Kitchen and W. G. Winterson; microlite, 0·0009 per cent.— R. J. Strutt; monazite, 0·014–0·043 per cent.—W. Ramsay and M. W. Travers, and R. J. Strutt; orangeite, 0·0019 per cent.—R. J. Strutt; pitchblende, 0·0002–0·0048 per cent. —W. Ramsay and co-workers, and R. J. Strutt; pyromorphite, 0·0004 per cent.— R. J. Strutt; samarskite, 0·005–0·027 per cent.—W. Ramsay and co-workers, R. J. Strutt, and V. Kohlschütter; sipilite, 0·011 per cent.—R. J. Strutt; thorianite, 0·15–0·19 per cent.—W. R. Dunstan and G. S. Blake, E. H. Büchner, and R. J. Strutt; zirconiferous mineral, 0·0016 per cent.—A. von Antropoff.

R. J. Strutt found helium in albite (A. Piutti), antimony-glance, apatite, argyrodite, astrakanite, autunite (W. Marckwald and A. S. Russell, and E. Gleditsch), barytes, basalt, beryl (R. J. Strutt, and A. Piutti), beryllonite, bornite, cadmium blende, calcite, carnallite, cassiterite, castor (A. Piutti), chromite, chrysoberyl, clausthalite, cœlestine, columbite, corundum, corundum, cryolite (A. J. Halland), cuprite, diorite, embolite, eudialite, galena, galliferous zinc blende, garnierite, granite, hæmatite, indiferous zinc blende, ilmenite, iodyrite, kainite, keilhauite, kieserite, krugite, kunzite (A. Piutti), langbeinite, lepidolite,

(A. Piutti), mellephanite, molybdænite, orthite, orthoclase, phenacite, phonolite, plumbocolumbite (W. Marckwald and A. S. Russell), polyhalite, quartz, rhodonite, rock-salt (R. J. Strutt, and S. Valentiner), rutherfordite (W. Marckwald and A. S. Russell), scheelite, schönite, smaltite, spodumene, sylvine, tachyhydrite, tin pyrites, topaz, tourmaline (A. Piutti), triphyllen, tuffa (C. Porlezza and G. Norzi), wolframite, zinc blende, zircon.

Helium was found by R. J. Strutt in cinnabar, pollux, and vanadinite ; by R. C. Wells, in brannerite ; A. A. C. Swinton found none in the diamond ; F. Soddy found the gas occluded in some, but not in all, gold nuggets ; he also found it to be present in all the samples of platinum he examined, but W. Ramsay and co-workers found none in two specimens of that metal. F. Bordas found helium in bismuth from Saxony but not in Cornish bismuth ; R. J. Strutt detected helium in silver (Broken Hill), iron (Greenland), iron meteorite (Virginia), bismuth (Australia), tellurium (Transylvania), and graphite (Cumberland). J. J. Thomson found that most substances give off helium when exposed to the cathode rays—e.g. lead, iron, nickel oxide ; zinc, copper, platinum and mica. The relation between the helium content, and the radium or uranium contents of minerals has been studied by A. S. Eve, W. Marckwald and A. S. Russell, H. N. McCoy, A. Piutti, E. Rutherford and B. B. Boltwood, A. S. Russell, R. J. Strutt, etc., and genetic relations have been established. B. B. Boltwood gave $Ra/U = 3.4 \times 10^{-7}$; F. Heimann and W. Marckwald, 3.328×10^{-7} ; and E. Gleditsch, and F. Soddy and R. Pirret, 3.15×10^{-7}. There are deviations which in some cases may be due to the leaching of the radium salts from the mineral by water. The ratio He/U_3O_8 has been examined by R. J. Strutt, and, expressing the results in c.c. of helium per gram of uranium oxide,

	Samarskite.	Hæmatite.	Galena.	Quartz.
Ratio He/U_3O_3 .	14	9	17	10

The low values of the ratio were explained by W. Marckwald and A. S. Russell as a result of the escape of the occluded helium ; but the high values for sylvine and carnallite were attributed by R. J. Strutt to the radioactivity of the contained potassium.

As indicated in connection with radium and thorium, the helium in minerals is produced by radioactive changes, and was not occluded at the time the mineral was formed. On the assumptions that a gram of radium produces 0.11 c.c. of helium per annum ; a gram of uranium oxide, U_3O_8, produces 9.13×10^{-8} c.c. of helium per annum ; and a gram of thorium oxide is eq. to 0.203 grm. of uranium oxide, attempts to estimate the geological age of some minerals have been made by R. J. Strutt, E. Rutherford and B. B. Boltwood, W. Ramsay and F. Soddy, H. N. McCoy, J. A. Gray, A. Piutti, F. Gleditsch, F. Soddy and R. Pirret, A. Holmes, F. Zambonini, and J. Joly. In illustration, R. J. Strutt gave :

	Sphærosiderite (Oligocene).	Hæmatite (Eocene).	Hæmatite (Carboniferous).	Sphene (Archaic).
Age . . .	84×10^5	31×10^6	150×10^6	710×10^6 years

E. Rutherford and B. B. Boltwood estimated 400×10^6 years for the age of fergusonite and thorianite. These periods are minimal values because of the unknown allowance for the leakage of helium, and R. J. Strutt showed that helium is not always present in larger quantity in geologically older minerals than in more recent minerals of equal radioactivity. W. A. Tilden expressed the view that the helium in these minerals is occluded, and not chemically combined ; and found that when the gas was removed from cleveite, some gas could be re-absorbed ; but W. Ramsay and co-workers, and V. Kohlschütter could not confirm this. A. Piutti, however, observed that some salts could absorb helium, and give it off again when heated. V. Kohlschütter and K. Vogdt suggested that the amount of occluded helium is related to the water-content of the mineral, but R. J. Strutt showed that this is not correct. W. Ramsay and M. W. Travers found that heat is developed during the

evolution of helium from heated fergusonite, etc.   This agreed with the assumption that the helium is united with the mineral as a helide, a view supported by J. Thomsen, and V. Kohlschütter.   M. W. Travers, however, showed that some minerals containing no helium suffer an exothermal change when heated, so that the helide argument is not valid.   The amount of helium given off by the mineral is very small, at temp. below 300°.   D. O. Wood found that with monazite the following percentage amounts of helium escaped at the temp. named :

	280°	350°	450°	720°	900°	1200°
Loss of helium	0·7	2·1	12·7	68·6	88·5	98·3 per cent.

and with thorianite :

	300°	500°	750°	1000°
Loss of helium	0·7	8·5	62·3	100 per cent.

F. Bordas obtained somewhat analogous results with thorianite ; and A. Sieverts and E. Bergner, with cleveite.   These results do not agree with the assumption that an endothermal helide is present in the mineral because the decomposition of such a compound at any temp. once begun, should continue to the end.   R. J. Moss suggested that the helium is contained in fine pores because he found about 1·17 per cent. of the total helium in pitchblende was given off during the grinding of the mineral.   M. W. Travers attributed this to the heat developed by friction during the grinding.   R. J. Strutt showed that helium is given off from powdered monazite and thorianite at a rate which far exceeds the rate of production of that gas by radioactive change.   Thus, with monazite the leakage in c.c. per day per gram amounted to

Time exposed	0·031	0·59	1·6	2·6	4·6	10·6	33·0
Leakage	0·261	0·0766	0·0171	0·0123	0·0097	0·00438	0·00114

This shows that the accumulation of the gas must be due to the conditions of existence of the minerals in nature which are much more favourable to the retention of the helium.   J. A. Gray found that with thorianite, the leakage of helium began when the grain-size is less than 0·01 mm. and more helium then escapes the smaller the grain-size ; when the particles were less than 0·003 mm., 28 per cent. of the helium was given off.

W. Ramsay [6] found 0·00123 per cent. by vol. or 0·00086 per cent. by wt. of **neon** to be present in atm. air : or one vol. of neon is present in 80,790 vols. of air, or one gram in 116,000 grms. of air.   C. Moureu estimated 0·0012 per cent. by wt., and 0·0018 per cent. by vol.   G. Claude gave 1·5 vols. in 100,000 vols. of air. H. E. Watson gave rather a higher value—one part by vol. of neon in 55,000 vols. of air ; G. Gehlhoff also reported on this subject.   W. Ramsay, W. Crookes, and G. D. Liveing and J. Dewar found neon in the gases from the springs at Bath ; C. Moureu and co-workers in the gases from the French thermal springs, Alsace-Lorraine, Madagascar, and Réunion ; and R. Nasini and co-workers, in the waters of Uliveto.   E. Erdmann found neon in the gases from the carnallite deposits of Leopoldshall.   The occurrence of neon in minerals is doubtful.   R. J. Strutt found traces of neon occluded in zircon, cyrtolite, syenite, and pumice from Lipari Island, but the amount was so small that it may have been derived from contamination with atm. air.   J. Schneiderjost denied H. Schultze's report that neon is present in the helium derived from monazite.   J. J. Thomson obtained neon as well as helium (q.v.) from many substances bombarded by the cathode rays.

W. Ramsay [7] found that one vol. of **krypton** is present in 20,000,000 vols. of air ; or one gram of krypton in 7,000,000 grms. of air.   C. Moureu estimated 0·0003 per cent. by wt., and 0·0001 per cent. by vol.; while E. Rabinowitsch gave 0·0001 per cent. by vol.   C. Moureu and co-workers found krypton in the ratio Kr/A=1·1 to 1·8 among the gases from 26 thermal springs ; and also in the gas from Vesuvius (vide Table I) ; while C. Moureu and co-workers found it in the gas from the thermal springs of Madagascar, and Réunion.   W. Ramsay detected krypton in the

helium obtained from cleveite ; and C. F. Hogley reported but 0·1 c.c. of krypton in 140 grms. of fergusonite. According to W. Ramsay, one vol. of **xenon** occurs in 170,000,000 vols. of air, or one gram of xenon in 40,000,000 grms. of air; C. Moureu estimated 0·00004 per cent. by wt., and 0·0001 per cent. by vol. ; and E. Rabino-witsch, 0·00001 per cent. per vol. C. Moureu and A. Lepape found xenon in the gases from 26 springs ; and also in the gas from Vesuvius (*vide* Table II); while C. Moureu and co-workers found it in gas from the thermal springs of Madagascar, and Réunion.

TABLE II.—OCCURRENCE OF ARGON, KRYPTON, AND XENON IN THE GASES FROM THERMAL SPRINGS, ETC.

Origin.	$A/N \times 10^2$	Kr/A	X/A
Aix-les-Bains	1·245	1·2	1·6
Bagnères-de Bigorre . . .	1·38	1·1	1·6
Bagnères-de-Luchon . . .	1·28–1·42	1·1–1·2	1·2–1·9
Bourbon-l'Archambault . .	0·92	1·5	1·6
Cauterets	1·29–1·40	1·2–1·3	1·2–2·2
La Bourboule	1·87	1·8	1·9
Longwy	1·39	1·2	1·6
Luxeuil	1·32–1·35	1·4	1·9
Nancy	1·35	1·5	1·9
Plombières	1·34–1·62	1·2–1·4	1·2–1·6
Saint Honoré	1·2	1·3	1·9
Vichy	1·66–3·37	1·4–1·5	1·2–2·5
Vesuvius	—	1·1	1·0

S. C. Lind [8] said that the inert gases cannot have been produced or retained in the earth's crust by chemical action. In the case of helium, its origin may be either primordial or due to radioactive decomposition. The gas will have been migrating slowly to the surface, be swept along at times by other gases, and be retained where a bed of shale, capped by clay, forms a favourable geological struc-ture. It is generally, but not always, found in hydrocarbon gases, but in some cases with nitrogen which may possibly have been produced by the action of α-particles on nitrogenous organic matter or nitrides ; it is almost universally associated with some nitrogen.

§ 3. The Preparation of the Rare Gases

Helium is formed, along with hydrogen and oxygen, from an aq. soln. of radium bromide—*vide* **4**. 26, 7. The relation between helium and the α-particles emitted in radioactive changes was discussed by E. Rutherford [1] and co-workers, P. Ewers, J. Dewar, E. Regener, etc. W. Ramsay and F. Soddy found that 50 mgrms. of radium bromide in 60 days produced about 30 c.c. of gas consisting of 19·5 c.c. of hydrogen, 10·1 c.c. of oxygen—the remainder was air. A trace of helium was present, and it was estimated that a gram of radium bromide gives 0·0022 mgrm. of helium per annum. The reaction has been also observed by J. Dewar and P. Curie, E. Rutherford, E. Rutherford and H. Geiger, H. Kauffmann, F. Himstedt and G. Meyer, R. Schenck, F. N. Indrikson, W. Crookes, A. Debierne, F. Giesel, and J. Danysz and W. Duane. W. Ramsay and F. Soddy, W. Ramsay and A. T. Cameron, E. Rutherford and B. B. Boltwood studied the formation of helium from radium emanation ; K. A. Hofmann and V. Wölfl, and E. Rutherford and B. B. Boltwood, from radium-D ; K. A. Hofmann and V. Wölfl, H. Greinacher, H. Greinacher and M. Kernbaum, F. Giesel, and E. Rutherford and B. B. Boltwood, from radium-F or polonium ; A. Debierne, and F. Giesel, from actinium salts ; F. Soddy, from uranium salts ; W. Ramsay and F. Soddy, from thorium salts ; and B. B. Boltwood, from ionium.

As previously indicated—**4**. 26, 14—W. Ramsay, J. N. Collie and H. S. Patterson, and I. Masson reported the conversion of hydrogen into neon by the action of the cathode rays ; but J. J. Thomson, R. J. Strutt, T. R. Merton, A. C. G. Egerton, and A. Piutti and E. Cardoso were unable to verify this. R. W. Riding and E. C. C. Baly found that by the bombardment of a hollow anticathode coated with the nitride of magnesium or of aluminium and placed in the focus of a concave cathode in a tube containing oxygen, the nitrogen atoms are disintegrated, helium, hydrogen, and neon being found as products. Previous failures are attributed to the strong occlusion of the rare gases in the electrode splash. By heating the powdered discharge tubes, after 60 hours' discharge, at 800° in vacuo, a considerable amount of helium was obtained. With a single induction coil giving a 6-inch spark, the rare gases were always obtained, only minor variations in their amounts being observed when the hammer break was replaced by a mercury break and when a condensed discharge was used. Negative results were obtained when a larger coil was used. R. C. Tolman discussed the thermodynamics of the transmutation of hydrogen into helium.

The extraction of helium from minerals.—Helium is conveniently obtained from a number of minerals—cleveite, monazite, thorianite, etc. W. J. Hillebrand obtained the gas by boiling the pulverized mineral with sulphuric acid. The yield is good, but the reaction is slow. The air should be removed from the apparatus by suction or by a stream of carbon dioxide. N. A. Langlet, and P. T. Cleve heated a mixture

of the mineral with potassium pyrosulphate in a current of carbon dioxide. In this process it is difficult to remove all the gas ; the mixture is liable to foam ; and the glass tube may crack. Fused alkali hydrosulphate, carbonate, or dichromate may be used. The gas is also extracted from the mineral by heating it in vacuo at a high temp. D. O. Wood, H. Wilde, F. Himstedt and G. Meyer, etc., used this process—*vide* Fig. 2. The extraction of helium was also described by A. Eggert, P. Ewers, E. Hochheim, N. A. Langlet, W. Ramsay, J. F. Schietloh, K. Schmitt, H. Schultze, J. Stark and co-workers, K. Peters, and R. Thomas. The purification of the crude gas has been previously described. The last purification can be effected by cooling the gas with liquid hydrogen as recommended by M. W. Travers and A. Jaquerod ; by treating the gas with red-hot calcium as recommended by F. Soddy ; with molten potassium, as recommended by G. Gehlhoff, and K. Mey ; with a mixture of magnesium and lime, as recommended by L. Maquenne; or by treatment with cocoanut charcoal at the temp. of liquid air, as recommended by J. Dewar. The last-named process removes all but neon and hydrogen from the helium. Hydrogen is easily removed, and neon does not usually accompany the helium extracted from minerals. W. Ramsay and M. W. Travers purified helium by fractional diffusion ; and A. Jaquerod and F. L. Perrot, by diffusion through a heated vessel of quartz glass.

The extraction of helium from natural gas.—J. Dewar extracted helium, contaminated with neon, from the gases emitted by the thermal springs of Bath. J. C. McLennan and co-workers, A. H. Graham, J. A. Rafferty and H. E. Thompson, R. L. Bottoms, G. A. Burrell, R. J. Lang, P. E. Haynes, M. A. Worobéeff, M. Bridel, P. Damm, F. G. Cottrell, J. W. Davis, W. S. Lesniansky, M. Gohlke, C. Porlezza, and R. B. Moore have studied the extraction of helium from natural gas with the idea of using it in place of hydrogen for dirigibles for war purposes since helium has 92 per cent. of the lifting power of hydrogen, and is not inflammable. The gas was first liquefied by a modified air-liquefying machine (1. 13, 26) and the helium recovered by fractionation of the liquid. The product finally purified with charcoal approaches 100 per cent. purity.

The extraction of helium from air.—W. Ramsay and M. W. Travers extracted helium from atm. air. When a large amount of liquid air is allowed to evaporate quietly, the residue, after the removal of oxygen and nitrogen, consists of argon mixed with a small proportion of krypton and xenon. Argon being the more volatile is separated by alternate liquefaction and evaporation ; and at the temp. of boiling liquid air, krypton has a marked volatility while xenon has an inappreciable vap. press. To obtain the neon and helium from liquid air, the gas— mainly nitrogen—escaping from the liquefier is condensed to a liquid and a current of air blown through. The first portion of the liquid to evaporate contains most of the neon and helium, along with nitrogen, oxygen, and argon. The oxygen and nitrogen are removed in the usual way, and the neon and helium separated from the argon by fractional distillation. Neon may be freed from helium by a few fractionations at the temp. of boiling hydrogen ; neon is liquefied or solidified at this temp., while the helium remains gaseous. J. Dewar took advantage of the selective adsorption of wood charcoal to separate rare gases from atm. air. All the gases excepting helium and neon are adsorbed by wood charcoal at the temp. of liquid air. E. Edwards and R. T. Elworthy, W. Heuse, T. S. Taylor, G. Gehlhoff, H. E. Watson, and A. von Antropoff used this process. In place of charcoal, G. P. Baxter and H. W. Starkweather used chabazite which had been dehydrated at 550°. M. W. Travers removed argon from helium by taking advantage of the fact that the former is alone adsorbed by platinum.

The extraction of neon from air.—As just indicated, W. Ramsay and M. W. Travers obtained neon by allowing liquid air to evaporate quietly. G. Claude devised an apparatus for producing considerable quantities of the lighter constituents of atm. air. W. Ramsay and M. W. Travers separated the neon from helium by fractionation from the mixture cooled by liquid-hydrogen. H. E. Watson found that the

diffusion of helium through a quartz glass tube at 1200° gave a poor separation. Since, as indicated above, all gases other than helium, neon, and hydrogen were found to have no appreciable vap. press. when in contact with charcoal at the temp. of liquid air, it is easy to separate these three gases from all other gases provided sufficient time for diffusion and absorption is allowed. If the dead space in the charcoal vessel is small, one hour is sufficient. H. E. Watson found that the helium and neon can be separated by a fractionation of the mixture from charcoal at liquid air temp. The preparation of neon has been also described by J. Dewar, S. Valentiner and R. Schmidt, A. von Antropoff, H. E. Watson, J. E. Coates, G. Claude, P. Siedler, R. Mewes, G. P. Jaubert, F. Pollitzer, F. Schröter, and C. A. Crommelin. C. A. Crommelin purified neon by solidification with liquid hydrogen, evaporating so as to collect the first portion, and repeated the treatment. The oxygen was separated by leading the neon at a low press. through a worm-condenser cooled to −253°.

The extraction of argon from air.—The separation of argon rests on the chemical indifference of the gas. The oxygen, nitrogen, and other constituents are removed by absorption; the product contains helium and neon which are more volatile than argon, and krypton and xenon which are less volatile. Hence, W. Ramsay and M. W. Travers [2] were able to separate argon from its companions by the fractional evaporation of liquid air. G. R. Fonda and co-workers studied the concentration of argon by the liquefaction of air, and found that if 5 per cent. of a given vol. of air is liquefied, the liquid will contain 40 per cent. of oxygen and 2·35 per cent. of argon ; and at the other end of the series, an 80 per cent. liquefaction gives a gas with 1·6 per cent. of argon. Hence, the most favourable condition for obtaining argon from air lies in condensing only a small fraction of the air. The purification of crude argon has been also discussed by Lord Rayleigh, A. Ladenburg and C. Krügel, W. P. Jorissen, G. D. Liveing and J. Dewar, J. F. Schierloh, J. Dewar, S. Valentiner and R. Schmidt, E. Barbet, R. Mewes, G. Claude, F. Pollitzer, J. Stark, G. W. Money, O. Ruff and F. Förster, C. A. Crommelin, F. Soddy, G. Gehlhoff, L. Holborn and H. Schultze, F. Fischer and G. Iliovici, H. Dember, P. Mey, F. Fischer and V. Froboese, etc., from different points of view. B. Brauner suggested separating argon from air by atmolysis, but this is impracticable. In one process for isolating crude argon, the nitrogen is removed by sparking the air mixed with an excess of oxygen in the presence of alkali-lye which absorbs the nitrogen oxides which are formed. The best conditions for this were studied by A. Becker, F. Henrich, W. Crookes, H. Schultze, Lord Rayleigh and W. Ramsay. The oxygen was then removed by passing the product over heated copper. In another process, the carbon dioxide is removed by alkali-lye ; the oxygen and hydrogen by hot copper ; and the nitrogen by hot magnesium. H. N. Warren, and A. Guntz used heated lithium for absorbing the nitrogen ; C. Limb, a mixture of sodium and barium fluorides ; L. Maquenne, W. Hempel, H. Sieveking and L. Lautenschläger, and H. Moissan and A. Rigaut, a mixture of magnesium and lime ; H. Moissan, A. Guntz and H. Bassett, F. Soddy, C. A. Crommelin, R. Brandt, O. Ruff, and F. Fischer and O. Hähnel, calcium. H. Moissan and A. Rigaut, F. Soddy, and G. Gehlhoff, potassium. J. Stark heated mercury ; A. Rossel, calcium carbide and magnesium (or aluminium, zinc, iron, or copper) ; and G. Vater, and F. Fischer and O. Ringe, calcium carbide. The magnesium-lime and the calcium carbide processes are considered to be the best. O. Ruff and H. Hartmann said that calcium alloys with 5 per cent. of nitride furnish argon from atm. nitrogen in a few minutes. J. Stark found that commercial oxygen in cylinders contained 6 per cent. of nitrogen and 4 per cent. of argon ; and when the gas was passed through heated tubes filled with mercury, the oxygen and nitrogen combine with mercury, leaving the argon alone. M. Bodenstein and L. Wachenheim found that commercial oxygen prepared from air contained as much as 3 per cent. of argon, and recommended that as the source of argon. K. Prytz, F. Fischer and O. Ringe, A. Becker, and C. A. Crommelin discussed the efficiency of the different

modes of isolating argon. The Osram G.m.B.H. described the preparation of argon from mixtures of nitrogenous gases.

The extraction of krypton from air.—The mixture remaining after the separation of most of the argon and the lighter constituents of liquefied crude argon contains some argon, krypton, and xenon. By repeatedly condensing and slowly evaporating the product, the argon can be removed. The mixture of krypton and xenon at the temp. of liquid air loses most of the krypton. By repeated liquefaction and slow evaporation it is possible to separate the xenon and krypton. This method was employed by W. Ramsay and M. W. Travers, R. B. Moore, A. Ladenburg and C. Krügel, and the Soc. Anon. d'Eclairage. The selective adsorption by charcoal —*vide supra*—was employed by J. Dewar, and S. Valentiner and R. Schmidt.

The extraction of zenon from air.—It is easier to prepare pure xenon than pure krypton since xenon is more readily freed from argon than is the case with krypton. The isolation of xenon by the processes outlined above was effected by W. Ramsay and M. W. Travers, A. Ladenburg and C. Krügel, R. B. Moore, and the Soc. Anon. d'Eclairage.

§ 4. The Physical Properties of the Inert Gases

The five gases—helium, neon, argon, krypton, and xenon—are colourless, and without odour. They are chemically indifferent and are hence called the *inert gases* or the *rare gases*, or the *noble gases* of the atm. For the **vapour density** of

helium W. Ramsay, J. N. Collie, and M. W. Travers,[1] found 2·152–2·187 for helium from bröggerite when that of oxygen is 16 ; and 2·205 for helium from cleveite ; and W. Ramsay gave 2·181 for helium from bröggerite ; 2·121–2·122 for helium from samarskite ; and 2·134–2·147 for helium from fergusonite. W. Ramsay and J. N. Collie, and A. Hagenbach separated helium of density, say 2·315, into fractions with the densities 2·032 and 2·576 respectively. The gas was probably contaminated with some argon and krypton. N. A. Langlet gave 2·00 for the density of the gas from cleveite, but M. W. Travers suggested that the gas was probably contaminated with hydrogen since raw helium obtained from that mineral has a higher density. W. Ramsay and M. W. Travers gave 1·98 as the best representative value for purified helium ; K. Olschewsky gave 1·995 ; A. Lonius, 1·979 ; H. K. Onnes, 1·99–2·04 ; J. F. Schierloh, 1·9815 ; R. Schmidt, and W. Schwarze, 2·083 ; K. Schmitt, 1·979 ; H. Schultze, 2·084 : P. Tänzler, 1·979 ; and H. E. Watson, 1·995. T. S. Taylor gave 1·17850 (oxygen 1·4290). A. Leduc also measured the density of neon. H. E. Watson gave for the weight of a normal litre of helium from thorianite, 0·1782 grm., hence, helium at 0° and 760 mm., weighs 0·0001782 grm. per c.c.; W. Heuse found 0·0001756 ± 0·00008 grm.; and G. P. Baxter and H. W. Starkweather, 0·00017846. The best representative values are :

	He	Ne	A	Kr	X	Nt
D_{gas}	0·0001782	0·0009002	0·0017826	0·003709	0·005842	0·00995

F. W. Aston found the vap. density of purified neon to be 10·096 when that of oxygen is 16. W. Ramsay and M. W. Travers, and G. Rudorf gave for neon at 792·05° K. and 306·5 mm., 0·01100 grm. per 32·697 c.c. ; or, at 292·2° K. and 313·8 mm., 0·01120 grm. per 32·697 c.c. This makes 0·890 grm. for the weight of a normal litre. H. E. Watson obtained 0·9002 grm. for neon of a high degree of purity. Hence, neon, at 0° and 760 mm., weighs 0·0009002 grm. per c.c. The first vap. density determinations of Lord Rayleigh, and W. Ramsay for argon gave 19·086 when that of oxygen is 16 ; later determinations gave 19·88–19·94. F. Fischer and co-workers gave 19·945 ; O. Mehliss, 19·96 ; O. Niemeyer, 19·94 ; R. Schmidt. 19·948 ; H. Schultze, 19·91 ; W. Schwarze, 19·948 ; and P. Tänzler, 19·946. A. Leduc also measured the density of argon. W. Ramsay found that while the vap. density of crude argon is 19·94, that of purified argon is 19·953 ; W. Ramsay and M. W. Travers gave 19·957 for purified argon ; A. Lonius, 19·969 ; and J. F. Schierloh, 19·964. The last value corresponds closely with the assumption that crude argon contains 99·785 per cent. of argon, 0·16 per cent. of neon, and 0·055 per cent. of helium. These values agree with 0·17809 grm. per litre of raw argon, and 0·17826 for purified argon. Hence, at 0° and 760 mm., raw argon weighs 0·00017809 grm. per c.c., and purified argon 0·0001786 grm. per c.c. W. Ramsay and M. W. Travers gave 0·003648 grm. per c.c. for the weight of krypton at 0° and 760 mm.; and R. B. Moore, 0·0037085 grm. Hence, a normal litre of krypton weighs 3·709 grms. W. Ramsay and M. W. Travers found that one c.c. of xenon at 0° and 760 mm. weighs 0·00567 grm.; and R. B. Moore, 0·005842 grm. Hence, a normal litre of xenon weighs 5·842 grms.

H. K. Onnes found the **specific gravity** of liquid helium to be 0·1452 at −271·53° ; 0·1459 at −270·60° ; 0·1393 at −269·74° ; 0·1275 at −269·02°; 0·1208 at −268·67°. J. Dewar gave 0·17 at −258°. H. K. Onnes, and E. Mathias and co-workers found the sp. gr. of liquid and vapour follow the law of rectilinear diameters such that $\frac{1}{2}(D_l + D_g) = 0·0831 - 0·00342T$. E. Mathias and co-workers found the sp. gr. of neon to be 1·23824 and 0·00534 respectively for liquid and sat. vapour, at 25·170 K.; at 33·09° K., 1·08832 and 0·03831; and at 43·02° K., 0·74866 and 0·23935. It is concluded that neon obeys the law of rectilinear diameters having for the equation of the line $y = -1·154406 - 0·00716146\theta$, at $\theta°$. K. Olschewsky gave 1·5 for the sp. gr. of liquid argon ; and W. Ramsay and M. W. Travers, 1·212 at −185°. E. C. C. Baly and F. G. Donnan gave for the **atomic volume,** 28·4 ; and they also

found 1·4233 for the sp. gr. at $-189°$; 1·4169 at $-188°$; 1·4104 at $-187°$; 1·4039 at $-186°$; 1·3975 at $-185°$; 1·3910 at $-184°$; 1·3845 at $-183°$; or at $T°$ K., sp. gr.$=1·42333-0·006467(T-84)$. E. Mathias and co-workers found that neon obeys the law of rectilinear diameters between its critical temp., $-228·71°$, and its normal b.p., $-245·92°$. The coeff. of the diameter is $-0·00716146$. C. A. Crommelin gave 1·0268 for the sp. gr. of liquid argon at $-140·80°$; 0·9339 at $-134·72°$; 0·8581 at $-129·83°$; and 0·7557 at $-125·49°$. E. H. Mathias and co-workers found

	$-183°15'$	$-175°39'$	$-161°23'$	$-150°76'$	$-140°20'$	$-135°51'$	$-131°54'$	$-125°17°$
Sp. gr. .	1·37396	1·32482	1·22414	1·13851	1·03456	0·97385	0·91499	0·77289

which are higher than those obtained by C. A. Crommelin. The law of rectilinear diameters for liquid and vapour is $\frac{1}{2}(D_v+D_l) \doteq 0·70956-0·0026235\theta$. H. K. Onnes and C. A. Crommelin, H. K. Onnes and J. D. A. Boks, C. A. Crommelin, E. H. Mathias, W. A. Goldhammer, J. J. van Laar, U. Karpen, and H. von Jüptner made observations on this subject. C. A. Crommelin found that at the m.p., solid argon is specifically heavier than the liquid. J. de Smedt and W. H. Keesom gave 1·68 for the sp. gr. of solid argon at $-250°$; and F. Simon and C. von Simson, 1·62. The best representative values for the sp. gr. of the liquid, D_l, and the at. vols. are :

	He	Ne	A	Kr	X	Nt
D_c . . .	0·1215	—	1·4039	c. 2·4	3·063	c. 5·53
At. vol. . .	32·9	—	28·4	34·6	42·6	40·4

H. Happel calculated values for the **specific volume** from the latent heat of vaporization, λ, when $\lambda=RT+a/v_l$, where a is constant, and $\lambda=RT^2(dp/d\theta)/p$, and obtained for the sp. vol., v_l, of the liquid, 0·707—in agreement with E. C. C. Baly and F. G. Donnan's value. H. Happel calculated values for the $dp/d\theta$ from $T=74·988 +1·645p+0·0213p^2-0·0034p^3$; and G. Rudorf used J. H. van der Waals' vap. press. equation $\log p_c-\log p=f(T_c/T-1)$, and obtained at $-189°$, 0·6829, and at $-183°$, 0·6890 when the observed values were respectively 0·7026 and 0·7223; he also calculated values from A. Keindorff's equation $\log (p+19)=6·9788-f(T-)8^{-1}$, where $\log f=2·5901$. C. A. Crommelin also calculated values from W. H. Keesom's equation $D_1=D\{1+0·9758(1-T/T_c)+1·999(1-T/T_c)^{0·3795}\}$.

W. Ramsay and M. W. Travers found the sp. gr. of liquid krypton to be 2·155 at $-127°$; and G. Rudorf calculated 2·155 at the b.p. $-121·33°$ from E. H. Mathias' equation $D_c=\frac{1}{2}(D_g-D_l)/(2-T/T_c)$. At the b.p., R. W. Gray obtained 2·47, and for the at. vol. 33·6. For liquid xenon at $-102°$, W. Ramsay and M. W. Travers obtained sp. gr. 3·52; G. Rudorf calculated 2·68; and H. S. Patterson and co-workers found

	$-66°8'$	$-42°9'$	$-20°25'$	$-5°$	$0°$	$5°$	$10°$	$16°$
D_l . .	2·763	2·605	2·297	2·074	1·987	1·879	1·750	1·468
D_g . .	0·059	0·103	0·235	0·363	0·421	0·501	0·602	0·844

The mean densities lie very closely on the straight line $\frac{1}{2}(D_l+D_g)=1·205-0·003055\theta$, in accord with the law of rectilinear diameters. J. J. van Laar studied this subject. The sp. gr. of the liquid at its b.p., $-106·9°$, is 3·063, and the at. vol. 42·7. The ratios of the sp. gr. of liquid and gas are :

	He	Ne	A	Kr	X	Nt
D_l/D_g . .	682·3	—	787·7	c. 646	524·3	c. 555

C. del Fresno studied the at. vol. of the inert gases. H. K. Onnes measured the **vapour pressure**, p mm., of liquid helium :

	$-268°71'$	$-269°03'$	$-269°74'$	$-270°66'$	$-271°53'$
p . .	760	565	197	51	3
f . .	1·581	1·499	1·339	1·227	1·073

and when the results are applied to J. H. van der Waals' vap. press. equation

log p_c log $p=f(T_c/T-1)$, for $T_c=5.25°$ K., and $p_c=1718$ mm., the values of f are not constant. W. Ramsay and M. W. Travers found the vap. press. of liquid argon to be:

	$-195.7°$	$-190°$	$-187.5°$	$-185.2°$	$-150.9°$	$-136.2°$	$-117.4°$
p . . .	215.0	485.8	633.4	821.6	10313	20700	40200

K. Olschewsky obtained rather lower values. W. Ramsay and S. Young compared the results with those for benzene, ethyl alcohol, and oxygen. H. Happel applied the above data to J. H. van der Waals' vap. press. formula; and to A. Keindorff's equation log $(p+19)=6.9787958-f(8+T)^{-1}$, where log $f=2.5901094$. H. von Jüptner, V. Dolezalek, J. J. van Laar, and H. K. Onnes and C. A. Crommelin also studied the observed data. C. A. Crommelin and co-workers measured the isotherms for neon between $20°$ and $-217°$. F. Born gave for the vap. press. of argon:

	Solid.				Liquid.		
$T°$ K. .	65.49	70.49	79.06	83.93	87.31	87.88	90.35
p. .	21.97	59.26	255.6	512.17	746.1	792.3	1026.0

and he represented the values for the solid by log $p=-366.87T^{-1}+1.75$ log T $-0.0028293T+1.0698$ between $65°$ K and $83.93°$ K.; and for the liquid, by log $p=-339.3T^{-1}+1.75$ log $T-0.006737T+1.0698$, between $83.93°$ K. and $91°$ K. P. G. Cath and H. K. Onnes obtained for liquid neon, log $p=-65.061T^{-1}+0.01118T$ $+2.8191$ (p in atm.); and E. Mathias and co-workers gave for neon log p $=-84.3796T^{-1}+2.81911+0.1118T$. A. C. Egerton discussed this subject.

W. Nernst gave 0.6 for the **chemical constant** of helium, and F. Pollitzer, 0.64; F. Born gave 0.79 ± 0.04 for that of argon. F. Simon, E. Brody, O. Stern, and M. Planck calculated the chemical constants of the inert gases. O. Sackur represented the chemical constants, C, by $C=-1.617+1.5$ log M, and also $C=-2.051+1.5$ log M, where M is the mol. wt.; A. Eucken gave $C=-1.587$ $+1.5$ log M; and F. Pollitzer, $C=1.33$ log $T_b-0.00098T_b$, where T_b denotes the b.p. on the absolute scale of temp.

E. Mathias and co-workers found the vap. press. of neon can be represented by log $p=2.81911-84.3796T^{-1}+0.1118T$. J. K. H. Inglis studied the isothermal distillation of mixtures of argon and oxygen at $82.09°$, and found the results indicated in Table III. The vap. press. of solid argon at 82.09 is 411 mm. C. A. Crommelin found the vap. press. of liquid argon could be represented by log $p=4.85033$

TABLE III.—VAPOUR PRESSURE OF MIXTURES OF LIQUID OXYGEN AND ARGON.

Molar per cent. argon.		Partial pressure mm.	
Liquid.	Vapour.	Oxygen.	Argon.
0	0	300.0	0.0
3.30	5.76	290.5	17.0
5.6	9.15	283.5	28.5
10.2	16.0	269.8	37.4
13.6	20.6	260.0	67.5
92.7	97.8	9.0	411.0

$-634.391T+30769.09T^2-107646T^3$ atm.; and E. Mathias and co-workers gave for argon log $p=4.8033-634.391T^{-1}-30769.09T^{-2}-1076464T^{-3}$. C. A. Crommelin observed:

Liquid { p . .	$-150.57°$ 1041.0	$-161.23°$ 564.53	$-183.01°$ 103.53	$-185.90°$ 79.371	$-189.30°$ 51.565 mm.
Solid { p . .	$-139.30°$ 51.565	$-191.36°$ 39.429	$-194.58°$ 25.101	$-197.62°$ 16.348	$-206.04°$ (6.717)

The number in brackets is doubtful. For the triple point, $(\delta p/\delta T)_1 = 0.08162$; and $(\delta p/\delta T)_s = 0.08623$; so that the vap. press. curve at the m.p. suffers only a small change of direction. F. Dolezalek measured the vap. press. of liquid mixtures of argon and nitrogen. W. Ramsay and M. W. Travers obtained for krypton

	−188·6°	−184·4°	−160·3°	−102·1°	−75·1°	−72°	−66·6°	−22·5°
p	9·0	17·4	386·6	11970	28808	30837	37006	41245

H. Happel applied J. D. van der Waals' vap. press. formula; and A. Keindorff's formula becomes $\log (p+12) = 7.0384730 - f(39+T)^{-1}$, where $\log f = 2.7157442$. At lower temp., W. Ramsay found

	−205°	−200°	−195°	−190°	188·8°	−182·4°
p	0·27	0·97	2·8	7·5	9·0	17·4 mm.

Solid krypton thus exerts an appreciable vap. press. W. Ramsay and M. W. Travers gave for the vap. press. of xenon :

	−189·8°	−41·6°	−31·8°	−20·4°	−15·6°	0·5°
p	2020	11134	14696	19984	22310	31501 mm.

and H. Happel applied J. D. van der Waals' vap. press. formula; and A. Keindorff's formula becomes $\log (p+12) = 7.0385481 - f(8+T)^{-1}$, where $\log f = 2.8531501$. H. von Jüptner also made observations on this subject. W. Ramsay found at

	−205°	−200°	−195°	−190°	−188·8°	−182·4°
p	0·0005	0·007	0·02	0·04	0·11	0·17 mm.

and H. S. Patterson and co-workers gave at −20°, 19056 mm.; at 0°, 31360 mm.; and at −16·6°, 44270 mm.

Isothermal **pv-curves** were determined by W. Ramsay and M. W. Travers,[2] L. Holborn and J. Otto, and H. K. Onnes. J. J. van Laar discussed the deviations from Boyle's law for helium, neon, and argon; and A. Leduc found 0.0_585 for the coeff. of deviation from Boyle's law for argon. Values for the constants a, b, c in the equation $pv = a + bv^{-1} + cv^{-2}$, were calculated by H. K. Onnes. The results for helium, with p expressed in atm., and v in normal vols., are as follow :

					a	b	c
100.35°	$\{\begin{array}{l}p\\pv\end{array}$	42·574 1·38725	54·459 1·39314	66·590 1·39929	1·36667	0.0_3673	0.0_616

−252.72°	$\{\begin{array}{l}p\\pv\end{array}$	53·948 0·09120	60·716 0·09533	65·997 0·09867	—	—	—
−258.82°	$\{\begin{array}{l}p\\pv\end{array}$	40·012 0·06150	53·326 0·07063	59·797 0·07531	—	—	—

Isotherms for helium at −205° to −258° were obtained by F. M. Penning and H. K. Onnes; and F. M. Penning measured isochores for helium over the same temp. range. F. P. Burt obtained the values for pv at 0° shown in Table IV. L. Holborn and J. Otto gave for helium $pv = 0.99930 + 0.0_369543p$ at 0°; $pv = 1.18223 + 0.0_368887p$ at 50°; and $pv = 1.36518 + 0.0_366804p$ at 100°. They also compiled a table of values between −183° and 400°. E. H. Amagat calculated values for the coeff. $dp/d\theta$, and found it to be almost independent of the temp. W. Ramsay

TABLE IV.—pv-CURVES FOR HELIUM AND NEON AT 0°.

Helium.			Neon.		
p mm.	v c.c.	pv	p mm.	v c.c.	pv

and M. W. Travers obtained isothermal pv-curves for neon when p is expressed in metres of mercury, and v in c.c. per mol. (Table V). G. Rudorf found that the

TABLE V.—ISOTHERMAL pv-CURVES FOR NEON.

142°			237·3°		
p	v	pv	p	v	pv
29·870	590·5	17638	33·810	925·9	31304

71·458	248·8	17777	71·840	433·2	31124

data are too irregular to permit the calculation of the constants for the gas equation. F. P. Burt obtained the results shown in Table IV for neon at 0°. L. Holborn and J. Otto compiled a table of values for neon between −183° and 400°.

W. Ramsay, and W. Ramsay and M. W. Travers investigated the isothermal pv-curves of argon; and H. Happel calculated for $T_c/P_c(dp/dT)_c$, 5·17-5·42; G. Rudorf, 4; G. van Rij, 6·19; and C. A. Crommelin, 5·712. H. Happel obtained for $(dp/dT)_c$, 1337–1400; and G. van Rij, 1477. H. K. Onnes and C. A. Crommelin obtained the following results for the isothermal curves when p is measured in atm., and v is expressed in normal vols. :

20·39°	$\begin{cases} p \\ v \\ pv \end{cases}$	.	21·783	27·320	34·487	37·248	49·604	61·741

The results were used in testing the relation $pv=a+bv^{-1}+cv^{-2}+dv^{-4}+ev^{-6}+fv^{-8}$. H. Happel applied the equation $p=RT/v\{1+1\cdot2v^{-1}+0\cdot625(1\cdot2v^{-1})^2+0\cdot2869(1\cdot2v^{-1})^3 +...\}-10\times10^8v^{-2}$, where $R=2\cdot083\times10^6$; and G. Rudorf, $pv=RTv(v-30\cdot18)^{-1} -9\cdot886\times10^5v^{-1}$, where $R=62\cdot372$. L. Holborn and J. Otto compiled a table

of values for argon between $-183°$ and $400°$. E. H. Amagat calculated values for $dp/d\theta$ at different temp.; and H. K. Onnes and C. A. Crommelin, values for $T(d^2p/dT^2)_v$; $T(dp/dT)_v-p$; $T(dp/dT)_v-p$; $(dp/dT)_v$, which did not give constant values; and $(d^2p/dT^2)_v$, which was not zero. W. Ramsay and M. W. Travers obtained the following values for the pv-curves of krypton, p being expressed in metres, and v in c.c. per mol :

11·2°	p	.	.	19·669	29·359	37·682	47·933	66·420	77·322
	v	.	.	879·2	562·8	422·8	318·8	214·8	180·1
	pv	.	.	17166	16523	15934	15280	14264	13924
237·3°	p	.	.	38·707	45·113	49·448	54·109	68·044	79·108
	v	.	.	824·8	704·5	644·0	583·7	462·5	402·4
	pv	.	.	31924	31783	31680	31583	31473	31830

H. Happel, and G. van Rij applied the equation $p=1·014\times10^6Tv^{-1}\{1+0·764v^{-1}+0·625(0··764v^{-1})^2+0·2869(0·740v^{-1})^3+ \ . \ . \ .\}-424\times10^6v^{-2}$; and G. Rudorf, $pv=62·372Tv(v-39·79)^{-1}-17·63\times10^5v^{-1}$. H. Happel gave $T_c/p_c(dp/dT_c)=5·17$, and 5·42; G. van Rij, 6·19; and H. Happel, $(dp/dT)_c$, 1085, and 1030. W. Ramsay and M. W. Travers obtained the following values for the pv-curves of xenon— p being expressed in metres, and v in c.c. per mol. :

11·2°	p	.	.	19·492	22·851	26·270	30·923	35·125	40·430
	v	.	.	771·6	632·6	525·5	417·0	339·4	234·3
	pv	.	.	15042	14456	13805	12894	11917	9240
237·3°	p	.	.	40·681	48·042	52·915	58·927	66·997	77·935

	pv	.	.	30114	29714	29655	29313	29223	29288

H. Happel, and G. van Rij applied the equation $p=RTv\{1+0·633v^{-1}+0·625(0·633v^{-1})^2+0·2869(0·633v^{-1})^3+ . \ . \ .\}-307\times10^6v^{-2}$; and G. Rudorf, $pv=RTv(v-51·57)^{-1}-312·4v^{-1}$. H. Happel obtained $T_c/p_c(dp/dT)_c=5·17$ and 5·40; H. S. Patterson and co-workers, 5·87; and G. van Rij, 6·19. H. Happel gave $(dp/dT)_c=796$. The best representative values are :

				A	Kr	X
$\dfrac{T_c}{p_c}\left(\dfrac{dT}{dp}\right)_c$	.	.	.	5·23	5·48	5·40

P. W. Bridgman found for the press., p, in kgrms. per sq. cm.; the vol., v c.c. per grm. of helium, at $65°$; and the product pv, where the v represents the vol. of helium which under 1 kgrm. press. per c.c. at $0°$, occupies 1 c.c.

p	.	.	.	3000	5000	7000	9000	11000	13000	15000

P. W. Bridgman found for the press., p in kgrms. per sq. cm.; and the change in vol. δv in c.c. per gram of argon at $55°$:

p	.	.	2000	3000	5000	7000	9000	11000	13000	15000
δv	.	.	0·083	0·000	0·085	0·134	0·167	0·190	0·209	0·224

J. H. Perry found the inversion temp. in the **Joule-Thomson effect** occurs at about $100°$ K. W. Meissner found that when compressed helium, at $15°$ K., is allowed to expand, the proportion liquefied is 0·19 of the whole. This is greater than is computed from the theory of corresponding states. F. P. G. A. J. van Agt and H. K. Onnes compared the hydrogen and helium thermometers; and W. Heuse studied helium, and neon thermometers. The subject was discussed by H. K. Onnes and co-workers, F. Henning, G. K. Burgess, J. Dewar, K. Olschewsky, J. P. Kuenen and W. W. Randall, M. W. Travers and co-workers, F. Dorn, F. Cario, etc.

J. P. Kuenen and W. W. Randall obtained for the **pressure coefficient** of argon, $\beta=0·003665$; M. W. Travers and co-workers, 0·00366255, the same as for hydrogen; H. K. Onnes gave 0·0036613–0·0036616. J. P. Kuenen and W. W. Randall found

for argon, $a=0.003668$. L. Holborn and F. Henning found for helium between 0° and 100° $a=0.0036618$; and L. Holborn and J. Otto gave for helium $\beta=0.003661$ at $p=0$, and 0.0036518 at $p=60$ m.; and the mean coeff. of thermal expansion 0.0036605, for $p=0$, and 0.0034552 for $p=80$ m. press. The constants in J. D. van der Waals' equation of state were studied by W. Ramsay and G. Rudorf, P. A. Guye and L. Friderich, and H. Happel. The results show that when p is expressed in atm., v is unity at 0° and 1 atm. press., and $R=1/273.09$:

	He	Ne	A	Kr	X	Nt
a	0.0_46898	—	0.002671	0.004633	0.008149	0.01291
b	0.001063	—	0.001435	0.001778	0.002277	0.002768

and when p is expressed in dynes per sq. cm., and v in c.c. per gram :

	He	Ne	A	Kr	X	Nt
9×10^{-6}	2204	—	833.3	342.2	243.5	83.16
b	5.969	—	0.8060	0.4798	0.3910	0.2209

F. G. Keyes gave for the equation of state of argon $p=2.0578(v-1.278)^{-1}T-995.7(v-0.247)^{-2}$; but P. W. Bridgman found that the compressibility at high press. does not fall off so rapidly as is indicated by this equation. M. F. Carroll replaced the constants a and b of J. D. van der Waals' equation by $a=a'(1-0.293a)$, and $b=b'(1-0.369a)$, where for helium, $a=0.269$, $a'\times10^{-6}=0.0282$, and $b'=22.80$; for argon, $a=0.380$, $a'\times10^{-6}=1.074$, and $b'=29.13$; and for xenon, $a=0.522$, $a'\times10^{-6}=3.268$, and $b'=46.77$. W. J. Walker studied the equation of state of helium. F. Zwicky calculated an equation of state for helium and argon from the electronic structure. J. E. Jones discussed the equations of state for these gases; and J. J. van Laar, the constants of the equations of state.

I. Masson and L. G. F. Dolley found that for mixtures of argon and ethylene, the total press. is greater than the sum of those of the constituents taken separately; while with argon-oxygen mixtures, the deviations from the additive mixture rule are less. Analogous deviations occur in the measurement of the volumes of the mixed gases. Assuming that internal pressure or cohesion in a gas of moderate density is due partly to the formation of mol. aggregates of varying complexity, it is concluded that at the ordinary temp. these complexes are in reversible equilibrium with their original constituents. Regarded from the point of view of the electronic theory of mol. structure, it would appear that mol. cohesion between any two gases would be that of the gas or gases of the argon group, the electronic configurations of which the gases simulate. J. P. Dalton calculated the sp. attraction coeff. of argon to be 4.963 when that of oxygen is 5.689, and that of hydrogen, 6.863. The effect of mol. attractions on the pressure of helium, etc., was investigated by O. Maass and D. M. Morrison.

A. Jaquerod and O. Scheuer found that, like hydrogen and neon, the compressibility of helium, corrected for argon, is positive, and it amounts to $+0.0006$; and later they obtained 0.001 when the value for hydrogen is $+0.00055$. F. P. Burt obtained a zero or negative value. P. A. Guye obtained 0.001009 from the equation $A=-a+b+0.0_4623T_c/22.412$, where $a=6.898\times10^{-5}$, $b=106.3\times10^{-5}$, and $T_c=5.25°$; the corresponding value for hydrogen is 0.000569. F. P. Burt obtained for the compressibility of neon between 0 and 1 atm. press. $+0.00105$; and P. A. Guye calculated $+0.00038$. Lord Rayleigh found -0.00076 at $11.2°$ and -0.00094 at 0°, for the compressibility of argon between 0.5 and 1 atm. P. A. Guye gave -0.000841; and H. E. Watson, -0.00103. With the formula $C_p-C_v=Tva^2/\beta$, A. Eucken calculated the compressibility of liquid argon to be $\beta=2.45\times10^{-4}$ kgrm. per sq. cm. For krypton gas P. A. Guye obtained -0.00227 and -0.002103; H. E. Watson, -0.00228 and -0.00210. For xenon, P. A. Guye obtained -0.005924, and H. E. Watson, -0.00690 and -0.00798. The best representative value is -0.00592. F. P. G. A. J. van Agt and H. K. Onnes measured the compressibility of helium between $-259°$ and $-180°$. S. F. Pickering compiled some data on this subject. P. W. Bridgman found for the change in vol. of argon, c.c. per gram at 55°, -0.083

at 2000 kgrms. per sq. cm. press.: zero, 3000; 0·112 at 6000; 0·201 at 12,000; and 0·224 at 15,000. The best representative values for the compressibilities of the inert gases are:

	He	Ne	A	Kr	X	Nt
Compressibility	+0·001	+0·00105	−0·000841	−0·00218	−0·00592	−0·01816

Lord Rayleigh [3] measured the **viscosity** of helium and found 0·96 with air unity; H. Schultze obtained $\eta = 0·0_31969$ at 15·3°; $0·0_32348$ at 99·6°; and $0·0_32699$ at 184·6°. J. F. Schierloh gave $0·0_31980$ at 18·7°; $0·0_32337$ at 99·8°; and $0·0_32681$ at 183·7°; M. N. States, $0·0_319623$ at 23°; and K. Schmitt, $0·0_31967$ at 17·6°; $0·0_31587$ at −609°; $0·0_31506$ at −78·5°; and $0·0_48947$ at −193·2°. H. K. Onnes and S. Weber found for the viscosity at low temp:

	21·5°	−22·7°	−69·9°	−102·5°	−183·25°	−198·3°	−252·83°	−258°
$\eta \times 10^7$	1994	1788	1564	1392	918·6	813·2	349·8	294·6

H. Vogel found $0·0_31876$ for helium at 0·1°; $0·0_31496$ at −78·4°; $0·0_4875$ at −191·4°; and $0·0_4348$ at −252°. W. J. Walker made some observations on the viscosity of helium. Lord Rayleigh gave $c=72·2$ for Sutherland's constant (1. 13, 3); H. Schultze, 80·3; J. F. Schierloh, 78·2; R. A. Millikan, 113; H. K. Onnes and S. Weber, 78·2; A. O. Rankine, 70. P. Tänzler measured the viscosity of mixtures of helium and argon; and calculated the results, using the formulæ of J. Puluj, and M. Thiesen. Y. Ishida gave 1·087 for the ratio of the viscosity of helium to that of air; and 1·212 for argon and air. Observations on this subject were made by S. Chapman, and P. Günther. The viscosity of neon, found by A. O. Rankine, is 1·721 for air unity at 10·1°; and in absolute units, $\eta = 0·0003036$, and at 0°, 0·0002981. Sutherland's constant is 56. Lord Rayleigh obtained 1·21, air unity, for the viscosity of impure argon. H. Schultze gave for purified argon, $0·0_31811$ at 15°; $0·0_32208$ at 99·7°; and $0·0_32571$ at 182·9°. P. Tänzler gave $0·0_32202$ at 11·9°; $0·0_32197$ at 12·1°; $0·0_32746$ at 99·6°; and $0·0_33231$ at 183°. W. Kopsch obtained $0·0_32207$ at 13·17°; $0·0_321156$ at −0·21°; $0·0_319866$ at −20·25°; $0·0_318535$ at −40·17°; $0·0_316966$ at −60·16°; $0·0_315746$ at −78·82°; $0·0_313797$ at −104·40°; $0·0_311061$ at −132·30°; and $0·0_47356$ at −183·17°. He also compared the results obtained with M. Knudsen's formula. S. Chapman and W. Hainsworth, J. F. Schierloh, A. O. Rankine, H. Markowsky, J. E. Jones, and K. Schmitt made observations on this subject. For Sutherland's constant for argon, Lord Rayleigh gave 150·2; H. Schultze, 169·9; W. Kopsch, 174·6; A. O. Rankine, 142. The viscosity of krypton, air unity, was found by A. O. Rankine to be 1·361 at 10·6°, and $\eta = 0·0_32405$; and at 0°, $0·0_32334$; K. Schmitt gave $\eta = 0·0_31736$ at 0°. A. O. Rankine's value for Sutherland's constant is 188 for krypton, and 252 for xenon. He also gave for the viscosity of xenon, air unity, 1·234 at 10·9° or $\eta = 0·0_32180$; and at 0°, $\eta = 0·0_32107$; while K. Schmitt gave $0·0_32121$ at 0°. M. Reinganum, W. J. Fisher, and A. O. Rankine studied the subject generally; and H. Sirk, and E. Lohr, the relation between the viscosity coeff. and the index of refraction. The best representative values for the viscosity η, and at 0°, and for Sutherland's constant C, are:

	He	Ne	A	Kr	X
η	$0·0_31879$	$0·0_32981$	$0·0_32102$	$0·0_32334$	$0·0_32107$
C	70	56	142	188	252

F. Schuster gave 860 atm. for the **internal pressure** of argon, and 1234 atm. for krypton. M. N. States, and E. Blanckenstein measured the **coefficient of slip** of helium and oxygen. W. Ramsay and J. N. Collie [4] found that the **diffusion** of helium through pipe-clay proceeds more rapidly than corresponds with Graham's law. A similar observation was made by W. Ramsay and M. W. Travers, who also found that at about 950°, platinum, palladium, and iron are impermeable to helium. A. Jaquerod and F. L. Perrot found that while platinum is impermeable to helium at 1000°, the gas passes readily through quartz. The diffusion through

fused quartz is rapid even at 520°, and perceptible at 220°. The gas also diffuses through porcelain so that vessels of fused quartz or porcelain are not suitable containers for helium at an elevated temp.—*vide* quartz and glass. E. Dorn found that a vessel of platinum-iridium alloy is impermeable at 1420°. A. Sieverts and E. Bergner, H. E. Watson, and A. Jaquerod studied the diffusion of helium through quartz and porcelain. O. W. Richardson and R. C. Ditto found that neon also diffuses through quartz glass at 1000°, but not so fast as helium. W. Ramsay and J. N. Collie showed that the rate of diffusion of argon through pipe-clay is in accord with Graham's law. D. Tsakalotos measured the diffusion of hydrogen mixed with argon through palladium at 280°—*vide infra*. Lord Rayleigh found that argon diffuses through indiarubber more quickly than nitrogen. J. Dewar found the rate of diffusion of argon through rubber 0·01 mm. thick to be 2·56 c.c. per sq. cm. per day at 15° and atm. press.; for helium, the rate was 3·5; and for nitrogen, 1·38. J. C. McLennan and W. W. Shaver, and R. T. Elworthy and V. F. Murray also measured the diffusion of helium through rubber fabrics; and J. C. McLennan and W. W. Shaver, through soap films. R. Schmidt investigated the interdiffusion of helium and argon and obtained $k=0.25405$ at 15° for the coeff. of diffusion. He also represented the effect of temp. by the expression $k=k_0\{(273+\theta)273\}^{1\cdot75}$. F. W. Aston, and A. Lonius also made observations on this subject. T. L. Ibbs studied the thermal diffusion of hydrogen and argon, and helium and argon; G. A. Elliott and I. Masson, helium and carbon dioxide mixtures; G. Jaumann, the separation of hydrogen and helium by a diffusion process; and S. Chapman and W. Hainsworth, the kinetic theory of the diffusion of argon and helium.

F. G. Donnan measured the rate of **effusion** or the efflux of helium through a small hole in a thin-walled partition. The efflux is faster than the speed calculated from the density even when a relatively large viscosity factor is introduced. It is concluded that the Joule-Thomson effect is negative because it can be shown that a gas will effuse more slowly or more rapidly than an ideal gas according as the Joule-Thomson effect is negative or positive. F. G. Donnan also measured the effusion of argon, and found it is in qualitative but not quantitative agreement with Graham's law.

The observations on the **surface tension** of argon by E. C. C. Baly and F. G. Donnan,[5] re-calculated by G. Rudorf, are as follow :

	−189°	−188°	−187°	−186°	−185°	−184°	−183°

a^2 .	1·925	1·90	1·87	1·84	1·81	1·78	1·755

The molecular **surface energy** is represented by (Mv), and the effect of temp. by $(Mv)=2\cdot02(145\cdot44-T)$; and J. D. van der Waals' equation assumes the form $=23\cdot20(1-T/Tc)^{0\cdot8102}$. The values for the **specific cohesion**, a^2, are indicated above. P. Walden represented the relation between the mol. wt., M, and the sp. cohesion by $M=0\cdot435T/a^2$. P. Walden and R. Swinne represented the temp. coeff. of the surface energy by $d\{\sigma(Mv^{\frac{2}{3}})\}/d\theta=-\{1\cdot90+0\cdot011(E\sqrt{A})\}$; and of the mol. cohesion, by $d(Ma^2)/d\theta=-\{0\cdot0027(E\sqrt{A})+0\cdot0103\}$, where $\sqrt{A}$ for argon is 6·32. A. T. van Urk and co-workers found for liquid helium the mol. surface tensions :

	−268·80°	−269·00°	−269·500°	−270·00°	−270·50°	−271·00°	−272·50°
$M\sigma$ . .	0·98	1·19	1·68	2·19	2·69	3·08	3·22

The **molecular constants** of the rare gases have been discussed in connection with the kinetic theory of gases by O. E. Meyer,[6] R. Gans, J. H. Jeans, G. Rudorf, H. Sirk, W. Hillers, M. Reinganum, W. Sutherland, etc. The **mean velocity** of mol. motion, V, and the velocity of mean square, U, of helium calculated by G. Rudorf, are respectively $13\cdot06\times10^4$ and $12\cdot035\times10^4$ cm. per sec.; the mean velocity, by O. E. Meyer, is $11\cdot62\times10^4$, and by R. Schmidt, $12\cdot077\times10^4$ cm. per

sec.; while the velocity of mean square, by J. H. Jeans, is 13.11×10^4 cm. per sec. G. Rudorf found for neon $V = 5.385 \times 10^4$ and $U = 5.845 \times 10^4$ cm. per sec.; and for argon, respectively 3.806×10^4 and 4.13×10^4 cm. per sec. H. Schultze gave for argon, $U = 4.148 \times 10^4 - 4.135 \times 10^4$; J. H. Jeans, 4.13×10^4 cm. per sec.; and P. Tänzler, 4.13×10^4 cm. per sec.; and for the mean velocity, V, O. E. Meyer gave 3.81×10^4 cm. per sec.; R. Schmidt, 3.806×10^4 cm. per sec., $U = 2.86 \times 10^4$ cm. per sec., and $V = 2.64 \times 10^4$ cm. per sec., and for xenon, respectively 2.28×10^4 and 2.10×10^4 cm. per sec. The **mean free path**, L, of the mols. of helium calculated by Lord Rayleigh is 2.40×10^{-5} to 2.6×10^{-5} cm.; H. Schultze, 2.857×10^{-5} cm.; J. F. Schierloh, 2.85×10^{-5}; and by A. O. Rankine, 2.421×10^{-5} cm. The last-named gave for neon, 1.709×10^{-5} cm. For argon, Lord Rayleigh gave 0.99×10^{-5} cm.; H. Schultze, 1.002×10^{-5} to 1.012×10^{-5} cm.; P. Tänzler, 1.004×10^{-5} cm.; and J. F. Schierloh, 1.006×10^{-5} cm. For krypton, G. Rudorf gave 0.659×10^{-5} cm. and 0.77×10^{-5} cm.; and for xenon, 0.474×10^{-5} cm. and 0.554×10^{-5} cm. The **molecular diameter**, D, of the rare gases calculated by A. O. Rankine, M. Reinganum, O. E. Meyer, J. H. Jeans, H. Sirk, J. Robinson, W. H. Westphal, G. Rudorf, C. C. Darwin, W. Sutherland, range from 0.4745×10^{-8} to 2.130×10^{-8} cm. for helium; 0.6440×10^{-8} to 2.532×10^{-8} for neon; 1.342×10^{-8} to 3.580×10^{-8} cm. for argon; 1.561×10^{-8} to 4.08×10^{-8} cm. for krypton; and 1.824×10^{-8} cm. for xenon. S. Chapman calculated for argon 2.84×10^{-8} cm.; P. W. Bridgman gave 1.98×10^{-8} to 2.20×10^{-8} cm.; and W. L. Bragg calculated 1.30 Å. for the diameter of the atoms of neon; 2.05 A., for those of argon; 2.35 A., for those of krypton; and 2.70 A., for those of xenon. A. O. Rankine calculated values from viscosity determinations. R. G. Lunnon, H. G. Grimm, W. Schütz, and H. G. Grimm and H. Wolff made some calculations on this subject. S. Mokruschin calculated for the mol. diameter of argon at the b.p., 1.212×10^{-8} cm., and for helium, 0.122×10^{-8} cm. M. N. Saha calculated from the ionization potential for helium 0.28×10^{-8} cm.; and neon, 0.33×10^{-8}; and H. Schmidt calculated from the viscosity, helium, 0.795×10^{-8} cm.; neon, 0.946×10^{-8} cm.; argon, 1.336×10^{-8} cm.; krypton, 1.553×10^{-8} cm.; and xenon, 1.794×10^{-8} cm. C. Ramsauer discussed the collision area of the mols. of the inert gases; and W. P. Davey, the packing radii of the atoms of the inert gases. The best representative values for the mol. constants may be taken as

			He	Ne	A	Kr	X	Nt
$U \times 10^{-4}$	.	.	13.06	5.182	4.13	2.86	2.28	1.75
$V \times 10^{-4}$	.	.	12.035	5.355	3.806	2.64	2.10	1.61
$L \times 10^5$	.	.	2.421	1.709	0.857	2.659	0.474	—
$D \times 10^8$	.	.	1.89	2.35	2.87	3.19	3.51	—

The at. radii calculated by M. Pierucci are roughly proportional to the numbers 3, 4, 6, 7, 8. B. Cabrera obtained values about half those computed from the kinetic theory when he calculated the values from Bohr's electronic struction, and from the magnetic susceptibility. J. E. L. Jones calculated the attractive and repulsive forces between the atoms of the inert gases. J. J. van Laar computed values for Avogadro's number; and V. Kiréef, values for the intermolecular attraction of helium, neon, and argon.

K. Olschewsky,[7] J. Dewar, and M. W. Travers and A. Jaquerod tried without success to liquefy helium. No **liquefaction** occurred, even by suddenly relieving the press. at 180 atm. at the temp. of solid hydrogen. H. K. Onnes reported having solidified the gas by cooling it in liquid hydrogen, and A. W. Porter accordingly suggested that helium passes directly from the gaseous to the solid state. The helium employed was probably contaminated with hydrogen, but by using the purified gas cooled to $-258°$, liquefaction occurred during the free expansion of the compressed gas.

According to H. K. Onnes, with a mixture of an ideal gas and an incompressible liquid without vap. press., in which the gas does not dissolve, under the action of gravity, the gas

will gather above the liquid if the press. is sufficiently low, whereas the compressed gas will sink in the liquid if the press. is made high enough. With a mixture of one part of helium and 6 parts of hydrogen, cooled by liquid hydrogen, at press. up to 49 atm., the liquid hydrogen is separated from the supernatant gaseous helium by a distinct hollow meniscus ; at 49 atm., the gas, mainly helium, sinks in the liquid just as water goes through oil, and remains at the bottom like a large drop. By increasing the compression up to 60 atm., and decreasing the press. to 32 atm., the vol. of the bubble seems to follow the change of press. as that of a gas ; at 32 atm. press., the bubble rises in the liquid. By changing the press., the bubble can be made to rise or sink in the liquid at pleasure.

J. C. McLennan and G. M. Schrum, and W. Meissner described an apparatus for the liquefaction of helium.

J. Dewar estimated the **boiling point** of helium to be about 5° K., while the determinations of H. K. Onnes showed the b.p. is 4·25° K. ; W. H. Keesom gave −268·87°. G. Rudorf estimated the b.p. of neon to be 47° K.–51° K., but the basis of the estimate—Ramsay and Young's rule—is not reliable. W. Ramsay and M. W. Travers liquefied neon at the temp. of liquid hydrogen, but it is not liquefied at −205° and 100 atm. press. M. W. Travers and A. Jaquerod estimated the b.p. of neon to be between −244·5° and −239°. W. H. Keesom gave −245·92° for the b.p. of neon. The b.p. of argon given by K. Olschewsky was −187° at 740·5 mm. ; W. H. Keesom, −185·84° ; and W. Ramsay and M. W. Travers gave −185·8°. The last-named also gave −101·67° for the b.p. of krypton, and −106·9° for xenon. W. Ramsay and M. W. Travers estimated the **melting point** of helium to be less than 1° K. H. Erdmann estimated 1° K., and H. K. Onnes, 0·9° K. H. Erdmann gave −253° for the m.p. of neon, and H. K. Onnes and C. A. Crommelin, −248·6°. K. Olschewsky gave −189·6° for the m.p. of argon, and W. Ramsay and M. W. Travers, −187·9°. The latter gave −169° for the m.p. of krypton, and −140° for that of xenon. The m.p. and b.p. of argon are only 1·8° apart. E. H. Mathias gave 4·99° K. for helium ; 44·74° K. for neon ; 150·65° K. for argon ; and 289·7° K. for xenon. W. H. Keesom gave −267·84° for helium, −228·35° for neon and −122·44° for argon. J. Narbut gave for the latent heat of fusion L Cals. per gram-atom at the m.p. :

	Helium.	Neon.	Argon.	Krypton.	Xenon.	Niton.
L	<0·004	0·08	0·268	0·33	0·43	0·65
m.p.	<−273·85°	−249°	−189°	−169°	−140°	−71°

K. Olschewsky said that the **crystals** of argon are white and transparent ; and W. Wahl showed that the crystals are isotropic belonging to the cubic system. The crystals grow rapidly, and usually furnish dendritic forms with many branches. F. Simon and C. von Simson observed that the **X-radiograms** of solid argon correspond with a face-centred cubic lattice with the closest spherical packing. At −233°, the edge of the cube is 5·42 A., and sp. gr. 1·62 ; J. de Smedt and W. H. Keesom gave 5·4 0A., and sp. gr. 1·63 at 20° K. J. E. Jones calculated the interatomic distances and the potential energy in the crystals of argon.

Estimates of the **critical temperature** of helium by J. Dewar, M. W. Travers and A. Jaquerod, K. Olschewsky, and W. M. Tate varied from 2° K. to 13° K. A direct determination by H. K. Onnes gave 5·25°K for the critical temp. of helium. E. Mathias and co-workers gave −267·90°. The ratio of the critical temp. to the b.p., $T_c/T_b=1·235$, has a value lower than is the case with the other inert gases. W. Ramsay and M. W. Travers said that the critical temp. of neon must be below −205° and above −250° ; M. W. Travers and A. Jaquerod said that the critical temp. lies between −213° and −223° ; A. O. Rankine estimated −211·9° to −210·3° ; E. Mathias, H. K. Onnes and C. A. Crommelin gave −228·62° ; and C. Cuthbertson, −227°. Working with neon of a high degree of purity, C. A. Crommelin found −228·71°. K. Olschewsky gave −121° for the critical temp. of argon ; W. Ramsay and M. W. Travers, −117·4° ; and C. A. Crommelin, −122·44° ; and E. Mathias and co-workers, −122·35°. W. Ramsay and M. W. Travers gave −62·5° for the critical temp. of krypton ; and 14·75° for that of xenon.

H. S. Patterson and co-workers gave 16·6° for the critical temp. of xenon. For the **triple point,** W. H. Keesom gave —248·67°, and 323·5 mm. press. for neon; and —189·30° and 515·64 mm. for argon. H. K. Onnes and C. A. Crommelin gave for neon —248·6° and 323·5 mm. of mercury; E. Mathias and C. A. Crommelin gave what they thought to be the best representative values for the critical constants :

	Helium.	Neon.	Argon.	Krypton.	Xenon.
Critical temp. . .	—267·90°	—228·71°	—122·44°	—	16·6°

Triple point { temp. .	—272·2°	—248·67°	—189·19°	—	—140°
{ press. .	0·002	32·35	51·217	—	— atm.

H. K. Onnes, and W. H. Keesom found 2·26 atm. for the **critical pressure** of helium, and later, 2·75 atm. The ratio T_c/p_c=2·32 is lower than for the other inert gases. He found the critical press. of neon is about 29 atm. W. H. Keesom gave 26·86 atm. K. Olschewsky gave 50·6 atm. for the critical press. of argon; W. Ramsay and M. W. Travers, 40,200 mm. or 52 atm.; W. H. Keesom, 47·996 atm.; and C. A. Crommelin, 47·996 atm. W. Ramsay and M. W. Travers gave 41,245 mm. or 54·3 atm. for the critical press. of krypton, and 43·500 mm. or 57·2 atm. for that of xenon. W. R. Fielding discussed the relations between the critical constants of xenon and nitrogen; W. Herz, the critical constants of argon, helium, etc.; and H. Carlson, some relation between the m.p. and the b.p. of the inorganic halides and hydrides.

H. K. Onnes found the **critical density** of helium to be 0·065, while values calculated from a number of other formulæ are lower. E. Mathias and co-workers gave 0·06930. D. Berthelot obtained 0·434 for the critical density of argon; H. Happel, 0·432–0·505; G. Rudorf, 0·488; P. Walden, 0·525; R. O. Herzog, 0·672; W. A. Goldhammer, 0·5149; C. A. Crommelin and co-workers, 0·509–0·53078. E. H. Mathias gave the values for the critical densities indicated in Table VI; C. A. Crommelin gave for neon, 0·483; A. Predwoditeleff, 0·4835; W. H. Keesom, 0·066 for helium, and 0·53078 for argon, and E. C. C. Baly and F. G. Donnan, 0·4841–0·5106. P. G. Rudorf calculated 0·775 for the critical density of krypton; and W. A. Goldhammer, 0·694–0·927. For the critical density of xenon, G. Rudorf gave 1·26; H. S. Patterson and co-workers, 1·155; H. Happel, 0·889; R. O. Herzog, 1·475; P. Walden, 1·147; and W. A. Goldhammer, 1·142–1·151. Best representative values for the critical constants are given in Table VI. J. A. Muller's values for the degree of polymerization, n, of some of these gases in the critical state are included.

TABLE VI.—SOME PHYSICAL CONSTANTS FOR THE INERT GASES (°K.).

	Helium.	Neon.	Argon.	Krypton.	Xenon.	Niton.
M.p. . .	c. 1°	24·4°	c. 85°	104°	133°	202°

n . . .	0·923	—	1·285	—	—	1·358

The **heat conductivity** of helium was found by W. Schwarze [8] to be 0·0003386 at 0°, and the temp. coeff. between 0° and 100° to be 0·00318. S. Chapman and W. Hainsworth studied the kinetic theory of conductivity. Observations were

made by M. Smoluchowsky, E. Schreiner, and A. Eucken ; the last-named found that the conductivity, k, varies with temp. as follows :

			$-192.7°$	$-78.4°$	$0°$	$100°$
$k \times 10^7$	.	.	33.40×0.436	3340×0.788	3340	3340×1.193
K	.	.	2.184	2.363	2.373	2.280

hence, the temp. coeff. increases rapidly as the temp. falls. $k = K/\eta c_v$, where k denotes the thermal conductivity ; c_v, the sp. ht. per gram ; K, a constant ; and η, the viscosity. S. Weber found for neon at $105.81°$, $\eta = 0.0_3 1344$; $0.0_3 1087$ at $0°$; $0.0_4 879$ at $-74.37°$; and $0.0_4 499$ at $-181.43°$. J. Wachsmuth, and S. Chapman studied the thermal conductivity of mixtures of argon and helium. M. Smoluchowsky, and F. Soddy and A. J. Berry investigated the thermal conductivity of gases at low press. If $Q = \frac{1}{6}(n/N)C_v V$, where n denotes the number of mols. in 1 c.c. of gas at 0.01 mm. press., and $\theta°$; N, the number of mols. per mol of gas at $0°$ and 760 mm. press. ; C_v, the mol. ht. at constant vol. ; and V, the mean mol. velocity at $\theta°$, then, F. Soddy and A. J. Berry obtained for helium, neon, and argon at $22°$, $k \times 10^5 = 1.99$, 1.78, and 1.32 respectively ; $Q \times 10^5$, 3.75, 1.68, and 1.18 respectively ; and K/Q, 0.53, 1.06, and 1.12 respectively. E. Schreiner also measured the mol. ht. of argon. O. Mehliss obtained for argon at $5.75°$, $k = 0.0_4 3852$, and at $0°$, $0.0_4 3796$ with a temp. coeff. of 0.0026. H. Schwarze gave at $0°$, $0.0_4 3894$; and A. Eucken,

			$-182.6°$	$-78.4°$	$0°$	$100°$
$k \times 10^7$	.	.	388×0.366	388×0.750	388	388×1.311
K	.	.	2.555	2.485	2.460	2.469

R. Thomas [9] measured the **specific heat** of helium at constant press. and found $c_p = 1.2504 \pm 0.0222$. A. Eggert obtained

			$-15°$ to $8°$	$15°$ to $50°$	$15°$ to $100°$	$15°$ to $150°$
c_p	.	.	1.26449	1.26485	1.26962	1.26298

These results are taken to mean that the sp. ht. of helium, between $-15°$ and $150°$, does not change, and that the best representative value is 1.2662 ± 0.0011. This result is about $1\frac{1}{4}$ per cent. higher than that of R. Thomas. The value calculated from the sp. ht. ratio $c_p/c_v = \frac{5}{3}$ is 1.246. If $c_p = 1.2662$, then $c_v = 0.7681$; and if $c_p = 1.246$, $c_v = 0.7477$. K. Scheel and W. Heuse gave $c_p = 1.245$ at $-180°$, and 1.260 at $18°$; or the mol. ht. $C_p = 4.97$ at $-180°$ and 5.03 at $18°$. A. Eucken found that the at. ht. of helium containing 9.30 mols per litre at $18°$ K. is 3.02 ; and at $26°$ K., 2.99 ; and with the gas having 34.1 mols per litre, 2.95 at $18°$ K., and 3.20 at $30°$ K. Liquid argon was found to have the mol. sp. ht. $C_p = 10.5$, and $C_v = 5.54$; and for the solid, $C_p = 7.8$, and $C_v = 5.66$. F. Richarz calculated from W. Ramsay's value for c_p/c_v, the sp. ht. c_p of neon is 0.247, and $c_v = 0.149$. For argon between $20°$ and $90°$, W. Dittenberger obtained $c_p = 0.1212 \pm 0.0019$; and when corrected by comparison with air, $c_p = 0.1252$. The value calculated from the sp. ht. ratio is $c_p = 0.1243$. M. Pier obtained $c_p = 0.1252$, and $c_v = 0.0746$. The at. ht. at constant press. was measured by M. Pier, and the results were recalculated by N. Bjerrum. E. Mathias and co-workers discussed this subject. W. Nernst's results are as follow :

			$0°$	$100°$	$200°$	$500°$	$1200°$	$2000°$
Ac_v	.	.	2.98	2.98	2.98	2.98	3.0	3.0

A. Eucken found that the at. ht. of solid argon is $C_p = 2.44$, and $C_v = 2.39$ at $17.8°$ K. ; and $C_p = 7.80$ and $C_v = 5.61$ at $78.3°$ K. The value of C_p was calculated from that of C_v from $C_p - C_v = ATC_p^2$, where the constant A is 4.5×10^{-4}. For liquid argon, $C_p = 10.50$ at $87.9°$ K., and 10.62 at $93.9°$ K. ; $C_v = 5.60$ at $87.9°$ K., and 5.44 at $92.8°$ K. W. Ramsay and M. W. Travers obtained for krypton, $c_v = 0.0362$, and $c_p = 0.0603$; and W. Ramsay obtained for xenon, $c_v = 0.023$, and $c_p = 0.0384$. L. I. Dana and H. K. Onnes gave 0.222 for the sp. ht. of liquid helium at $2.5°$ K.

W. Ramsay's value for the ratio of the two sp. hts. of helium, $\gamma = c_p/c_v$, was too high; but, working with purified helium of vap. density 2·133, W. Ramsay and co-workers obtained $\gamma = 1·652$. N. A. Langlet found for helium from cleveite, $\gamma = 1·667$; U. Behn and H. Geiger, $\gamma = 1·63$; and K. Scheel and W. Heuse, 1·668. For neon, W. Ramsay obtained $\gamma = 1·642$; and for argon, 1·648. O. Niemeyer found that for argon at 0°, $\gamma = 1·6671$; at 12·86, 1·66715; and at 99·84°, 1·6673. Hence, the value of γ between 0° and 100° does not change, and $\gamma = 1·6628$. J. Kapp measured the ratio of the sp. hts. of mixtures of argon with nitrogen and with carbon dioxide. W. Ramsay and M. W. Travers found for krypton $\gamma = 1·666$; and W. Ramsay gave for xenon, $\gamma = 1·666$. The best representative values are (when $R = 1·9875$ cals.):

	He	Ne	A	Kr	X	Nt
c_p	1·2662	0·247	0·1252	0·0603	0·0384	0·0225

According to A. Eucken,[10] the **heat of fusion** of argon is 267·9 cals. per mol. The **heat of vaporization**, λ, of helium calculated from W. Nernst's equation is $\lambda = 6·37$ Cals., and $M\lambda = 25·42$ Cals. O. Sackur gave for neon at absolute zero, 223 Cals. per mol. For the latent heat, L, of vaporization of neon, E. Mathias and co-workers gave $L^2 = 43·56922(T_c - T) - 1·744347(T_c - T)^2 + 0·0371203(T_c - T)^3$ Cals. per gram. For argon, A. Eucken gave 1501 cals. per mol; W. Nernst, $\lambda = 38·95$ Cals. per gram; G. Rudorf, $\lambda = 42·8 - 44·4$ Cals.; C. A. Crommelin, 69·4 Cals. at $-185·5°$; D. L. Hammick, 38·7 cals.; H. Happel, $\lambda = 38·1 - 38·8$ Cals.; and E. Mathias and co-workers, 38·10 Cals. per gram, or $L^2 = 41·59246(T_c - T) - 0·448963(T_c - T)^2 + 0·0026163(T_c - T)^3$ Cals. per gram. For krypton, G. Rudorf gave $\lambda = 25·5 - 27·7$ Cals.; and for xenon, 22·49 $-25·36$ Cals. R. de Forcrand gave for the latent heats of vaporization:

	He	Ne	A	Kr	X	Nt
λ	5·13	—	37·86	27·04	24·62	19·11
L	<0·004	0·08	0·268	0·33	0·43	0·65

The last line shows J. Narbut's values of the latent heat of fusion: L Cals. per gram-atom at the m.p. A. Henglein calculated values for krypton, and xenon; and F. S. Mortimer calculated for helium. L. I. Dana and H. K. Onnes obtained a maximum of 6 cals. at about 3·5° K. in the curve of the variation of the latent heat of vaporization of liquid helium with temp. The **entropy** of the inert gases was studied by K. Bennewitz and F. Simon. G. N. Lewis and co-workers calculated for 25° and one atm. press., the at. entropies : He, 29·83; Ne, 34·66; A, 36·70; Kr, 38·88; Xe, 40·23; and Nt, 41·81.

Lord Rayleigh[11] found a sample of helium from clevite had a **refractive index** of 0·146 (air unity) with white light; W. Ramsay and J. N. Collie obtained 0·135 with a purified sample; and W. Ramsay and M. W. Travers, 0·1238 for a sample of a high degree of purity. The last-named obtained for D-light a refractive index $\mu = 0·0000361$. W. Burton, and C. Cuthbertson and co-workers obtained values about 3 per cent. lower. W. Burton gave $\mu = 0·0_43510$ for light of wave-length $\lambda = 486·1\mu\mu$; $\mu = 0·0_43500$ for $\lambda = 587·6\mu\mu$; and $\mu = 0·0_43506$ for $\lambda = 656·3\mu\mu$. W. Burton represented his results by the formula $\mu - 1 = 0·0_43478(1 + 2·2 \times 10^{-11}\lambda^{-2})$, while C. Cuthbertson and E. P. Metcalfe gave $0·0_4347(1 + 2·4 \times 10^{-11}\lambda^{-2})$, and M. Cuthbertson gave $\mu - 1 = 2·42476 \times 10^{27}/(34991·7 \times 10^{27} - n^2)$, where $n = V/\lambda$, v denoting the velocity of light. C. Herrmann gave $\mu = 0·0_4353$ for $\lambda = 453·9\mu\mu$; and $0·0_43405$ for $\lambda = 643·8\mu\mu$. J. Koch obtained for ultra-violet light, $\mu = 0·0_436254$ for $\lambda = 237·9\mu\mu$; $0·0_435598$ for $\lambda = 334·2\mu\mu$; and $0·0_435138$ for $\lambda = 410·9\mu\mu$. C. Herrmann, and H. Erfle studied the dispersion of helium. K. F. Herzfeld and K. L. Wolff studied various dispersion formulæ for the inert gases. W. Ramsay and M. W. Travers measured the index of refraction

of mixtures of helium and hydrogen, and the results were about 3 per cent. higher than corresponded with the mixture rule ; a similar result was obtained with a mixture of hydrogen and carbon dioxide. W. Ramsay and M. W. Travers found that the index of refraction for neon with white light was 0·2345 (air unity), or $\mu = 0 \cdot 0_4 685$. C. and M. Cuthbertson gave for 0° and 760 mm. :

$$2(\mu-1)\times 10^6 \begin{cases} \lambda & . & . & 479\cdot9 & 508\cdot6 & 520\cdot9 & 546\cdot0 & 576\cdot9 & 579\cdot0 & 643\cdot8 & 670\cdot8\mu\mu \\ \text{Neon} & . & 134\cdot62 & 134\cdot46 & 134\cdot42 & 134\cdot32 & 134\cdot21 & 134\cdot21 & 134\cdot03 & - \\ \text{Krypton} & 863\cdot61 & 860\cdot68 & 859\cdot55 & 855\cdot48 & 855\cdot29 & 855\cdot22 & 851\cdot60 & 850\cdot66 \\ \text{Xenon} & . & 142\cdot57 & 141\cdot85 & 141\cdot58 & 141\cdot09 & 140\cdot58 & 140\cdot55 & 139\cdot78 & 139\cdot46 \end{cases}$$

They represented the results by $\mu-1 = 0 \cdot 0_4 666(1 + 2 \cdot 38 \times 10^{-11}\lambda^{-2})$ or by $\mu-1 = 2 \cdot 5936 \times 10^{27}/(38916 \times 10^{27} - n^2)$, when $n = V/\lambda$, V denoting the velocity of light. Lord Rayleigh gave for argon, with white light, 0·961 when air is unity ; and for D-light, $\mu = 0 \cdot 0_3 2828$. W. Burton represented his results by $\mu-1 = 0 \cdot 0002792(1 + 5 \cdot 6 \times 10^{-11}\lambda^{-2})$, and C. and M. Cuthbertson, $\mu-1 = 9 \cdot 124 \times 10^{27}/(16335 \times 10^{27} - n^2)$, where $n = V/\lambda$ as indicated above. F. Ahrberg gave $\mu = 0 \cdot 0002851$ for $\lambda = 435 \cdot 9\mu\mu$; 0·0002802 for $\lambda = 576 \cdot 95$; C. and M. Cuthbertson, $\mu = 0 \cdot 0002838$ for $\lambda = 479 \cdot 9\mu\mu$; and $\mu = 0 \cdot 0002808$ for $\lambda = 643 \cdot 8\mu\mu$; and W. Burton, $\mu = 0 \cdot 0002860$ for $\lambda = 486 \cdot 1\mu\mu$; and $\mu = 0 \cdot 0002829$ for $\lambda = 656 \cdot 3\mu\mu$. W. Ramsay and M. W. Travers studied binary mixtures of argon with air, oxygen, and nitrogen ; and for krypton, with white light, they gave 0·450 (air unity), or $\mu = 0 \cdot 000423$. C. and M. Cuthbertson's results are indicated above, and they represented their results by $\mu-1 = 0 \cdot 0004189(1 + 697 \times 10^{-11}\lambda^{-2})$, and by $\mu-1 = 5 \cdot 3446 \times 10^{27}/(12767 \cdot 9 \times 10^{27} - n^2)$, where n has the value indicated above. W. Ramsay and M. W. Travers gave 1·364 for the refractive index of xenon in white light, air unity ; or $\mu = 0 \cdot 000292$. The results of C. and M. Cuthbertson are indicated above, and they employed the formula $\mu-1 = 0 \cdot 0006823(1 + 10 \cdot 14 \times 10^{-11}\lambda^{-2})$, or $\mu-1 = 6 \cdot 1209 \times 10^{27}/(8977 \cdot 87^{27} - n^2)$, where n has the value indicated above ; and for krypton $\mu = 1 + 10 \cdot 945 \times 10^{27}/(13039 \times 10^{27} - n^2)$, or $1 + 12 \cdot 47 \times 10^{27}/(9140 \times 10^{27} - n^2)$. J. A. Wasastjerna calculated values for the atomic refraction equivalents of the inert gases and obtained for neon, 1·01 ; for argon, 4·23 ; for krypton, 6·42 ; and for xenon, 10·56. J. E. Calthrop made estimates of the refractivity and the size of the atoms. M. Czerny and G. Hettner studied the radiometer phenomena in argon and helium ; Lord Rayleigh, and J. Cabannes, the scattering of light by argon and helium ; W. H. McCurdy and A. Bramley, the effect of the glow discharge on the refractive index ; and C. P. Smyth discussed the relation between the refractivity and the mol. structure. W. H. Keesom and J. de Smedt studied the diffraction of X-rays in liquid argon ; and J. Cabannes and A. Lepape, the scattering of light by argon. The indices of refraction, and the **atomic refraction,** C. and M. Cuthbertson calculated, are :

	He	Ne	A	Kr	X
μ . . .	$0 \cdot 0_4 3465$	$0 \cdot 0_4 6663$	$0 \cdot 0_3 27729$	$0 \cdot 0_3 41860$	$0 \cdot 0_3 68180$

The **spark spectra** of the inert gases, with the exception of helium, are very rich in lines. Those of helium, neon, and niton are only slightly changed by the introduction of a Leyden jar into the circuit, those of argon, krypton, and xenon give different coloured spectra with and without the condenser. The general
FIG. 3.—Line Spectrum of Helium.

colour with helium is greenish-white ; with neon, orange-red ; and with niton, bluish-green. Argon, krypton, and xenon without the Leyden jar are respectively

red, greenish-lilac, and dark violet ; and with the condensed discharge, respectively blue, blue, and sky-blue. The blue spectra of argon, krypton, and xenon are mixtures of three spark spectra of successive orders. The line spectra of helium, neon, argon (red and blue), krypton, and xenon are shown in Figs. 3–7.

The spectrum of helium in sun and stars was discussed by H. Faye,[12] G. Rayet, J. N. Lockyer, E. Frankland and J. N. Lockyer, A. Secchi, H. L. d'Arrest, A. Cornu, H. A. Rowland, W. Huggins, G. E. Hale, C. A. Young, A. de Forest Palmer, R. Ricco, etc. The different spectra of helium are relatively simple and complete ; and the series arrangements are clear and definite, although the allocation of the sequence types is not yet definitely settled. Four spectral systems have been observed with helium : (i) The ordinary spectrum ; (ii) a spectrum corresponding with the enhanced type requiring a highly condensed discharge, and generally referred to ionized helium ; (iii) a spectrum far in the ultra-violet ; and (iv) a spectrum of the band type. The spectrum of helium has been examined by W. Ramsay and J. N. Collie, C. B. Bazzoni and J. T. Lay, J. F. Mohler and L. E. Jewell, W. Heuse, J. H. van Vleck, H. C. Offerhaus, A. L. Hughes and P. Lowe, Lord Rayleigh, P. Kunze, W. Ritz, C. V. Raman, J. Schniederjost, A. Hagenbach and H. Konen, E. Gehrcke and O. von Baeyer, H. M. Hansen and S. Werner, etc. ; the ultra-red spectrum, by F. Paschen ; the intensity relations of the arc spectrum lines with voltage, by C. B. Bazzoni and J. T. Lay ; and the spectrum excited by electronic bombardment, by A. Udden and J. C. Jacobsen ; the effect of the inert gases on the spectrum of nitrogen, by W. Steubing and M. Toussaint ; the effect of press., by L. W. Taylor, and R. T. Dufford and L. Thompson. The ordinary spark spectrum of helium was first measured by W. Crookes, and he gave for the yellow line, $\lambda = 5874 \cdot 5 A$, and P. T. Cleve gave $\lambda = 5875 \cdot 9 A$. The helium lines were accurately measured by C. Runge and F. Paschen between 7281 and 2644A, and by P. W. Merrill. The ultra-red spectrum was measured by F. Paschen. It was found by C. Runge and F. Paschen that all the lines could be arranged in two systems, one consisting of series of single lines, and the other of doublets with the weaker constituent on the red-side—usually the stronger constituent is on the blue-side. At first it was assumed that the two complete series systems represented two different elements. The one producing the doublet system was called helium, and the other producing the singlet system, *parhelium*. In connection with his work on stellar spectra, J. N. Lockyer called the latter *asterium*. The doublet and singlet systems are sometimes distinguished as He-I and He-II respectively. R. W. Merrill gave for the singlet series $\lambda = 27175 \cdot 17 - 109723 \cdot 2(m + 0 \cdot 862157 - 0 \cdot 010908 m^{-1})^2$; and for the doublet system, $\lambda = 29223 \cdot 88 - 109723 \cdot 2(m + 0 \cdot 996982 + 0 \cdot 001698 m^{-1})^2$. All the observed lines are included either in the main series of singlets or doublets, or accounted for as combinations. This subject was discussed by A. Fowler, J. S. Forster, W. E. Curtis, W. M. Hicks, A. Kratzer, Y. Takahashi, and L. S. Ornstein and H. C. Burger.

The two separate systems of spectral series produced by helium are said to belong to two forms of helium—*viz.* normal helium and **parhelium.** J. Hanck and F. Reiche said that the electronic orbits of the former are co-planar, and in the case of parhelium, they are supposed to be inclined at an angle as described by A. Landé. Parhelium is the less stable form and the ordinary ionizing potential is really that of parhelium. F. M. Kannenstine found that helium has an abnormal post-arc conductivity which persists for 0·007 second after the extinction of the arc, and the phenomenon was attributed to the formation of the so-called **metastable helium.** The valency electron of an atom in such a state is supposed to move in an orbit whose energy is greater than that of the normal orbit. This energy cannot escape from the atom without the co-operation of some external agent, most likely another atom, and a process involving two atoms is much less probable, other things being equal, than one involving a single atom. The phenomenon was studied by J. Franck and F. Reiche, T. B. Dorgelo, J. S. Forster, H. Nyquist, T. Takamine and H. Kokubu, A. Unsöld, A. J. Dempster, and M. Marshall. It is

estimated that the life of metastable helium is of the order 10^{-2} to 10^{-3} seconds. C. Eckart said that the phenomenon is not due to metastable helium at all but is produced by positive ions and their accompanying electrons. For the supposed isotope of helium—*isohelium, vide* **4.** 26, 14.

W. H. Pickering observed in the spectrum of the star ζ-Puppis a set of lines which were ascribed to hydrogen ; J. R. Rydberg made a study of these lines, and showed that the lines could be represented by $n = N\{2^{-2} - (m+0\cdot5)^{-2}\}$; and A. Fowler showed that the whole of the lines formed two series, one of which corresponded with W. H. Pickering's set. According to N. Bohr's theory of atomic structure, helium should exhibit a set of lines analogous to those of hydrogen, but involving · the constant $4N$ in place of N (*cf.* **4.** 27, 3). When the theory was modified with $n/(1+m/M)$ in place of N, where m denotes the mass of the electron, and M that of the nucleus, the series corresponded with those under observation. The work of A. Fowler, E. J. Evans, J. Stark, H. Rau, and J. S. Plaskett showed that W. H. Pickering's lines were probably due to the helium series $\nu = 4 \times 109723\cdot22(4^{-2} - m^{-2})$; and A. Fowler represented another series corresponding with $\nu = 4 \times 109723\cdot23(3^{-2} - m^{-2})$. These lines were further discussed by T. Lyman, H. A. Kramers and co-workers, and W. M. Hicks. N. Bohr's theory was later modified to allow for the increased effective inertia due to the moving field of the electron, and applied by A. Sommerfeld to the structure of these lines. The series spectrum of helium was discussed by L. S. Ornstein and H. C. Burger, R. A. Millikan and I. S. Bowen, M. Deslandres, R. Brunetti, S. Werner, E. O. Hulburt, L. B. Ham, L. Silberstein, N. Bohr, W. M. Hicks, S. Goudsmit and G. E. Uhlenbeck, R. S. Mulliken, F. Hund, F. Paschen, W. H. McCurdy, H. Bell, A. Landé, J. J. Hopfield and S. W. Leifson, C. V. Raman and A. S. Ganesan, A. Kratzer, and A. E. Ruark and co-workers. J. C. Slater emphasized the relations between the spectra of helium, hydrogen, the alkali metals, and the alkaline earth metals. F. Skaupy said that the spectrum of helium has a greater resemblance to the spectra of the alkali metals than to any other spectrum, and this is attributed to the presence of a negative helium ion. L. Janicki and E. Lau studied the effect of metallic surfaces on the spectrum of helium. The enhanced lines of the helium spectrum produced in strong electric fields were studied by T. R. Merton, W. Tschulanowsky, J. S. Foster, J. Stark, G. Liebert, and F. Paschen. The system of lines produced by the action of strong discharges on helium are assumed to be produced by the ionized gas He^+. The lines observed by T. Lyman far in the ultra-violet are represented by $\nu = 4 \times 109723\cdot22(2^{-2} - m^{-2})$, where m denotes 3, 4, 5, and 6. W. Grotrian, R. A. Millikan and I. S. Bowen, H. Fricke and T. Lyman, J. J. Hopfield and S. W. Liefson, J. C. McLennan and P. A. Petrie, H. B. Dorgelo and J. H. Arbink, T. Lyman, and L. Silberstein and A. C. Davies discussed the ultraviolet spectrum of helium. K. T. Compton and co-workers found that the ordinary and the parhelium lines are excited whenever the arc strikes, but the line $\lambda = 4686$ was never observed below 55 volts and was stronger above 80 volts. C. Déjardin found the band spectrum cannot be observed unless the press. exceeds 3 mm.; and the minimum voltage for its excitation is approximately 20·4 volts. At 3 mm. press., the lines 4686, 13203, and 2733 appear strongly at 80 volts, and they can be seen at 51 volts when the press. is 4–8 mm.; but they do not appear at 10 mm. press., presumably because the number of electrons which can acquire the minimum velocity required for double ionization at the higher press. is too small. F. J. von Wisniewsky computed the energy levels of the spectral lines of helium and neon. C. B. Bazzoni and J. T. Lay measured the voltages necessary to stimulate the different spectral lines of helium—*vide infra,* ionizing potentials.

A **band spectrum** of helium was observed about the same time by A. Fowler, A. W. Curtis, and E. Goldstein. The spectrum is said to include some conspicuous bands with single heads, others with double heads, and a number of complex regions in which no heads are recognizable at sight. The double-headed bands follow closely the series law, corresponding lines in each band being represented with

rough accuracy by ordinary series formulæ. W. M. Hicks added that it may be suspected that the supposed bands are only apparent and that the observed lines are analogous to the very large number of satellites which are conspicuous in the blue spectra of the inert gases from argon onwards; and that they may be representatives of the triplet series. The band spectrum was studied by. T. R. Merton and J. G. Pilley, and W. E. Curtis. W. E. Curtis and R. G. Long, W. A. McNair and W. H. McCurdy, and D. Burger examined the doublet bands of helium.

T. R. Merton and J. W. Nicholson, and C. B. Bazzoni and J. T. Lay, discussed the relative intensities of the spectral lines of helium; L. W. Taylor, and T. Takamine, the effect of press.; and B. Curry, the effect of current intensity. A. Udden and J. C. Jacobsen studied the excitation of the spectrum by electronic bombardment. A. A. Michelson, G. Berndt, A. Gray and co-workers, J. E. Purvis, H. Nagaoka, N. A. Kent and R. M. Frye, F. Paschen and E. Back, W. E. Curtis and W. Jones, P. Tartakowsky, H. P. Waran, A. Landé, and W. Lohmann investigated the **Zeeman effect** with helium lines; and H. Nyquist, U. Yoshida, A. Sommerfeld, J. S. Foster, and T. Takamine and N. Kokubu, the effect of an electric field, or the **Stark effect.** The broadening of the spectral lines analogous to the **Doppler effect** was examined by D. Fabry and H. Buisson, G. F. Hull, H. Rau, H. C. Urey, J. Stark and co-workers, E. Dorn, H. Gerdien and R. Holm, and H. M. Hansen and J. C. Jacobson. According to R. W. Lawson, a high frequency discharge has very little influence on the spectrum of helium. J. Stark, W. Tschulanowsky, J. S. Foster, and E. Böttcher and F. Fuczek studied the influence of an electric field on the spectrum; R. Seeliger and F. Pommering, the emission of light from the cathodic dark space; F. W. Aston and T. Kikuchi, the striations in the discharge tube; R. C. Johnson, the effect of argon and helium on the spectrum of hydrogen, etc.; K. W. Meissner, the effect of neon on the spectrum of helium; D. A. Keys, and M. S. Home, the effect of hydrogen and of nitrogen on the spectrum of helium; and J. C. McLennan and co-workers, the effects of helium on the spectra of various elements; J. Stark and G. von Wendt, and W. Wein, the spectrum of the positive rays; and F. J. von Wisniewsky, the K-series of the helium **X-ray spectrum.** H. B. Lemon found that helium plays only a secondary role in the spectra of comets' tails. J. C. McLennan obtained the auroral green line, 5577·35 ± 0·15A, in the spectrum of air mixed with an excess of helium—*vide* nitrogen.

W. Ramsay and M. W. Travers [13] found a yellow line λ=5849·6 to be characteristic of neon. The values of λ for the corresponding lines of sodium, helium, neon, and krypton are :

	Na	He	Ne	Kr
λ	5896·16	5876·209	5852·65	5871·12
λ	5890·19	5875·870		

The spectrum of neon is marked by the sharpness and homogeneity of its lines. There is a large number of lines in the red region, and a number of strong individual monochromatic lines. The lines were measured by G. D. Liveing and J. Dewar, E. C. C. Baly, H. E. Watson, L. St. C. Broughall, A. Pérard, H. Buisson and
FIG. 4.—Line Spectrum of Neon.

C. Jausseran, L. and E. Block and G. Déjardin, W. H. J. Childs, T. Lyman and F. A. Sanders, I. G. Priest, W. F. Meggers, G. S. Monk, K. Burns, W. H. J. Childs, K. Burns and P. W. Merrill, G. Wentzel, K. W. Meissner, F. Hand, P. Jordan, and F. Paschen. The more important lines of neon are shown in Fig. 4. K. W. Meissner

examined the ultra-red spectrum of neon, and also the absorption spectrum; and T. Lyman and F. A. Saunders, and H. B. Dorgelo and J. H. Arbink, the ultra-violet spectrum. H. E. Watson found that many of the strong lines of neon could be arranged in quadruplets or triplets. Fifteen such groups were found. R. Rossi found two doublet series. The great achievement with this element, added W. M. Hicks, is the allocation of the whole of the 840 measured lines, with the exception of about 50, to definite series. These have been discussed by A. Fowler, W. M. Hicks, F. Paschen, K. W. Meissner, H. Deslandres, S. Goudsmit, A. Sommerfeld, J. S. Foster, L. B. Ham, W. Grotrian, A. Landé and co-workers, G. Wentzel, etc. T. R. Merton found a second spectrum of neon is developed under the condensed discharge. M. R. and R. C. Johnson studied the variations in the intensities of the spectral lines of neon. The Zeeman effect was examined by W. Lohmann, E. Back, H. P. Waran, J. E. Purvis, H. Nagaoka, H. Nagaoka and T. Takamine; and the Stark effect, by H. Nyquist. The broadening of the spectral lines analogous to the Doppler effect was examined by C. Fabry and H. Buisson, and E. Dorn. K. W. Meissner studied the effect of helium on the spectrum of neon; F. W. Aston and T. Kikuchi, the striations in the discharge tube; H. B. Dorgelo, the distribution of energy over the lines in the series spectra; F. Holweck, the K-series in the X-ray spectrum; and G. Hertz and J. C. S. de Visser the excitation of spectral lines by electronic impact. L. Vegard and co-workers studied the spectrum of the light produced when mixtures of nitrogen and neon are bombarded with high velocity cathode rays of the temp. of liquid helium; and W. H. B. Cameron, the effect of neon on the spectra of carbon, oxygen, and nitrogen.

In their memoir on the discovery of argon, Lord Rayleigh and W. Ramsay [14] reported some measurements of the spectral lines. They regarded the red lines with λ=7056·4 and 6965·5 as being characteristic. The spectrum of argon was examined by H. F. Newall, W. N. Hartley, M. Berthelot, E. Dorn and H. Erdmann, H. Kayser, J. Trowbridge and T. W. Richards, J. R. Rydberg, G. Stead, A. Ladenburg and C. Krügel, A. Hagenbach and H. Konen, E. Warburg, J. E. Lilienfeld, A. S. King, F. Fischer and G. Iliovici, W. W. Shaver, K. W. Meissner, and G. Déjardin and co-workers. W. Crookes showed that argon furnishes two spectra: the one rich in red lines—called the *red spectrum*—is obtained without a condenser; and the other rich in blue and ultra-violet lines—called the *blue spectrum*—is obtained with a condenser. Many of the strong lines in the red spectrum appear in the blue spectrum with diminished intensity, or appear to be replaced by a number of weak lines in the immediate vicinity. W. Crookes measured 80 lines in the red spectrum and 119 lines in the blue. Twenty-six lines were common to both spectra. Other observations were made by J. M. Eder and E. Valenta, H. Kayser, H. Deslandres, P. Lowe and D. C. Rose, S. Friedländer, E. Paulson, A. Ladenburg and C. Krügel, C. Runge, W. F. Meggers, C. Runge and F. Paschen, F. Paschen, R. Nasini and co-workers, E. C. C. Baly, W. Stahl, J. Frommel, E. Gehrcke and O. von Baeyer, P. Lowe and D. C. Rose, K. W. Meissner, A. E. Ruark and
FIG. 5.—Red and Blue Line Spectra of Argon.

R. L. Chenault, and W. W. Shaver. The more important lines respectively in the red and blue spectra of argon are shown in Fig. 5. Many of the lines in the red spectrum were arranged by J. R. Rydberg, K. A. Nissen, and E. Paulson in quadruplets, some of which were incomplete; but neither F. R. Rydberg nor

H. Kayser, and C. Runge could trace typical series spectra. W. M. Hicks says that the spectrum shows definite systems of triplets, but the analysis is yet incomplete. E. Paulson, and K. A. Nissen also found some groups of lines in the blue spectrum. G. Berndt, A. A. Michelson, W. Lohmann, A. Dufour, J. J. Hopfield and G. H. Dieke, and O. Lüttig investigated the Zeeman effect with argon. The effect of an electric field, and the Doppler effect were examined by E. Dorn, W. Steubing, K. Friedersdorff, and E. Böttcher and F. Tuczek; the ultra-red spectrum, by R. Nasini, W. Meissner and co-workers, C. Runge, T. Lyman, T. Lyman and F. A. Saunders, F. A. Saunders, and J. J. Hopfield and S. W. Leifson; the X-ray spectrum, by L. A. Turner; D. Coster and J. H. van der Tuuk, the K-series in the X-ray spectrum; the spectrum of the electrodeless discharge, by H. Donaldson; the cathode spectrum, by P. G. Nutting; E. Böttcher and F. Tuczek, and T. Takamine and N. Kokubu, the effect of an electric field, or the Stark effect, and the effect of current density and capacity, by C. Sheard. The spectrum of the high frequency discharge was examined by R. W. Lawson; J. M. Eder and E. Valenta found in addition to the blue and red spectra of argon, a *white spectrum* obtained by the application of a very large condenser. Under press. of 2–10 mm. the third spectrum is distinguished by the fact that many of the lines peculiar to the blue argon spectrum appear more distinct, and others weaker, and that entirely fresh lines become visible. The red spectrum of argon disappears completely in low press. tubes, but appears again partially when the press. is increased. At 20 mm. press. many of the lines completely coincide with those of the red and blue spectra, but whole groups of lines show a displacement towards the red end of the spectrum, although the connection between these and corresponding lines of the blue spectrum is apparent. P. Zeeman and H. W. J. Dijk compared the spectra of ionized argon and potassium; and T. L. de Bruin and P. Zeeman found the relation is closer with the blue argon spectrum than with the red one. R. C. Johnson and co-workers, and A. G. Worthing and R. Rudy examined the effect of nitrogen on the spectrum of argon.

W. Ramsay and M. W. Travers,[15] the discoverers of krypton, made approximate measurements of 14 spectral lines. Other measurements were made by E. C. C. Baly, G. D. Liveing and J. Dewar, C. Runge, R. Schmidt, A. Ladenburg and C. Krügel, W. Ramsay, W. F. Meggers, L. and E. Block and G. Déjardin, J. N. Collie, O. Otsuka, and P. W. Merrill. The more important lines in the spectrum of krypton are shown in Fig. 6. Some describe the ordinary spark
FIG. 6.—The Line Spectrum of Krypton.

spectrum, without the Leyden-jar condenser, as greenish, others as lilac or lilac-grey. The condensed discharge is blue. E. Paulson, and P. W. Merrill found a number of pairs of lines in the condensed discharge, but definite series have not been established; W. M. Hicks found a number of triplets in the complex spectrum of krypton. W. Lohmann examined the Zeeman effect with krypton. The broadening of the spectral lines analogous to the Döppler effect was examined by C. Fabry and H. Buisson; and the X-ray spectrum by M. de Broglie and A. Lepape.

Measurements of the spectrum of xenon were made by E. C. C. Baly,[16] W. F. Meggers, P. W. Merrill, L. and E. Block and G. Déjardin, C. Runge, J. N. Collie, and G. D. Liveing and J. Dewar. The more important lines in the spectrum of xenon are shown in Fig. 7. Like argon, and krypton, xenon furnishes two spectra. The one, without a Leyden jar in the circuit, is blue, and relatively poor in lines;

and the other, with a Leyden jar in circuit, is greenish or greenish-violet, and rich in lines. E. Paulson, and W. M. Hicks found some triplets in these lines ; but no typical series have yet been recognized. L. A. Sommer has, however, arranged
FIG. 7.—The Line Spectrum of Xenon.

148 lines in pairs and groups. W. Lohmann examined the Zeeman effect with xenon ; B. B. Ray, A. Lepape and A. Dauvillier, and M. de Broglie and A. Lepape, the X-ray spectrum.

K. Fredenhagen [17] examined the effect of helium on the light absorption of sodium vapour ; R. W. Wood and J. Franck, the effect of helium on the resonance spectrum of iodine, and on the resulting fluorescence spectrum ; R. W. Wood also examined the effect of neon, argon, krypton, and xenon on the resonance spectrum of iodine. W. Ramsay and F. Soddy found that the inert gases are not radioactive. P. G. Nutting, N. Schoorl, K. von Auwers, C. C. Paterson, E. Liebenthal, F. W. Aston, A. Boltzmann and A. Basch, R. A. Brockbank and L. E. Ryall, A. Palme, and E. Karrer and A. Poritsky showed that the yellowish-white light emitted by helium in a discharge tube is well suited for photometric work. He studied variations in the **luminosity** of the gas with current, potential gradient, gas density, frequency of alternation of current, orientations of tube and diameter of capillary. J. Taylor and W. Stephenson, J. C. McLennan and G. M. Shrum, P. G. Nutting and O. Tugman examined the luminosity of tubes containing argon, helium, and hydrogen. L. Vegard found solid argon to be luminous when bombarded by cathode rays below 237·5°. S. O. Pearson and H. S. G. Anson found that the resistance of the neon tube increases as the current decreases. There is a critical voltage below which the lamp does not glow. No current passes when the lamp is not glowing. If the voltage is just above its critical value the lamp will glow even though only a fraction of a microampère is passing. The intensity of the glow decreases with the current. H. E. Watson found that the current passing through the lamp is intermittent when the anode is in the dark space, and the current density is low. J. W. Ryde, and B. N. Ghose showed that the whole of the light from these tubes comes from the negative glow, the electrodes being so close together that the positive column is absent. He also studied the variation in the resistance of the tube with current ; and the relation between the intensity of the lamp with current. A. L. Foley examined the effect of the exposure of the five inert gases to ultra-violet light and to X-rays, on the spectra ; M. N. Saha, the temp. radiation of helium, etc. ; H. E. Watson, the physiological effect of the light from the helium tube. The inert gases have been advantageously employed in the filling of bulbs, etc., for illuminating and other purposes. This, said F. Schröter,[18] is because of their high luminosity during the passage of an electric current, their high electrical conductivity, and their small heat conductivity in comparison with other gases. This subject has been discussed by O. von Auwers, G. Claude, W. R. Cooper and P. C. Hewitt, H. Danzer, F. Dorn, J. Elster and H. Geitel, H. Greinacher, A. Gunther-Schulze, T. Hamburger, P. Hardegen, H. Harting, K. Hellmuth, L. K. Hirshberg, G. Holst and E. Oosterhuis, J. C. McLennan, R. B. Moore, J. Nienhold, P. G. Nutting, U. A. Oschwald and A. G. Tarrant, J. Pintsch, M. Pirini and A. R. Meyer, W. Ramsay and G. Rudorf, I. Rosenthal, O. Schaller, N. Schoorl, B. E. Shackelford, F. Skaupy, H. C. Snook, E. Urbain, C. Scal and W. Feige, H. E. Watson, L. Zehnder.

H. Dember [19] examined the relation between the **photochemical effect** and the cathode fall of potential with an alkali electrode in various gases. The cathode fall was larger in helium than in hydrogen, or in argon. J. Elster and H. Geitel

constructed a photoelectric cell with potassium and helium or argon; and
J. Rosenthal, a rubidium-helium cell. K. Bergwitz, and P. P. Koch also made a
study of these cells. V. L. Chrisler examined the photoelectric effect with a number
of metals—Al, Sb, Bi, Cd, Fe, Pb, Ni, Pt, Ag, Sn, Zn—in helium and found it to
be much less than in hydrogen. He inferred that if the metals were quite free
from hydrogen no effect would occur in an atm. of helium. J. S. Townsend and
S. P. McCallum studied photoelectric currents in helium; and U. A. Oschwald
and A. G. Farrow, in neon. P. Auger obtained evidence of the emission of photo-
electrons by means of the photographic cloud method, with a beam of X-rays in
argon, krypton, and xenon. F. L. Mohler studied the photoionization of neon and
argon.

J. N. Collie and W. Ramsay [20] measured the distance through which electric
sparks from an induction coil strike in helium and argon. The distance with
argon is greater than with air, oxygen, or hydrogen; while with helium the spark
can pass very large distances. Thus:

			O_2	Air	H_2	A	He
Sparking distances	.	.	23·0	33·0	39·0	45·0	250–300 mm.
Change to ribbon .	.	.	81	73–74	42–43	—	1270 mm.

The press. at which the spark discharge changes to a ribbon discharge is
also indicated. Helium, unlike other gases, exhibits the phenomena of a vacuum
tube discharge at ordinary atm. press. R. J. Strutt found the minimum sparking
potential in helium to be about 230 volts., and noticed that for a definite spark
length, the press. in helium is about five times greater than in air. The presence
of impurities in the gas has a great influence on the results. J. S. Townsend and
H. E. Hurst found a relation between the conductivity and sparking potential with
the gap between the electrodes. Measurements were also made by H. E. Watson.
E. W. B. Gill and F. B. Pidduck tested the relation, and measured the minimum
voltage required to produce a spark in argon or helium, and the conductivity at
various press. Argon is more readily ionized than air by both positive and negative
ions. Helium is much more readily ionized than hydrogen. It was found that after
the passage of one spark a higher potential was required to pass another immediately
afterwards; the passage of a spark in the reverse direction facilitated recovery.
E. R. Stockle measured the sparking potential of argon under reduced press.
F. Ritter found that the ratio of the sparking potentials of helium and air diminishes
as the sparking distance and press. increase. The curves obtained by plotting
sparking potential against sparking distance are concave to the horizontal axes
for all gases excepting helium when the curve is a straight line. S. P. McCallum
and C. M. Focken studied the current-voltage relation with neon; J. S. Townsend
and S. P. McCallum, with helium; and R. Rudy, the transition to the arc stage
in discharges through argon. F. Soddy and T. D. Mackenzie found that non-con-
ductance equivalent to that represented by an inch gap in air at atm. press. was
attained at the following press. :

			He	A	Ne	H_2	N_2	CO_2
Press. in mm.	.	.	0·35	0·04	0·07	0·03–0·04	0·035	0·02

Mercury vapour resembles helium in the high press. at which it ceases to be con-
ducting. The difference between helium and other gases is one of degree only;
the monatomic gases being inert chemically and electrically.

K. T. Compton and co-workers found the arcing voltage of helium under various
conditions of gas press. and voltage. The arc could be made to strike at the
minimum voltage of 20 volts, but the arc could be maintained under favourable
conditions at 8 volts with a gas press. of 5 mm. and a current of about one ampère.
F. M. Kannenstine, and F. A. Thees examined the effect with an alternating current.
E. Warburg, T. E. Foulke and co-workers, A. Moskvin, and J. P. Ewers investi-
gated the discharge in helium and argon; K. Przibram, the brush and oscillating

and H. A. Jones; T. L. R. Ayres discussed the ionization of argon by collision; and F. Horton, the effect of impurities on the velocity of the ionization of helium. V. L. Chrisler concluded from observations on the absorption of helium in discharge tube that the negative helium ions exist; F. Skaupy, from spectroscopic observations. L. Hamburger inferred that the negative ion may contain a number of atoms. The ionization press. in helium, neon, and argon was measured by R. T. Beatty, J. Franck, and G. Hertz; the absorption of a-rays, by N. Bohr; the scattering of a-rays, by E. Rutherford and J. M. Nuttall; the range of the a-particles in the five inert gases, by L. B. Loeb and E. Condon, R. H. Fowler, G. H. Henderson. S. Rosseland, and L. F. Bates; the production of δ-rays by a-particles, by J. Chadwick and K. G. Eméleus; and the β-rays associated with scattered X-rays in argon, by J. M. Nuttall and E. J. Williams. The secondary cathodic radiation in helium was examined by W. Kossel; the absorption coeff. for electrons in helium, and argon, by A. Becker, R. B. Brode, and J. Robinson; the mobilities of the positive ions in helium, by H. B. Wahlin; the diffusion in neon, by T. E. Foulke and W. H. McCurdy; and in argon, by H. A. Erickson; the velocity of cathode rays in helium, and argon, by P. Lenard; the effect of helium and neon on cathode and anode rays, by R. Rudy; the influence of press. on the passage of X-rays, by C. L. and F. A. Lindemann; and ionization by photoelectrons, by J. T. Tykociner and J. Kunz. According to P. Auger, when X-rays are passed into pure argon only secondary β-rays are produced, but, if the argon is diluted with hydrogen, tertiary β-rays of a few millimetres range are also formed. In krypton diluted with hydrogen, the tertiary rays have a range comparable with that of the secondary rays, and there are traces of quaternary β-rays. The tertiary rays start from the same origin as the secondary and are distinguished from the latter in that they are not affected by changes in the tension of the exciting X-rays.

According to F. Horton and A. C. Davies, radiation occurs when electrons impressed by a velocity of about 20·5 volts—resonance potential—collide with helium atoms, but this is not accompanied by any ionization of the gas. The ionization occurs—ionization potential—when the velocity is raised to 25·7 volts. The positive ions from a glowing filament do not ionize helium when they collide with helium atoms up to 200 volts, but they liberate electrons from a negatively charged platinum surface when they bombard it with velocities greater than 20 volts. J. Franck and P. Knipping gave 20·5 ± 0·25 volts and 25·3 ± 0·25 volts respectively for the resonance and ionization potentials of helium. W. de Groot studied the resonance of neon. According to W. M. Hicks, for helium the preliminary potential required to raise one electron to the radiating state is 20·8 volts; and to raise the second electron to this state after the ejection of the first, 45·7 volts. The true radiation potentials are therefore 1·14 and 7·4 volts, and the observed radiating potentials are 21·9 and 73·9 volts; while the true ionizing potentials are 4·75 and 13·5 volts, and the observed volumes are 25·6 and 80 volts. W. H. McCurdy studied the resonance potential of helium. For neon, its radiating potentials are 11·8 and 17·8 volts; and the ionizing potentials 16·7, 20·0, and 22·8 volts; for argon, the radiating and ionizing potentials are respectively 11·5 and 15·1 volts. W. P. Jesse said the maximum ionization occurs at 140 volts with helium; 220 volts with neon; and 100 volts with argon. The ionizing potentials of argon, etc., were investigated by J. C. McLennan, F. Horton and co workers, E. G. Dymond, G. Déjardin, F. Holweck, G. Hertz, A. L. Hughes and A. A. Dixon. A. L. Hughes and E. Klein, K. T. Compton and co-workers, H. D. Smyth and H. A. Barton, H. A. Barton, L. A. Turner, C. G. Found, H. C. Rentschler, G. Stead and B. S. Gossling, C. A. Mackay, J. Franck and P. Knipping, F. S. Goucher, F. L. Mohler, L. S. Palmer, F. Strewe, E. R. Stoekle, R. Seeliger and E. Schramm, C. B. Bazzoni, and J. Franck; the critical electron velocities, by F. Holweck, and F. Horton and A. C. Davies; the ionizing potential of helium was discussed by A. C. Davies, L. Silberstein, F. M. Kannenstine, E. G. Dymond, G. Glockler,

G. Déjardin ; that of neon by G. Hertz F. L. Mohler, F. Holweck, and G. K. Rollefson ; that of krypton by G. Déjardin ; and G. Glockler found 10 volts for niton. G. Hertz and co-workers gave :

	He	Ne	A	Kr	X
Resonance potentials . . .	19·77	16·6	11·5	9·9	8·3
	20·55	18·5	13·0	10·5	9·9
	—	—	13·9	11·5	11·0
	—	—	—	12·1	—
Ionizing potentials . . .	24·5	21·5	15·4	13·3	11·5

The motion of electrons in helium and the other inert gases was discussed by F. Horton, H. Compton, L. St. C. Broughall, H. A. Erikson, L. B. Loeb, H. B. Wahlin, H. R. Hassé, H. Sponer, R. Minkowsky and H. Sponer, V. A. Bailey, J. C. McLennan and E. Evans, and J. S. Townsend and V. A. Bailey ; and G. P. Thomson, the free path of protons in helium. C. G. Found and S. Dushman investigated the relation between the ionization current and the number of electrons per molecule of neon and helium ; and W. W. Merrymon, the effect of press. on the residual ionization of helium. The active cross-sections of mols. of the inert gases for the absorption of slow electrons were shown by C. Ramsauer to exhibit a maximum with increasing electron velocity which for neon, argon, krypton, and xenon is 13, 82, 98, 141 sq. cm. per c.c. at 0° and 1 mm. press. respectively. The active cross-sections for electrons of 1 volt. press. were for hydrogen 1260×10^{-18} cm., and for argon and helium respectively 75×10^{-18} and 550×10^{-18}. A. J. Dempster, C. Ramsauer, and R. B. Brode estimated the mean free path of electrons in argon, and helium. The energetic relations in collisions between electrons and gas molecules show that, in general, the process is essentially non-mechanical. The slow electrons in rare gases possess free-paths longer than would be anticipated from the kinetic theory. I. Langmuir, E. G. Dymond, and W. Elsasser studied the angles of scattering after collision. H. F. Mayer, F. M. Kannenstine, and A. J. Dempster discussed the life of metastable, partially ionized helium—*vide supra*. L. St. C. Broughall calculated the frequency of the electrons in the neon atom ; and W. Kossel found the luminosity of the discharge depends on electronic movements. S. P. McCallum and C. M. Focken measured the rate of increase of current due to ionization when the electrons are produced by a heated filament, and by ultra-violet light ; and they compared the effects of ionization by collision with that due to radiation. J. J. Thomson examined the radiation produced by the passage of cathode and anode rays through argon.

T. Alty [22] studied the cataphoresis of bubbles of helium in water. E. Hochheim found the **dielectric constant** of helium at 15° and 735 mm. to be 1·000068 ; and at 0° and 760 mm., 1·000074. C. and M. Cuthbertson gave 1·0000693 ; and M. Wolfke and H. K. Onnes, 1·048 for liquid helium at −268·8° and 765 mm. G. L. Addenbrooke studied the relation between the dielectric constant and the optical properties of helium—liquid and gas. E. Lehrer observed no change in the dielectric constant of argon with variations of press. ; and B. B. Weatherby and A. Wolf no change with helium in a magnetic field. G. Jung discussed the orientation of the molecules in the five inert gases considered as dielectrics. P. Tänzler found helium to be feebly diamagnetic, and gave -0.00175×10^{-3} for the **magnetic susceptibility** ; A. P. Wills and L. G. Hector gave -0.80×10^{-10} for the vol. susceptibility of helium ; L. G. Hector gave -0.780×10^{-10} for helium ; 2.77×10^{-10} for neon ; and -7.52×10^{-10} for argon at 20° and 760 mm. T. Soné gave -5.86×10^{-6} for the sp. susceptibility of argon at 20°, and 0.0104×10^{-6} for the vol. susceptibility. L. Crow gave -31.5×10^{-6} and -32.8×10^{-10} for the respective mass and vol. susceptibilities of krypton at 20° and 760 mm. ; and respectively -58.2×10^{-6} and -16.2×10^{10} for xenon. G. Joos and W. Pauli studied the atomic structure to account for the diamagnetism of the rare gases.

§ 5. The Chemical Properties of the Inert Gases

The term inert gases is applied to this family of elements because of their chemical indifference towards other elements. The small density of helium and its. chemical inactivity—*e.g.* its non-inflammability—make it better suited than hydrogen for filling air-ships. The subject was discussed by H. Erdmann, J. C. McLennan,.

G. S. Rogers, C. Porlessa, C. Loeser, G. Gallo, W. S. Andrews, etc. The inflam-
mability of mixtures of hydrogen and helium was studied by P. G. Ledig,[1] and
J. Satterly and E. F. Burton. A mixture of helium with 15 per cent. of hydrogen
is non-inflammable and non-explosive. The supplies of helium associated with
natural gas are a convenient source of helium in Canada, and the United States.
Other applications of the inert gases have been previously indicated—e.g. in place
of hydrogen in thermometry; helium with a b.p. of $4.21°$ K. has been used as a
cryoscopic agent in the study of the properties of matter in the vicinity of absolute
zero; and neon, etc., have been used in bulbs for electrical discharge to be employed
for illuminating and other purposes. The use of an artificial atmosphere, with
inert gases in place of nitrogen, is indicated below.

W. Ramsay[2] gave 0·0073 for the coeff. of absorption of helium in water at
18·2°; and 0·0394 for argon at 12°, and 0·0405 at 13·9°. Lord Rayleigh found
100 c.c. of water dissolve 4·05 c.c. of argon at 13·9°. T. Estreicher determined the
solubility of helium and argon in water, and obtained the results indicated in
Table VII, expressed in S, the weight of gas taken up by 100 grms. of solvent
at a press. of 760 mm. which includes the partial press. of the gas plus that of water;

TABLE VII.—THE SOLUBILITIES OF HELIUM AND ARGON IN WATER.

	Helium.				Argon.

β, the absorption coeff. representing the vol. of gas at 0° and 760 mm. absorbed by
one vol. of the liquid. The data were also examined by C. J. J. Fox, and A. von
Antropoff. H. P. Cady and co-workers measured the solubility of helium and
found no minimum on the curve. A. von Antropoff obtained the solubilities of
neon, krypton, and xenon, and the results are indicated in Table VIII. Excepting

TABLE VIII.—SOLUBILITIES OF THE INERT GASES IN WATER.

Temp.	He	Ne	A	Kr	X
0°	0·0134	0·0114	0·0561	0·1207	0·2189
10°	0·0100	0·0118	0·0438	0·0921	0·1500
20°	0·0138	0·0147	0·0379	0·0729	0·1109
30°	0·0161	0·0158	0·0348	0·0679	0·0900

50°	0·0226	0·0317	0·0343	0·0716	0·0878

neon, the solubilities increase with increasing at. wt. The data for neon and

krypton are less accurate than those of the others. Minima occur at 10° for helium, 0° for neon, 40° for argon, 35° for krypton, and 40° for xenon. T. Estreicher gave 25° for the minimum with argon. The solubilities of helium and argon were discussed by L. W. Winkler, W. M. Tate, and T. E. Thorpe and J. W. Rodger. P. Villard considered that an *argon hydrate* existed with a dissociation press. of 150 atm. at 0°, and 210 atm. at 8° ; R. de Forcrand calculated A.5·14–5·50H$_2$O for the formula at 8° ; vap. press., 98·5 atm. at 0°–0·4°, and 210 atm. at 8° ; and heat of formation, 14·855 Cals. He also reported *krypton hydrate*, Kr. 5·08H$_2$O ; vap. press. 14·5 atm. at 0°, 23·5 atm. at 4·8°, 38·7 atm. at 10·3°, and 47·5 atm. at 12·5° ; heat of formation, 14·712 Cals. between 0° and 12° ; and the critical point of decomposition, 12·5°–13·0°. The dissociation press. of *xenon hydrate* is 1·15 atm. at 0°. The heat of formation from liquid water is 18·266 cals. No *neon hydrate* was formed at 260 atm. press. at 0°. The dissociation pressures of the hydrates Kr.5H$_2$O, and of A.5(or 6)H$_2$O, were discussed by G. Tammann and G. J. R. Krige.

W. Ramsay found that liquid oxygen at −205° dissolves one part of helium in 80 parts, and a small amount of argon in the *oxygen* raises the solubility. Neon is less soluble than argon in liquid oxygen. He also found that helium is insoluble in *benzene* and in *alcohol*. M. Berthelot said that argon is not absorbed by members of the fatty series of organic compounds, but with members of the aromatic series, absorption varied from 8 per cent. by volume for benzene, and one per cent. for *aniline*. A. von Antropoff measured the solubility of krypton and xenon in *pentane*, and of krypton in *acetic acid*, and aniline. P. Régnard and T. Schlösing found that a litre of *blood* absorbs 25·3 c.c. of argon ; G. Gaertner said that nitrogen at high press. is the cause of diving sickness, whilst pure oxygen at press. above 2·5 atm. acts on the lungs as a rapid poison. Helium is innocuous and suitable for the dilution of the oxygen. The subject was discussed by R. R. Sayers and co-workers. J. D. Edwards and S. F. Pickering found that if the permeability of *rubber* to hydrogen be unity, the value for argon is 0·26, and helium 0·65—*vide supra*, diffusion. F. Garelli observed no definite depression of the f.p. when helium is dissolved in several organic solvents.

The **occlusion** of helium by glass electrical discharge tubes was discussed by A. A. C. Swinton,[3] B. Hodgson, N. R. Campbell and J. W. H. Ryde, R. Pohl, and F. Soddy and T. D. Mackenzie. J. Plücker noted that when a discharge tube has been running some time, the gas press. becomes progressively lower with the continuation of the discharge. S. Brodetsky and B. Hodgson favour the view of older workers that the phenomenon is due to the absorption of gas by the metal of the cathode, but add that the disintegrated part is the effective absorber. S. E. Hill found that the phenomenon occurs even with electrodeless tubes, and hence the glass wall of the tube is the absorber. A. A. C. Swinton concluded that the gas is driven into the glass by the discharge so that when the glass is subsequently melted, the gas collects as small bubbles as previously observed by L. G. Gouy, and by P. Villard. The depth of the absorption layer did not exceed 0·015 mm. S. E. Hill, and R. S. Willows attribute the effect to chemical action between the glass and the gas. W. Ramsay found helium, a trace of neon, and hydrogen in the glass of an old X-ray bulb ; and A. N. Goldsmith found that high speed molecules of helium and hydrogen can penetrate a mica sheet 0·001–0·006 mm. thick under conditions where air, argon, or carbon dioxide cannot penetrate. G. Claude noted the occlusion of neon by the metal spluttered from the metal cathode of a discharge tube. With a mixture of helium and argon, M. W. Travers found that the latter is more readily absorbed than the former gas. The absorption of argon by magnesium, aluminium, or platinum under similar conditions was discussed by L. Troost and L. Ouvrard, J. M. Eder and E. Valenta, S. Friedländer, B. Brauner, and V. Kohlschütter and co-workers. The occlusion of helium, and argon by solid and liquid metals—Cu, Au, Ni, Fe, Pd, U, Ta—by A. Sieverts and E. Bergner, R. W. Lawson, and A. Jaquerod and F. L. Perrot, and Lord Rayleigh and W. Ramsay found argon is not absorbed by platinum black ; and W. Ramsay and

J. N. Collie, and A. F. Benton found that helium is not absorbed by that substance. The occlusion of helium by glass, porcelain, or quartz was studied by A. T. Cameron and W. Ramsay, A. Jaquerod and F. L. Perrot, B. Iliin, and A. Sieverts and E. Bergner—*vide* glass and quartz glass. A. Lo Surdo found hydrogen, helium, and neon are able to pass through hot glass, and G. A. Williams and J. B. Ferguson, E. Cardoso, H. M. Elsey, and C. C. van Voorhis, have discussed this subject. A. Piutti and E. Boggio-Lera found that at 480°, helium cannot traverse thin sheets of mica or thin sections of quartz cut either parallel or perpendicular to the optic axes, though it is able to pass through both ordinary and silica glasses—these glasses are liquids of high viscosity. The occlusion by charcoal has been investigated by J. Dewar, and J. F. Homfray—*vide* carbon ; the occlusion of neon, etc., by J. Dewar, W. Ramsay, H. E. Watson, and S. Valentiner and R. Schmidt ; of argon, by J. Dewar, and J. F. Homfray.

It is not certain that any chemical compound of the inert gases has been yet prepared. W. Ramsay and J. N. Collie [4] said that if combination occurs, the reaction will be endothermal. No method known for the preparation of endothermal compounds has given any result. It is, therefore, assumed that argon and helium cannot form chemical compounds, and that their valency is zero. This view was supported by J. Thomsen, and M. Berthelot—*vide infra*. The chemical affinity of the rare gases is not necessarily zero under all conditions, even though they appear to be so under ordinary conditions. In discussing the architecture of the atom—**4**. 27, 3—it was shown that atoms like the inert gases, supposed to possess two or eight external electrons, are particularly stable, and null-valent. Helium has two electrons belonging to the external or K-ring or K-shell—Fig. 7, **4**. 27, 3—and when bombarded by cathode rays one of these might be knocked off. When a new electron darts back, it may not get into the K-ring at once, but be less firmly bound in some metastable position farther out. Under these conditions the atom of helium might appear to act like an atom of hydrogen. Thus, J. J. Thomson observed particles of mass 5 in the gas which had been in contact with radium chloride for 13 years ; and F. W. Aston observed particles of mass 5 in his examination of helium. It was supposed that these particles are molecules of **helium hydride,** HeH.

Lord Rayleigh and W. Ramsay found that no combination occurs when argon is subject to the electrical discharge in the presence of oxygen, water, and dry or moist chlorine. At a red heat sulphur, phosphorus, tellurium, and sodium have no action on the gas ; soda-lime, sodium peroxide, molten sodium hydroxide or nitrate are without action. Liquid oxidizing agents—bromine-water, a mixture of potassium permanganate and hydrochloric acid, and aqua regia are without action. Copper, copper oxide, and magnesium at a red heat have no action. T. Schlösing said that heated magnesium absorbs argon ; but R. Nasini and F. Anderlini, and H. von Wartenberg observed no evidence of this at 1500°–2000°. T. Schlösing found cupric oxide, porcelain, asbestos, copper, and steel have no action on argon. H. Moissan detected no sign of combination between argon and titanium, boron, uranium, or lithium ; and C. Matignon, none with thorium, cerium, lanthanum, praseodymium, neodymium, or samarium. W. Ramsay thought that carbon and argon could enter into combination. In 1896, M. Berthelot reported that when argon or helium is submitted to the silent electric discharge in the presence of benzene or carbon disulphide, the gas is absorbed, and a solid substance is deposited on the walls of the containing vessel. When this solid is heated, the gas is given off again. This was taken to prove that helium and argon can form chemical compounds. R. J. Strutt showed that the solid product with carbon disulphide is a decomposition product of that compound, and that very little helium is absorbed mechanically or chemically. This was confirmed by W. Crookes, W. Ramsay and J. N. Collie, H. Deslandres, and E. Dorn and H. Erdmann. According to R. J. Strutt, the little absorption which takes place may be likened to the absorption of helium by the aluminium scattered from the

cathode of a vacuum discharge tube observed by F. Soddy and T. D. Mackenzie. There is no ground for assuming that helium is chemically absorbed by carbon disulphide under the influence of an electric discharge. Helium is slightly absorbed by phosphorus under electric discharge, but in much less quantity than is hydrogen or nitrogen.

W. Ramsay found that helium is not absorbed by heated cupric oxide, or magnesium ; and no change occurs when a mixture of helium and oxygen is sparked in the presence of potassium hydroxide. W. Ramsay and co-workers demonstrated that red-hot uranium absorbs no helium, and W. Ramsay and J. N. Collie found that at a red-heat sodium, sulphur, selenium, silicon, zinc, cadmium, thallium, tin, lead, phosphorus, arsenic, antimony, bismuth, or cobalt ; or a mixture of magnesium dust and the oxide of beryllium, boron, yttrium, titanium, thorium, or uranium has no action on helium. The silent electric discharge produces no result with a mixture of helium and chlorine. Helium at a red-heat has no action on a mixture of soda-lime with nitre or sulphur. Benzene vapour does not react with helium.

F. Fischer and co-workers tried if sparking between metal cathodes under liquid argon would produce a chemical compound, but in no case was such formed. The metals tried were—Li, Na, K, Rb, Cs, Cu, Ag, Au, Be, Mg, Ca, Sr, Ba, Zn, Cd, Hg, B, Al, In, Tl, C, Si, Ti, Zr, Ce, Th, Sn, Pb, V, Cb, Ta, As, Sb, Bi, Cr, Mo, W, U, Te, Mn, Fe, Co, Ni, Pd, Ir, and Pt. The spluttering of metal cathodes in the inert gases was studied by E. C. C. Baly, W. Crookes, S. Valentiner and R. Schmidt, and V. Kohlschütter and co-workers. The relative degrees of spluttering of different metals in argon, helium, etc., reported by V. Kohlschütter and co-workers are as follow :

				Al	Fe	Cu	Pt	Ag	Au
Hydrogen	.	.	.	0	0	0·23	0·23	0·27	0·5
Helium	.	.	.	0	1	0·1	0·1	0·4	0·25
Nitrogen	.	.	.	0	0	0	0·3	0·4	1·1
Oxygen	.	.	.	0	0·1	0·35	1·2	2·05	3·3
Argon	.	.	.	0·15	0	0·4	1·9	4·1	9

The spluttering was considered to be due to a chemical process. The subject was also discussed by F. Fischer and co-workers, J. Stark, and B. Walter, without any definite conclusion being evident. According to W. T. Cooke, the vapour density of zinc in argon being 12 per cent. higher than in nitrogen, it may be concluded that zinc and argon have a distinct tendency to form a compound. This tendency is found to exist also in the case of cadmium and helium, mercury and argon, mercury and helium, selenium and argon (slight), selenium and helium (slight). H. von Wartenburg considered that there is no evidence of combination ; the results with bismuth, lead, and zinc are normal within the limits of experimental error. J. J. Manley reported that in presence of an electric glow discharge mercury and helium can be made to combine, forming *mercury decahelide*, $HgHe_{10}$, as a stable substance, which decomposes at a bright red-heat. J. J. Manley added that the formation of the helide is accompanied by a decrease in the press. of the helium. The maximum decrease in press. during any synthesis was never greater than 3·3 per cent. of the initial press. of 6 mm. As the synthesis progressed, the refractive index of the mixture became somewhat greater than that of the helium alone. At ordinary temp. the helide possesses stability ; but on passing the gas over a red-hot platinum spiral it is completely resolved into its components ; and as a result of the decomposition the helium is restored to its original vol. and press. The compound is neither liquefied nor absorbed by charcoal at the temp. of liquid air. The helide is most readily formed when the press. of the helium approximates 6 mm. of mercury. J. J. Manley prepared a second helide, *mercury monohelide*, HgHe. This is a gas of density 1·150 (helium unity). It is gaseous at the temp. of liquid air, it is not absorbed by charcoal ; and it is decomposed by passage over a red-hot platinum spiral. E. H. Boomer examined mixtures of helium with mercury, iodine, sulphur, and phosphorus vapours under the influence of electron

bombardment and in the presence of surfaces cooled by liquid air. The helium disappears more quickly than under the ordinary conditions in a discharge tube. Solid substances, believed to be compounds of helium, were obtained which suddenly liberate the original amount of helium when warmed to —70° in the cases of *mercury* and *sulphur*, and —125° in the case of *phosphorus*. The vap. press. at —185° are of the order of 0·0005 mm. E. H. Boomer also found that when helium is subjected to an intense electronic bombardment (1000 volts,.5 to 10 milliamp.) at low press. in the presence of a heated tungsten filament, both helium and tungsten disappear and a black deposit is formed. In general, the atomic ratio between the loss in weight of the filament and the loss of helium was 1 : 2, but the proportion of tungsten was increased when a large amount of mercury was present in the discharge tube. In nitric acid or potassium hydroxide, the black deposit was decomposed with the evolution of helium, and the formation of tungstic oxide or a clear soln. If the ratio of tungsten to helium which had disappeared was greater than 1 : 2, only the amount of tungsten necessary to form **tungsten helide**, WHe_2, was dissolved from the black deposit in potassium hydroxide, the tungsten in excess of this ratio remaining in the metallic state. The rate of disappearance of helium was greatest in the press. range 0·1 to 0·45 mm., reaching a value 4 to 5 c.cm. helium at n.p. θ per minute. The velocity of the reaction decreased as the discharge voltage was decreased, and was markedly affected by the material composing the leads, or by the presence of mercury vapour. A. Günther-Schulze inferred from his observations on the cathode fall of potential with mixtures of oxygen with argon and with helium, that reactions do occur though the products cannot be isolated. S. C. Lind and D. C. Bardell could get no evidence of the combination of mercury and helium bombarded by radium rays ; but they found that helium, neon, and argon act catalytically in accelerating the polymerization of acetylene, cyanogen, and hydrogen cyanide, and the synthesis of water.

§ 6. The Atomic and Molecular Weights of the Inert Gases

The **molecular weight** of helium obtained by H. E. Watson[1] from the relative density is 3·99; or, calculated from the limiting density, 3·998. W. Heuse gave 4·002; G. P. Baxter and H. W. Starkweather, 4·000; and J. J. van Laar, 3·9998; H. E. Watson found that the mol. wt. of neon is 20·20; and F. W. Aston, 20·19. M. C. Neuberger calculated 3·00113 for the at. wt. of iso-helium. The relative density of argon likewise furnished H. E. Watson, 39·881; J. J. van Laar, 39·95; and P. A. Guye, 39·866. H. E. Watson gave 82·955 for the mol. wt. of krypton, and R. B. Moore, 130·82 for that of xenon, or 130·71 calculated from the compressibility. From the ratio of the sp. hts. of helium it follows that the **atomic weight** and mol. wt. are probably the same; *i.e.* the mol. is monatomic. W. Ramsay obtained a similar conclusion with respect to neon. Lord Rayleigh and W. Ramsay likewise showed the at. wt. of argon is the same as the mol. wt. The experiments of W. Ramsay and co-workers, E. A. Hill, W. Crookes, W. N. Hartley, S. Friedlander, E. C. C. Baly, and F. Fischer and V. Fröböse show that there is no reason to regard argon as anything but a simple element. E. W. Wetherell discussed the at. wt. of argon. W. Ramsay, and W. Ramsay and W. M. Travers found the ratio of the sp. hts. of krypton agreed with the at. wt. 83 in accord with the observed mol.

wt. W. Ramsay also found xenon has monatomic molecules with an at. wt. 130·17–130·82. The best representative values are :

	Helium.	Neon.	Argon.	Krypton.	Xenon.
At. wt.	4·00	20·2	39·88	82·92	130·2

The isothermal curves of press. and vol. show no evidence of a polymerization of the mols. of the inert gases on passing into the liquid state. E. C. C. Baly and F. G. Donnan, and G. Rudorf showed that the mol. wt. of argon deduced from the cohesion corresponds with 39·9 ; and S. Chapman obtained values for the viscosity and sp. ht. in harmony with the assumption that the inert gases have monatomic mols. in both the liquid and gaseous states. J. J. Thomson reported the possible existence of xenon and krypton as diatomic mols. because the positive ray analysis of the higher boiling constituents of air showed masses with mol. wts. 163 and 260. F. W. Aston attributed the results to multiple charged xenon, and mercury complexes.

The positive ray analysis of helium by F. W. Aston showed that it is a simple element with no **isotopes**. J. J. Thomson, and F. W. Aston showed that neon possesses two isotopic forms with at. wts. respectively 20 and 22, with a faint possibility of a third isotope of mass 21. F. W. Aston likewise found that argon has two isotopic forms of masses 36 and 40 ; krypton, six isotopes of masses 78, 80, 82, 83, 84, and 86 ; and xenon, seven isotopes of masses 124, 129, 130, 131, 132, 134, and 136 with two other possibles 126 and 128. E. Rutherford and J. Chadwick obtained evidence of **atomic disintegration** where neon, and argon are bombarded by α-rays ; but not with helium, krypton, and xenon. E. Briner observed no evidence of any transmutation when a mixture of helium and hydrogen is exposed to the electric arc.

The alleged synthesis of helium or neon by the action of cathode rays on hydrogen by W. Ramsay,[2] J. N. Collie and H. S. Patterson, and I. Masson was considered by J. J. Thomson to be a *mal*-inference because of the possible evolution of the gas condensed in the occluded state in the electrodes—**4.** 27, 14. A. Lo Surdo thought the foreign gas passed through the heated glass from outside ; but E. Cardoso showed this explanation will not do. No confirmation of the alleged synthesis could be obtained by E. Cardoso, R. J. Strutt, R. T. Merton, A. C. G. Egerton, and A. Piutti and E. Cardoso. S. K. Allison and W. D. Harkins found no helium in the gases left after the passage of electrical discharges between fine wires in vacuo ; through hydrogen ; or through mercury vapour. G. Kirsch and H. Pettersson, and L. F. Bates and J. S. Rogers, discussed the formation of helium as a product of atomic disintegration—*vide* **4.** 26, 7.

The nugatory attempts to prepare compounds of the inert gases with other elements are in harmony with the assumption of L. Errera [3] that these elements are **null-valent**. The possibility of the existence of such elements was indicated by J. Thomsen, F. Flawitzky, and G. J. Stoney. G. Woodiwiss suggested, on unreliable grounds, that the valency of these elements is one-half ; and A. P. Mathews, that the valency has a fractional value. After the discovery of argon, Lord Rayleigh and W. Ramsay suggested that argon should be allocated between chlorine and potassium in the **periodic tables ;** after the discovery of helium, W. Ramsay favoured placing argon and helium between the alkali metals and the halogens ; and after the discovery of neon, krypton, and xenon, W. Ramsay and M. W. Travers proposed arranging the five elements in a special series between the halogens and the alkali metals. It was afterwards suggested by B. Brauner, R. Abegg, A. Werner, and G. Rudorf that the inert gases be placed either as a special group before the alkalies, or else in the eight group. The former suggestion has been adopted. This subject has been discussed by M. Berthelot, L. de Boisbaudran, H. Wilde, C. J. Reed, W. Sedgwick, W. Crookes, A. Piccini, A. von Antropoff, J. L. Howe, P. J. F. Rang, W. W. Andrews, R. Nasini, W. Preyer, R. M. Deeley, J. H. Gladstone, K. Skraupy, and E. A. Hill. Mathematical formulæ for representing the at. wts. of these elements were suggested by A. L. Bernoulli, and J. W. Nicholson.

The **electronic structures** of the atoms of the inert gases are assumed by N. Bohr [4] to be :

Helium (2)	.	.	(2)				
Neon (10)	.	.	(2)	(4,4)			
Argon (18)	.	.	(2)	(4,4)	(4,4)		
Krypton (36)	.	.	(2)	(4,4)	(6,6,6)	(4,4)	
Xenon (54)	.	.	(2)	(4,4)	(6,6,6)	(6,6,6)	(4,4)
Niton (86)	.	.	(2)	(4,4)	(6,6,6)	(8,8,8,8)	(6,6,6)	(4,4)

and the occurrence of isotopes is explained on the assumption that the nuclear protons in, say, the atoms of neon have 20 or 22 positive charges and respectively 10 or 12 electrons, leaving in both cases the same number of orbital electrons.

E. Rutherford thus described the probable structure of the atoms : The nuclei of the atoms are supposed to be exceedingly minute, and in them is concentrated almost all the mass of the atoms. They carry a positive charge, and are surrounded at appropriate distances (very large in comparison with their own dimensions) by a number of electrons sufficient to render the normal atom neutral. This number is the atomic number of the element. It is 1 in the case of hydrogen, 2 in the case of helium, and so on up to uranium, which has 92 electrons around its nucleus. The hydrogen atom has but one electron, and is the simplest ; the helium atom has 2. It is not quite certain how these two electrons move, but it is generally believed that they move in crossed orbits. The atomic number of lithium is 3, and it has three electrons external to the nucleus. Of these, 2 are arranged in the same way as the 2 of helium, but the third moves in a very much larger orbit. In all the elements, save hydrogen, the two innermost electrons are arranged on the helium model, and are known as the K-electrons. As we pass in order from element to element, ·the atomic number increases, and when we come to neon there are 10 electrons, of which the two innermost are arranged as in helium and the remaining 8 form an outer shell. The electrons in this shell belong to what is known as the L-group. The next element after neon is sodium, which has 11 electrons, of which 2 belong, as stated, to the K-group and 8 to the L-group ; whilst with the eleventh a third or M-shell, of much greater radius than the L-shell, commences. After sodium comes magnesium, which has two electrons in the M-shell. This is followed by aluminium, which has in all 13 of these electrons, of which 3 are in the M-shell. Proceeding in this way up the list of the chemical elements, the number in the M-shell increases until it contains 8. The total number is then 18, which is the atomic number of the inert gas argon. After argon comes potassium with 19 electrons, with one of which a new shell known as the N-shell is commenced. In all cases the inert gases mark stepping stones in the list of the chemical elements, and in their outermost shell these inert gases always contain eight electrons. These are not, in all cases, moving in exactly the same way, but in some sense it is evident that they must be very symmetrically arranged, and they, more or less, mark out a space, outside of which there is very little stray force. It is owing to this that the atoms of these gases have very little attraction, either for each other or for those of other elements. All the elements immediately preceding an inert gas have similar properties, and this is also true of those immediately following an inert gas.

W. Kossel, W. Pauli, and E. C. Stoner have suggested other systems ; and the subject has been discussed by H. G. Grimm, J. H. van Vleck, J. H. Jones, H. A. Kramers, M. S. Vallarta, H. Deslandres, R. del Kronig, F. J. von Wisniewsky, I. Woodward, Y. Takahashi, A. Landé, H. S. Allen, H. O. Newboult, C. P. Smyth, H. Collins, O. Halpern, I. Langmuir, W. Kossel, M. Born and W. Heisenberg, A. Sommerfeld, T. M. Lowry, R. T. Birge, R. Reinicke, E. Brummer, V. Trkal, F. R. Bichowsky and H. C. Urey, J. Kudar, P. Tartakowsky, R. S. Mulliken, K. K. Darrow, and A. O. Rankine. The electronic orbits of the atoms of the rare gases were studied by G. E. Gibson, L. St. C. Groughall, J. H. Jones, R. A. Milliken, E. Rutherford, E. Gehrcke, W. Lenz, A. Smekal, W. D. Harkins, T. W. Nicholson, A. C. Crehore, J. Beckenkamp, J. Franck and P. Knipping, J. Franck and F. Reiche, F. C. Kemble, K. F. Herzfeld and K. L. Wolf, etc.

The **atomic numbers** are : helium, 2 ; neon, 10 ; argon, 18 ; krypton, 36 ; xenon, 54 ; and niton, 86. J. C. Thompson found that at. numbers form a simple arithmetical series. L. A. Turner found that a linear relation subsists between the at. number and the quantum defect $n-x$, where n is the quantum number of the electronic orbit ; and x, the effective quantum number defined by $\gamma = R/x^2$, where R is Rydberg's constant, and γ is the value of a spectroscopic term. The life of

metastable helium was discussed by A. P. Dempster, and F. M. Kannenstine— *vide supra ;* and the general subject, by L. Brüninghaus. G. E. M. Jauncey and A. L. Hughes investigated the radiation which occurs when helium is obtained by the disruption of hydrogen. A. S. Eve discussed this subject.

Owing to the formation of helium as a product of so many radioactive changes —**4**. 26, 7—it has been suggested that helium—as just indicated, a proton with two electrons—is a structural unit in the architecture of the atoms. This subject has been discussed by A. van den Brock,[5] K. Fajans, E. Gehrcke, W. D. Harkins, E. Kohlweiller, W. Kossel, L. Meitner, S. Miall, M. C. Neuburger, J. W. Nicholson, E. Rutherford and co-workers, J. J. Thomson, F. P. Valeras, H. Wilde, and H. T. Wolff. Attempts to measure the mass of the helium nucleus were made by F. W. Aston,[6] D. M. Rose and S. K. Ghosh, A. Einstein, W. D. Harkins and E. D. Wilson, M. C. Neuburger, F. Paneth, E. Rutherford and co-workers, A. Smekal, A. Sommerfeld, and L. A. Turner ; and attempts to measure the dimensions of the helium nucleus were made by C. G. Darwin, M. C. Neuburger, E. Rutherford, L. Silberstein, and A. Smekal.
